ABSTRACT

Experimental studies to test interventions for people living with HIV in low- and middle-income countries are essential to ensure appropriate and effective clinical care. The implications of study participation on outcome data in such populations have been discussed theoretically, but rarely empirically examined. We aimed to explore the effects of participating in a randomised controlled trial conducted in an HIV clinic in Mombasa, Kenya. We report qualitative data from the Treatment Outcomes in Palliative Care trial, which evaluated the impact of a nurse-led palliative care intervention for HIV positive adults on antiretroviral therapy compared to standard care. Participants in both arms attended five monthly quantitative data collection appointments. Post-trial exit, 10 control and 20 intervention patients participated in semi-structured qualitative interviews, analysed using thematic analysis. We found benefit attributed to the compassion of the research team, social support, communication, completion of patient reported outcome measures (PROMs) and material support (transport reimbursement). Being treated with compassion and receiving social support enabled participants to build positive relationships with the research team, which improved mental health and well-being. Open and non-judgmental communication made participants feel accepted. Participants described how repeated completion of the PROMs was a prompt for reflection, through which they began to help themselves and self-care. Participant reimbursements relieved financial hardship and enabled them to fulfil their social responsibilities, enhancing self-worth. These findings emphasise the importance of compassion, support and effective communication in the clinical encounter, particularly in stigmatised and isolated populations, and the potential of the integration of simple PROMs to improve patient outcomes. Participation in research has unexpected positive benefits for participants, which should be taken into account when designing research in similar populations. Researchers should be aware of the effects of financial reimbursement and contact with researchers in isolated and impoverished communities.

Background

Rigorous and well-reported clinical trials are essential if researchers and service providers are to evaluate the impact of innovation and development in healthcare and improve clinical outcomes. However, the unintended effects of participation in research are rarely reported in publications of trial findings. There is growing recognition of the importance of fully understanding context and process to interpret and translate trial findings and advance intervention theory (Moore et al., 2014; Oakley, Strange, Bonell, Allen, & Stephenson, 2006).

The effects of participation in research on study outcomes are rarely explored; when they are, they are often attributed to a Hawthorne effect and their potential relevance for study outcomes and future learning is dismissed (Padian, McLoy, Balkus, & Wasserheit, 2010).

The Treatment Outcomes in Palliative Care trial (TOPCare) trial was designed to evaluate the effectiveness of a nurse-led palliative care intervention for people living with HIV (PLWH) (Lowther et al., 2012). To contextualise the trial findings and contribute towards trial methodology...
in low- and middle-income countries (LMIC), we aimed to explore the consequences of TOPCare trial participation.

Methods

The methodology of the randomised controlled trial (RCT) and details of the intervention are reported extensively elsewhere (Lowther et al., 2012), as are the initial results of randomisation and follow-up (Lowther, Higginson et al., 2014) and the outcomes of the RCT (Lowther et al., 2015). In brief, the intervention was developed in response to evidence that PLWH continued to experience physical and psychological symptoms (Farrant et al., 2012; Harding et al., 2010), even in the context of widely available antiretroviral therapy (Lowther, Harding, Selman, & Higginson, 2014). A review of observational data suggested that palliative care might be able to address these symptoms (Harding et al., 2005), but no experimental evidence was available.

The intervention consisted of seven palliative care appointments over four months, comprising assessment and care for their physical, social, spiritual and psychological well-being and specialist referral for complex cases.

120 PLWH were equally randomised to the intervention or to standard HIV clinic care, and attended five monthly quantitative data collection appointments with research nurses. Participants were given 5 USD (400 KSH) to reimburse their transport costs at each appointment.

An explanatory sequential mixed methods design was used (Creswell, Plano Clark, Gutma, & Hanson, 2002) with qualitative data collected via semi-structured qualitative interviews on study exit. A sub-sample of 30 participants was judged as likely to achieve data saturation while allowing in-depth interrogation (Sandelowski, 1995). Participants were purposively sampled based on study arm allowing in-depth interrogation (Sandelowski, 1995). Participants were given 5 USD (400 KSH) to reimburse their transport costs at each appointment.

An explanatory sequential mixed methods design was used (Creswell, Plano Clark, Gutma, & Hanson, 2002) with qualitative data collected via semi-structured qualitative interviews on study exit. A sub-sample of 30 participants was judged as likely to achieve data saturation while allowing in-depth interrogation (Sandelowski, 1995). Participants were purposively sampled based on study arm allowing in-depth interrogation (Sandelowski, 1995). Participants were given 5 USD (400 KSH) to reimburse their transport costs at each appointment.

Results

The demographic characteristics of the sample are reported in Table 1.

Three main themes were identified: (i) compassionate care, social support and communication; (ii) patient reported outcome measures (PROMs) as prompts to self-care and (iii) material support.

