Divergence from the classical hydroboration reactivity; boron containing materials through a hydroboration cascade of small cyclic dienes

Anna Andreou, Michal Leskes, Pablo G. Jambrina, Gary J. Tustin, Clare P. Grey, Edina Rosta and Oren A. Scherman

The hydroboration 1,3- and 1,4-cyclic dienes has been systematically investigated. The behavior of such dienes towards mono and dihydroboration was monitored directly by $^{11}$B NMR to identify the actual boron species formed, as opposed to the most common analysis of the resultant oxidation products. Quantitative dihydroboration was achieved for the full range of cyclic dienes investigated including those, which were previously reported to be resistant to dihydroboration, leading to the formation of new boron-containing polymeric materials. The conditions favoring dihydroboration are reported as well as full characterisation of the materials. Furthermore, a hydroboration cascade mechanism is proposed for the formation of such boron-containing polymers, supported by both experimental and theoretical data.

1 Introduction

Hydroboration is undoubtedly a popular and widely used synthetic reaction. More specifically, hydroboration and subsequent oxidation of dienes to their corresponding diols has received much attention mainly on account of their wide usage in applications such as adhesives, polymers, pharmaceuticals, boronic acid–diol sensors and as intermediates for further synthetic transformations such as in the synthesis of chiral ligands BINAP, DuPHOS amongst others. Despite the fact that dihydroboration of dienes followed by basic oxidation appears an attractive synthetic route to obtain diols, such compounds are typically prepared using epoxide hydrolysis, oxidation of alkenes, the Prévost reaction (anti diols) and the Woodward cis-hydroxylation (cis diols) giving rise to high stereo and regio control.

It is possible that dihydroboration of cyclic dienes to generate diols has not been thoroughly explored as a result of the strong and contradicting conclusions drawn in a series of published studies by H. C. Brown et al. In these publications, the hydroboration of a series of cyclic dienes was explored. Brown et al. concluded that smaller cyclic rings, such as 1,3-cyclohexadiene 1, undergo dihydroboration only to a very small extent and were therefore concluded to be resistant based on the observation of selective formation of the monohydroboration products. In the case of 1, basic oxidation and gas chromatography (GC) analysis of the hydroboration mixture was reported to yield the formation of 2-cyclohexene-1-ol 2 and 3-cyclohexene-1-ol 3 as shown in Fig. 1. Contradictingly, in a singular older report, H. C. Brown et al. mentioned the possibility of polymer formation via dihydroboration of cyclic dienes but have never investigated the outcome of such reactions. Research conducted by contemporaries in the field reported improved yields, however, generally following the same trend that smaller rings appeared to be resistant to dihydroboration. For example, when K. J. Saegebarth used a large excess (80%) of diborane(6) with 1,3-cyclopentadiene, an increased yield of cis-1,3-cyclopentanediol was obtained after oxidation, with monohydroboration, however, still being the main reaction. We found the exceptional resistance of smaller rings towards dihydroboration, even in the cases where excess hydrobating agent was used, rather puzzling. Although a diene is certainly a more electron rich system when compared to an alke, the non-conjugated nature of the C=C bond present in the formed monohydroboration products could potentially compel them to be more reactive than the starting diene, on account of the non-conjugated double bond compared to the initial system. Additionally, both the cyclic diene and the borane reagents (both the starting borane and the formed products) are capable of undergoing further hydroboration reactions. Thus, one might expect the formation of polymeric and/or network materials, as was previously reported in the case of straight-chain dienes or the formation of oligomers through ring opening polymerization.
Unfortunately, almost all of these studies relied upon indirect observations of the subsequently isolated hydroxylated species formed after oxidation, rather than gaining direct evidence arising from the borane species. To date there have only been a few published hydroboration studies that analyze the reaction outcome directly, i.e. by identifying the boron species present.\textsuperscript{12,32} We describe herein a systematic investigation of the hydroboration of 1,3-cyclohexadiene \textsuperscript{1} (for other cyclic dienes see ESI S10†) and its behavior towards mono and dihydroboration by direct observation of the boron species formed. The reaction conditions favoring dihydroboration lead to the formation of new boron-containing polymeric materials, and a mechanism for the formation of such materials is proposed and supported by both experimental and theoretical data.

