Abstract

Background: Frail patients in any age group are more likely to die than those that are not frail. We aimed to evaluate the impact of frailty on clinical mortality, readmission rate and length of stay for emergency surgical patients of all ages.

Methods: A multi-centre prospective cohort study was conducted on adult admissions to acute surgical units. Every patient presenting as a surgical emergency to secondary care, regardless of whether they ultimately underwent a surgical procedure was included. The study was carried out during 2015 and 2016.

Frailty was defined using the 7 point Clinical Frailty Scale. The primary outcome was mortality at Day 90. Secondary outcomes included: Mortality at day 30, length of stay and readmission within a day 30 period.

Results: The cohort included 2,279 patients (median age 54 years [IQR 36-72]; 56% female). Frailty was documented in patients of all ages: 1% in the under 40’s to 45% of those aged 80+. We found that each incremental step of worsening frailty was associated with an 80% increase in mortality at Day 90 (OR 1.80, 95% CI: 1.61-2.01) supporting a linear dose-response relationship. In addition, the most frail patients were increasingly likely to stay in hospital longer, be readmitted within 30 days, and die within 30 days.

Conclusions: Worsening frailty at any age is associated with significantly poorer patient outcomes, including mortality in unselected acute surgical admissions. Assessment of frailty should be integrated into emergency surgical practice to allow prognostication and implementation of strategies to improve outcomes.
Introduction

The concept of frailty is well established. Many clinicians diagnose it and know that it may negatively impact on a patient’s clinical condition. However, it is often diagnosed in a subjective “end of the bed” test rather than by using specific diagnostic criteria, despite being recognised as a factor influencing outcomes in geriatric research for many years (1–4). Frailty is a state in which a vulnerable individual, has a diminished physiological capacity to respond to external stress such as infection or trauma (5). The deleterious effects include death, falls, disability, prolonged hospital stays and institutionalisation (2,5–7). (7–14).

There are many instruments used to measure frailty, with variation in their composition (15). Some use scoring systems based on multiple domains (16–18), whilst others use a single functional measurement as a proxy for frailty, such as grip strength or the timed up and go test (19,20). The Clinical Frailty Scale (CFS) (18), is a quick, simple and validated tool. Previous work in emergency general surgery (8) has shown that when used as a binary measure (frail or not frail) this scale predicts mortality and length of stay. This seven point scale ranges from 1 (very fit) to 7 (severely frail) and uses clinical descriptors, with all information needed available from brief observation or review of the clinical notes. In a community setting a frailty assessment may be used as a preventative tool to monitor general health, or in a surgical setting to help explain to patients, their families and carers potential additional risks of clinical management procedures (21). Development of these tools, and frailty research generally, have historically focused on older populations, but the recent publication finding the existence of frailty and its’ negative impact on outcomes in younger adults (aged over 40 years) admitted as a surgical emergency (22) suggests that frailty is not a diagnosis exclusive to older adults. The exact prevalence of frailty is currently unknown, recent studies have reported this between 8% and as high as 37%, but any estimate is a combination of heterogeneous subgroups and shows variation depending on the tool used to detect frailty (23). In older, predominantly elective surgical populations frailty is associated with adverse outcomes (8,13,14). In all specialities, not just surgery, these associations have been assessed using frailty as predominantly a binary exposure variable (frail or not frail) or occasionally tertiary exposure variable (not frail, pre-frail and frail). While useful they are of limited value in relating the full range of frailty seen in clinical practice to outcome.

This study aimed to evaluate the prevalence of frailty its associated risk of mortality, readmission rate and length of hospital stay in all adults, regardless of age, admitted as a surgical emergency. To evaluate the impact of frailty across the full range of the frailty spectrum the 7 point Clinical Frailty Scale was used and the outcome measures assessed for each incremental point increase.
Methods

Prospective patient data were collated from six U.K. acute surgical units during two timeframes: May to July 2015 and June to August 2016. Data collection was performed in accordance with the STROBE Statement and associated checklist (24). Inclusion criteria: patients aged over 18 years old admitted with a general surgical complaint, including those undergoing surgery and those managed conservatively. Patients were excluded if they had a urological, gynaecological or vascular diagnosis.