Compassion, social support and communication

Compassion, social support and communication related to development of positive and trusting relationships with the research team:

For instance one may come here broken hearted and feeling down but you would encourage and give him the best. Female, 33 years, control

Participants derived social support from their peers in the study, from the study team and from religious practice, which the intervention nurses encouraged:

The more I used to come here for questioning the more I got encouraged, to get that advice that I should not worry, as I am not alone in this sickness. Male, 43 years, control

The relationship with the study team thus appears to have enabled many patients to rebuild their self-image, improving their mental health and well-being:

It is because when you used to ask me questions, I used to feel much free inside … I felt like a very normal person without any form of illness, I felt so good. Female, 54 years, intervention

**PROMs as prompts to self-care**

Completing the data collection tools was seen as a form of mental exercise for some patients:

- Sitting down to be asked questions made me better, because were it not for those questions it would have taken me a lot of time to get back to my normal psychological status. Female, 36 years, intervention

In particular, participants allocated to the control arm reported how completing the outcome measures prompted self-care:

- To be honest when I first came here and sat down with you for a discussion I felt different … the discussion we used to have made me feel at peace and I got rid of all the bad thoughts I had, on my way home … so I started helping myself to change step by step. Female, 42 years, control

Other participants described how the PROMs provided an opportunity to consider making positive changes in their lives:

- When I used to come here, we would talk with you and you would ask me the questions and I’d reflect back … So I would think about it – reflect, reflect about it … and once I’d reflected I’d sit down and think, now, something should change. Female, 41 years, intervention

**Material support**

Many participants experienced financial hardship, exacerbated by their illness and subsequent inability to work:

- As it was, I couldn’t go on with my work at that time because I wasn’t in good health. Female, 36 years, intervention

Participants used the money they received for participating in the study to buy food for themselves and their dependents, enabling participants to fulfil their social role as providers for their families:

- That fare, it really amazed me. It gave me special joy such that whenever you told me to come here. I’d feel delighted and say, “Today we must eat some chicken – I’m a going to be rich”. So this made me very happy. Female, 30 years, intervention

**Discussion**

The therapeutic aspects of study participation described by participants highlight the rarely examined, unintended and unanticipated effects of conducting research in HIV populations in LMIC countries. In the TOPCare trial, these effects influenced important secondary outcomes, improving the mental health of study participants.

Building positive relationships with study staff increased participants’ feelings of social acceptance and integration.

These data may well reflect the stigmatising nature of HIV, which leads to social isolation, secrecy, guilt and shame, reducing opportunities for socially supporting experiences (Hutton, Misajon, & Collins, 2012; Rankin, Brennan, Schell, Laviwa, & Rankin, 2005). During data collection, the researcher worked to minimise social desirability bias and encourage open communication by conveying acceptance of the participant. There is resonance here with Roger’s theory of unconditional positive regard (Rogers, 1957), in which therapists are encouraged to bring about therapeutic change by expressing neither approval nor disapproval, but simply acceptance.

Encouraging feelings of acceptance may have been particularly powerful in this study because of participants’ previous experience HIV-associated stigma. Other research in socially isolated populations has found evidence of benefit due to participation in research (Hall, Goddard, Speck, Martin, & Higginson, 2013). This effect warrants further exploration, potentially through starting data collection before initiating the intervention (i.e., in a time series design), to allow participants to adjust to the increased social contact and support prior to the intervention being tested.

It is noteworthy that interactions with the researcher were reportedly therapeutic. Although the researcher was experienced, she had no training or experience in delivering clinical care. However, she did have time, in contrast to the nurses in the clinic where our study was conducted. Research has shown that when time is short, tasks demonstrating compassionate care are omitted for tasks concerned with medical management (Ball, Murrells, Rafferty, Morrow, & Griffiths, 2013). Our findings suggest that task-shifting may improve clinical outcomes; for example, training lay workers as peer mentors to manage common mental disorders in PLWH (Chibanda et al., 2015).

Participants from both study arms described use of PROMS during the process of data collection as a useful mental exercise. The effectiveness of integrating brief holistic patient assessments into routine clinical encounters should be tested in future research.

The provision of material support enabled participants in both study arms to fulfil their social role and expectations, which reduced anxiety and improved their mental health and well-being. Trialists must recognise that reimbursement of participants may impact outcomes, particularly in populations experiencing poverty. Recommendations state that travel expenses be reimbursed using a clear decision-making process that takes into account participants’ distance from study site, in addition to providing refreshments to demonstrate hospitality and appreciation for participants’ contribution (Molyneux, Mulupi, Mbaabu, & Marsh, 2012).
A limitation of the study is the potential for social desirability bias. Also, as these findings were unanticipated, the topic guide was not designed to explore therapeutic aspects of trial participation, and it is possible that more probing in this area could have contributed towards more refined theory.

This study demonstrates the value of integrating qualitative methods in trials of complex interventions. The qualitative findings reported here provide the context to interpret and reflect on the findings of the TOP-Care trial, and highlight important lessons for those conducting trials in marginalised populations.