2 Results and discussion

As a result of our interest in preparing substituted diboranes, we aimed to systematically investigate the hydroboration of cyclic dienes in order to identify the suitable conditions for dihydroboration of smaller rings. While the results and conclusions by Brown et al.\textsuperscript{24,25} were certainly a concern, we were encouraged by the singular literature report by Saegebarth, who reported up to 40\% dihydroboration of 1,3-cyclopentadiene when a large excess of diborane(6) was used.\textsuperscript{26}

We first focused our attention on the number of equivalents of diene present in the reaction, as the large excess of 1 utilized by H. C. Brown et al.\textsuperscript{24,25} seemed unnecessary and was possibly the determining factor for the selective monohydroboration observed in their system. The number of equivalents of diene used was kept constant (1 equivalent) while the amount of borane was varied. Additionally, we investigated two modes of reagent addition: borane to diene and diene to borane. As can be clearly seen in Table 1, irrespective of borane molar equivalents and the mode of reagent addition, all entries yielded a white, insoluble precipitate. When THF was used as the solvent, a glassy material was formed as shown in Fig. 2, which gave rise to complications in characterisation of the products; therefore, in an attempt to eliminate the possibility of side reactions such as THF ring opening (known to be initiated by borane),\textsuperscript{34} diglyme was chosen as the reaction solvent (see ESI S6†). Moreover, the use of diglyme allowed for direct comparison of the reactions performed when two different borane sources were explored [BH\textsubscript{3}·SMe\textsubscript{2} vs. B\textsubscript{2}H\textsubscript{6} prepared from NaBH\textsubscript{4} and BF\textsubscript{3}·OEt\textsubscript{2}].

In order to fully characterise the reaction, the precipitates were collected by filtration (under nitrogen) and the filtrates were analysed by NMR. All B–H bonds appeared to undergo hydroboration, as unsaturated C–C bonds were only observed in entry 1, while the borane starting reagent was fully consumed. Analysis of the filtrates obtained for entries 2–4 (molar borane equivalents of 0.5, 1.0 and 2.0, respectively), revealed large amounts of unreacted starting borane, seen as a quartet at \textasciitilde{}20 ppm in the \textsuperscript{11}B NMR. Furthermore, the absence of any C–C bonds in the \textsuperscript{1}H NMR for these entries suggested that full dihydroboration has taken place utilising all C–C bonds.

When the source of borane was changed to diborane(6), produced \textit{in situ}, the same trend was observed (see Table 1). As diborane(6) was prepared \textit{in situ}, two alternative modes of addition were employed, leading to either slow or fast diborane(6) gas production. This was achieved by either adding BF\textsubscript{3}·OEt\textsubscript{2} to a solution containing both NaBH\textsubscript{4} and 1, resulting in a slow release of the desired gas (as the reaction proceeds \textit{via} the formation of the NaBH\textsubscript{4}·BF\textsubscript{3} complex first), or by addition of NaBH\textsubscript{4} to a solution containing both BF\textsubscript{3}·OEt\textsubscript{2} and diene 1, which resulted in the instantaneous release of diborane(6). As in the case of BH\textsubscript{3}·SMe\textsubscript{2}, all reactions yielded a white precipitate, with only NaBF\textsubscript{4} being observed in the filtrate, appearing at approximately \textasciitilde{}0.4 ppm in the \textsuperscript{11}B NMR, indicating reaction completion.

As dienes can undergo cationic polymerisation initiated by BF\textsubscript{3}·Lewis base adducts,\textsuperscript{29} a control experiment was carried out to ensure that such a polymerisation was not the cause of the observed white precipitate. Thus, the reaction was performed in the absence of NaBH\textsubscript{4} (see ESI S6.1†). The presence of BF\textsubscript{3} alone did not lead to the formation of a white precipitate, confirming that the origin of these solid materials resulted indeed from the dihydroboration reactions.