Individual patient consent was not required as the study was deemed a service evaluation. As such it registered and approved with each institutional audit department, according to local guidelines. Anonymised data from each site was collected using a secure and anonymous data collection tool, stored in accordance with local guidelines, using standard commercially available spreadsheet software.

Baseline demographic data were recorded in order to adjust for potential comorbidity, additional markers of poor health and adverse outcome following surgical intervention were also recorded; these were the number of regular medications (≤5, >5); haemoglobin (≤12.9g/L, >12.9g/L) and albumin (≤35g/L, >35g/L).

Whether a patient underwent surgery was also recorded. Within 24 hours of admission and prior to any surgery, participants were assessed for frailty, recorded using CFS (Supplementary Figure 1). Each local team screened all new surgical admissions with the data gathered from patient electronic records, or case notes. Outcome data were collected from the hospital electronic clinical records. Data recorders were trained in the use of the CFS, by the local site lead, through face to face teaching sessions. Clinical outcomes of mortality (at 30 and 90-days), re-admission rates (at 30-days) and length of hospital stay were recorded.

Public and Patient Involvement

This work was conducted by the Older Persons Surgical Outcomes Collaborative (opsoc.eu). Public and patient involvement is integral to all of the projects developed. Our team compromises of patient representation, provided by Involving People Wales.

Statistical analysis

The study analysis was carried out using an a priori statistical analysis plan (available on request). Descriptive continuous data was reported with a mean and standard deviation (or with a median and interquartile range [IQR] for data exhibiting skew); and dichotomous data with a percentage and numerator and denominator.

The primary outcome was mortality at Day 90, with secondary outcomes of: mortality at day 30; length of stay and readmission within 30 days of discharge from hospital. Baseline demographic and clinical data were summarised for each surgical unit.

Dichotomous outcomes were analysed using a multi-level logistic regression. Surgical units were fitted as hierarchical levels, to account for the clustered data. Length of stay was analysed with a negative binomial distribution to allow for modelling a varying variance structure. Our primary analysis evaluated the crude effect of frailty on clinical outcomes,
fitting frailty as a categorical predictor. The secondary analyses fitted the effect of frailty after adjustment for: age group (<65, 65-79, ≥80); sex; and albumin. Odds ratios (ORs) and 95% confidence intervals (95% CI) were reported. In an additional analysis, the effect of frailty was fitted as a continuous predictor of Day 90 mortality. All statistical analysis was performed using Stata 13.0.
Results

There were 2,279 patients included in the study [median age 54 years (IQR 36-72); 56% female (1276/2279)]. No patients were excluded. Recruitment varied in number per surgical site, but demographic and baseline clinical status of patients were similar across sites as were outcomes (Supplementary Tables 1 and 2 respectively). On admission, 12.7% (289/2279) of the cohort were frail (CFS >=5). Frailty was present across the entire age range; 1% (8/646) under 40’s; 5% (32/668) 40-59 years; 9% (30/331) 60-69 years; 25% (82/328) 70-79 years and 45% (137/306) ≥80 years old (Supplementary Table 3). For follow-up data, seven patients (0.3%) had missing data. The analyses were based on a complete case analysis. A total of 128 patients were dead at Day 90 (6%) (Table 1). For secondary outcomes, the median length of hospital stay was 4 days (IQR 2-7); 404 patients were re-admitted (19%) and 79 (4%) had died at 30 days post-admission (Supplemental Table 2). Within the frail group (CFS >=5), 19% (54/286) experienced mortality at 90-days compared to 3.6% (72/1985) of non-frail (Supplementary Table 4). Similar results were found from 30-day mortality. Re-admission occurred in 23% (64/284) of frail patients versus 17% (340/1974) of non-frail patients. The length of stay was 3 (IQR 2-5) days in those who were not frail compared to 5 (IQR 3-11), 7.5 (IQR 4-18) and 5 (IQR 3-7) days for patients who were mildly frail (CFS=5), moderately frail (and CFS=6) severely frail (CSF=7). Primary outcome: The odds of mortality at Day 90 was higher for those patients with an increased level of frailty. Patients with a CFS of very well (CFS=2) had a crude odds ratio (OR) of 2.25 (95% CI 1.08-4.68) compared to patients with a CFS of very fit (CFS=1). The OR of mortality increased to 8.54 (95% CI 4.12-17.73), 19.5 (95% CI 9.16-41.88) and 58.2 (95% CI 22.6-149.9) for patients with a CFS of: mildly frail (CFS=5); moderately frail (CFS=6); and severely frail (CFS=7) respectively (Table 2). An incremental single unit increase in frailty was found to increase odds of Day 90 mortality by 80% (95% CI 1.61-2.01; Figure 1). Secondary outcomes: Increased frailty was linked to increased mortality at Day 30 (Supplementary Table 5). The mean length of stay was found as 4.6 days for patients with a CFS of very fit (CFS=1). The increase mean length of stay increased for patients with worsening frailty. The mean length of stay increased by 2.60 (95CI% 2.25-3.02), 2.89 (95% CI 2.37-3.53), 2.30 (95% CI 1.64-3.30) times for patients with CFS of mildly to severely frail (CFS=5-7) (Supplementary Table 6). Increased frailty was associated with an increased re-admission rate, the ORs were 1.96 (95% CI 1.28-2.98), 2.56 (95% CI 1.49-4.37), and 0.90 (0.26-3.06) for a CFS of mildly to severely frail (Supplementary Table 7).