2.1 Analysis and characterisation of the boron-containing precipitates

The solubility of the formed materials was investigated in a range of solvents. These materials, however, were found to be insoluble in acetic acid, acetone, acetonitrile, benzene, chloroform, cyclohexane, DCM, DMF, DMSO, 1,4-dioxane, 1,3-dioxane, ethyl acetate, diethyl ether, hexane and THF under a nitrogen atmosphere, even after being left for a week. Interestingly, these materials reacted with acetonitrile, methanol and triphenylphosphine (solution in diglyme) serving as indirect evidence that boron hydrides are present in these materials (see ESI S.7.1†).

As a result of the insoluble and air-sensitive nature of these materials, only a limited number of characterisation techniques including solid state NMR and FT-IR could be employed. Additionally, basic oxidation of the materials was also carried out. It is worth noting that the mass of these isolated materials was consistently above the maximum expected value (based on a yield of 100\%, even after a week under vacuum) indicating the presence of trapped solvents, which was confirmed by solid state NMR. Moreover, this strongly suggested the formation of a polymeric network. Addition of Lewis bases such as PPh\textsubscript{3} did not fully dissolve the solid material. Future work will further
investigate additional reactions that might take place and the possible role of solvent in subsequent reactions.

2.1.1 Analysis by FT-IR. Analysis of the materials by FT-IR under anaerobic conditions indicated the presence of C–H (2900–2800 cm\(^{-1}\)), terminal B–H (2600–2500 cm\(^{-1}\)), bridged B–H\(_{5}\) (1600–1500 cm\(^{-1}\)) and B–C (1200–800 cm\(^{-1}\)) bonds and the absence of any C=C bonds (1800–1700 cm\(^{-1}\)). All solids analysed resulted in similar spectra despite originating from a number of different reaction conditions. The FT-IR spectra of four selected materials are shown in Fig. 3, which correspond to the materials also analysed by solid state NMR (vide infra). The B–H\(_{4}\) bond stretches could indicate either presence of a R\(_2\)BHBH\(_3\) species (see Fig. 2), which was found to form during the reaction between a \([\text{R}_2\text{BH}]_2\) species and unreacted borane or diborane(6) starting material, due to R\(_2\)BHHBH\(_2\)R or RBH\(_2\)BH\(_2\)R, or unbridged R\(_2\)BH species or even due to BH\(_3\) trapped inside the material network. The latter option, however, could be dismissed based on solid state NMR data (see Fig. 5c–f). Finally, the absence of any C=C double bonds in both the filtrate and the solid confirmed that full dihydroboration had taken place.

2.1.2 Hydroboration of cyclohexene. The preparation of several model compounds was required in order to unambiguously assign peaks in the solid state NMR; therefore, cyclohexene 7 was treated with borane resulting in soluble cyclohexyl derivatives 8 and 9 as shown in Fig. 4 (see ESI S.7.2.2†).

Three equivalents of cyclohexene 7 were reacted with a single equivalent of BH\(_3\)·SMe\(_2\) leading to the formation tricyclohexylborane 8. However, when the borane was added quickly to 7, the product ratio significantly favoured the formation of the B–H–B bridged species 9 as confirmed by FT-IR (see ESI S.7.2.1†). Importantly, diethyl ether was chosen as the solvent to prepare model compounds 8 and 9 as opposed to diglyme as it enabled a straightforward method to isolate the two compounds. A white precipitate in ether was readily filtered and isolated to yield cyclohexyl B–H–B bridged 9, and confirmed by solution NMR spectroscopy (+29 ppm in \(^{11}\text{B} \) NMR). Conversely, tricyclohexylborane 8 remained soluble in ether and could be isolated upon concentration followed by recrystallisation (+81 ppm in solution \(^{11}\text{B} \) NMR). The dominant formation of dicyclohexylborane 9 \([\text{R}_2\text{BH}]_3\), especially at the earlier stages of hydroboration, suggested that it was the kinetic product, which could be converted to the thermodynamic tricyclohexylborane 8 although with a high barrier, likely due to the steric effect of the substituent (20.4 kcal mol\(^{-1}\), see ESI S11, Table S1†). Interestingly, the powerful stabilisation offered by the B–H–B bridges provides 9 with enough

---

This page contains a table that lists the conditions and observations for hydroboration reactions using different equivalents of borane. The table includes entries for borane and diene molar equivalents ranging from 0.25 to 2.0, along with the mode of reagent addition and the resulting observations, such as white precipitate formation and unreacted borane. The table is used to illustrate the conditions under which different borane species are formed, including unbridged R\(_2\)BH and BH\(_3\) species. The analysis is supported by FT-IR spectroscopy and solid state NMR, which are used to confirm the presence of C–H, terminal B–H, bridged B–H\(_{5}\), and B–C bonds, as well as the absence of C=C double bonds. The table serves as a tool for understanding the reaction outcomes under various conditions.
stability in air over short periods of time (ca. 5 min) as opposed to the instantly pyrophoric and highly unstable tricyclohexylborane 8. The direct dependence on the rate of reagent addition towards the formation of kinetic product 9 vs. thermodynamic product 8 led to materials with different physical properties and reactivities. For example, materials which are mainly consisted of the kinetic products bearing the boron hydride bridges (as opposed to the trialkylboranes, the thermodynamic products) are highly moisture sensitive but not pyrophoric. When these materials where exposed to moisture they transformed from solid to liquid clearly breaking the B–H–B bridges which hold the insoluble polymeric network together. We are currently investigating the applications of these materials especially as instant moisture scavengers.

2.1.3 Analysis by NMR. Solid state $^{11}$B NMR analysis of model compounds 8 and 9 indeed allowed for deconvolution and assignment of the NMR spectra obtained from the white insoluble materials prepared by hydroboration of cyclohexadiene 1. As seen in Fig. 5a, the $^{11}$B resonance from tricyclohexylborane 8 has a relatively broad line shape due to large anisotropic interactions (quadrupolar coupling of 5 MHz and chemical shift anisotropy of ~90 ppm determined from a simulation of the spectrum), which are not efficiently reduced by magic angle spinning at 10 kHz. The isotropic chemical shift of +82 ppm fits well with the value measured in solution $^{11}$B NMR (see ESI S.7.3, Fig. S21†). On the other hand, the $^{11}$B resonance of dicyclohexylborane 9 shown in Fig. 5b, has a much narrower line shape, which can be fitted with quadrupolar coupling of about 2.7 MHz and an isotropic chemical shift of +30 ppm (a good fit with its solution resonance at +29 ppm). It is clear from their $^{11}$B NMR spectra (Fig. 5c–f) that the boron species present in the insoluble materials are similar, with the only difference being their relative abundance serving as additional evidence for the formation of a network polymer. The absence of any significant amount of a trisubstituted borane species was expected on account of the relatively fast reagent addition used during the preparation of these materials.

The remaining signals appearing at approximately +50 and +18 ppm most likely correspond to other boron hydride species such as $\text{R}_2\text{BH}_2\text{H}_2$ and $\text{R}_2\text{BH}_2\text{H}_2\text{R}$ (Fig. 2). This is further supported by the effect on the NMR signal intensities when the solid state $^{11}$B NMR is acquired with and without $^1$H decoupling (see ESI S.7.3, Fig. S20†), as well as by FT-IR and circumstantially by the reactivity of these materials with Lewis bases. Additionally, the presence of trapped diglyme solvent observed in the solid state $^1$H and $^{13}$C NMR spectra (see ESI S.7.3, Fig. S22 and S23†), lends strong support to the formation of polymeric networks. Most importantly, the absence of any unreacted C–C bonds critically points to quantitative dihydroboration of 1 using a variety of borane sources and reaction conditions.