Secondary analyses, after adjustment by age group, sex and albumin the effect of frailty was lower, but remained clinically important (Table 2, Supplementary Tables 5-7). The adjusted odds ratio (aOR) of mortality at Day 90 was 2.62 (95% CI 1.14-6.03), 5.39 (95% CI 2.28-12.76), and 24.6 (95% CI 8.42-71.88) for frailty score 5 to 7. Similar results were reported from the other secondary outcomes (Supplementary Tables 5-7).
Discussion

This is the first study to assess frailty in adults of all ages admitted as a surgical emergency, finding that frailty exists in all age groups and is not exclusive to the older adult population. In addition, the presence of frailty predicts mortality in these patients regardless of age and for each incremental point of frailty, the OR for 90 day mortality increased by 80%. After adjusting for key confounding effects, including patient age, gender and comorbidity, frailty was still associated with poorer clinical outcomes. Given the fact that our study was conducted in the real world setting using data from consecutive surgical admissions, our findings highlight the need for routine integration of frailty scores in clinical practice and interventions to modify frailty and improve outcomes.

In other studies, mortality rates for frail people have varied widely (OR ranging from 1.1 to 31.84), with results being difficult to compare due to the heterogeneity in study designs, and the type of frailty assessment used (8,14,25–28). In acute general surgery, two studies have previously reported an association between frailty and 90 day mortality (8,14), however, these studies focussed on older patients only. Other studies have linked length of stay to frailty however these are predominantly from elective surgical populations who are likely to have been pre-operatively assessed as fit enough to undergo planned surgery (10,12,13,29–31). For example Robinson et al found that in both elective colorectal, and a mixed cohort of cardiothoracic and colorectal patients increasing frailty was associated with readmission to hospital and an increased length of hospital stay (13,32).

This study demonstrated that for each incremental shift to a higher level of frailty there was an associated worsening of outcomes, a concept that is readily understood and explainable to patients and carers. Previously frailty has been evaluated in terms of frail or not, and occasionally with an intermediate category of pre-frail in between. By demonstrating that frailty is associated with worsening outcome across an incremental range of the condition and changes for each step-wise increase the opportunities for frailty research and potential interventions are substantially broadened. These results clearly demonstrate the potential impact and likely benefit on clinical outcomes through population level frailty prevention strategies or interventions. Furthermore, the CFS has the benefit of being an extremely simple, quick and easy to perform frailty measure.

Strengths and Limitations of the study

There are several strengths to this study: consecutive emergency patients recruited under general surgeons in multiple UK acute hospitals resulted in inclusion of differing populations and minimising of any influence of local population or admission practices; patient characteristics and outcome data demonstrated that the patients were similar across all of the sites and finally, less than 0.5% of outcome data were missing.

However, the authors acknowledge limitations, primarily that the population assessed was based in the UK which could limit generalisability beyond similar Western populations and settings. Most notably the surgical population used in this study considered any patient admitted under a surgical team, regardless of whether they undergo surgery or not. While
that may limit some of the precision from a purely surgical perspective, for non surgical and community referral patients for an acute surgical opinion the CFS represents the whole surgical population. Thus allowing community teams to educate and inform patients and their relatives before a surgical opinion is even received, thus potentially influencing referral decisions, especially in those with the very highest frailty scores. Another potential limitation is that although the data collectors were trained to use the CFS tool, no validation took place meaning that intra-rater bias cannot be excluded. However, the prevalence of individual frailty scores were consistent across sites, which does potentially mitigate against this.

The implications for future clinical practice:

The management of the frail, emergency surgical patient is challenging, regardless of age. Patients are living longer and are becoming increasingly co-morbid (33). The idea that frailty contributes to an increased risk of mortality is not new in older patients but these data show that this can now be applied to all surgical admissions irrespective of age. Surgeons are faced with challenging decision-making processes and it is not standard practice to ‘turn down’ a frail patient for emergency surgery based on their clinical condition. In the UK, recent recommendations from the National Emergency Laparotomy Audit NELA framework are that higher risk surgical patients are managed in intensive care (34). Unfortunately, however, resources for intensive care post operatively are costly, not limitless and not appropriate for all patients. This has led to an increased focus on futility of surgical intervention and what the likelihood is of returning the patient to reasonable quality of life. This simple frailty assessment should be included in that rigorous assessment process alongside American Society of Anaesthesiologists (ASA) grade and P-Possum score.

Public health awareness and education is required to manage frail patients in the community, and the CFS could be used to identify those at risk by clinicals in primary care. By the time a frail patient presents as a surgical emergency, it is too late to alter the potential risk of death. Whilst Interventions to try to improve frailty can be started in the community if those at risk are identified and offered the opportunity to reduce their risk. Part of any frailty intervention should include clear information on the risk of death associated with the frail state and the decision making process that may occur if they were to develop an acute surgical problem. The CFS could easily be used by emergency physicians before assessment by surgical teams has begun to begin to inform health care choices in relation to surgical intervention.

Much work has been done to improve outcomes in all patients undergoing elective major surgery, regardless of age. For example, the enhanced recovery programme after surgery (ERAS) consists of a multi-modal approach that includes: pre-operative counselling; shorter-fasting times; early mobility and avoidance of drains. This pathway is now standard peri-operative practice across the UK, leading to optimisation of patient outcomes (35,36). However, these programs are typically focused on older age groups, in future a more targeted approach to improve post-operative outcomes may be facilitated by using the
CFS. In high resource settings, use of electronic frailty index has been shown to be associated with mortality in older adults (37) and thus such electronic based tools may also provide useful information in surgical patients, but the prognostic value in surgical setting in all ages needs to be tested perhaps using the same approach.

**Conclusions**

This study has shown that frailty can exist in all ages of the adult emergency general surgical population. There is an approximately linear relationship between increasing CFS at admission and increased odds of Day 90 mortality. The CFS should be integrated into primary care for education and management. Frailty can be used emergency surgical practice to allow prognostication and implementation of strategies to improve outcomes in this vulnerable population.
1 Very fit
Robust, active, energetic, well-motivated and fit; these people commonly exercise regularly and are in the most fit group for their age

2 Well
Without active disease but less well than those in category 1

3 Well, with treated comorbid disease
Disease symptoms are well controlled compared with those in category 4

4 Apparently vulnerable
Although not frankly dependent, these people commonly complain of being “slowed up” or have disease symptoms

5 Mildly frail
With limited dependence on others for instrumental activities of daily living

6 Moderately frail
Help is needed with both instrumental and non-instrumental activities of daily living

7 Severely frail
Completely dependent on others for activities of daily living, or terminally ill