2.1.4 Analysis of the oxidised products by GC-MS. Basic oxidation of these insoluble materials with hydrogen peroxide, adapted from literature procedures and subsequent analysis of the oxidation products by GC-MS revealed the statistical formation of all expected cyclohexane diols, shown in Fig. 2, as the main products. Interestingly, the formation of considerable amounts of cyclohexanol 12 was observed in the absence of any unsaturated C=C bonds. The formation of this alcohol could be attributed to a diborane elimination side reaction similar to what is shown in Fig. 6. However, contrary to what was proposed by A. Hassner and B. H. Braun,48 we believe that such an elimination of 1,2-diboranes, such as $\text{R}_2\text{BH}_2\text{H}_2$ and $\text{R}_2\text{BH}_2\text{H}_2\text{R}$ (Fig. 2), is highly unlikely in the absence of a driving force, such as a Lewis base. Perhaps, SMes$_2$, THF (if present), diglyme or even a species formed during the reaction could mediate such an elimination. Protonolysis of the α-boron atom, in the 1,2-disubstituted diborane case, could also possibly lead to the formation of an oxidised allylborane which resembles a carboxylic acid ([[(RO)$_2$,B(OR)OH$^-$]) thus eliminating one of the boron atoms and replacing it with a hydride. However, we believe that this is unlikely due to the large amounts of cyclohexanol 12 observed in some cases and the highly uncontrolled nature of this hydroboration system leading to a statistical mixture of 1,2-, 1,3- and 1,4-substitution patterns. Furthermore, during our studies we observed that β-hydride elimination of diboranes is possible, however, such an elimination followed by oxidation would not result in the formation of cyclohexanol but rather the unsaturated compound 2-cyclohexene-1-ol 2. Finally, elimination reactions caused by oxidation would also produce alcohols with C=C double bonds rather than cyclohexanol and therefore must also be discounted. We are currently further investigating the mechanism of this elimination.
Several attempts were made to avoid the formation of the insoluble precipitates including lowering the reaction temperature (−78 °C), decreasing the concentration, or carrying out the reaction in non-ethereal solvents, known to considerably slow down the rate of hydroboration, such as DCM. Nevertheless, the insoluble materials formed in all cases, albeit at different rates, even when DCM was used as the solvent. The retarded rate of formation of these materials in DCM further suggested that a hydroboration cascade mechanism was indeed likely leading to chains and three dimensional networks as shown in Fig. 2. A number of additional observations further supported our hypothesis that the isolated materials were indeed borane-containing network polymers. The difunctional nature of 1 combined with the trifunctional nature of BH₃ and the energetic stabilisation gained from the formation of B–H–B bridges is akin to an A₂ + B₃ step-growth polymerisation leading to insoluble, crosslinked networks. Moreover, the solids readily transform into liquids upon exposure to air, further suggesting that oxidation leads to facile disruption of the borane-hydrocarbon polymeric network. Finally, the dependence of the materials’ physical appearance on the reaction solvent (glassy in THF and a white powder in diglyme) together with the high solvent content present in these materials are also indicative of the formation of a polymer network.

2.2 Proposed mechanism for the formation of the boron containing polymers

We believe that these materials are polymeric species formed via a cascade of hydroboration reactions. Detailed inspection of the boron species formed during hydroboration by NMR gave rise to the following proposed mechanism shown in Fig. 7. Initially, 1 undergoes monohydroboration to form either an allyl RBH₂ species 13a or homoallyl RBH₂ species 13b. The ratio of 13a to 13b is likely to be highly dependent on the particular diene structure and is beyond the scope of this study. However, it was expected that the allyl RBH₂ species 13a is slightly more stable compared to the homoallyl 13b on account of conjugation with the C=C bond. Indeed, during our calculations we found that the BH₂ group is stabilised in an axial position, when SMe₂ is absent, by interactions with the adjacent double bond that partly delocalises to the boron 2p orbital (see ESI S11, S53). However, the TS₂ barrier towards both 13a and 13b is almost identical, which cannot explain the selectivity. It is possible that the overall dynamics may determine the product selectivity as reported previously for the hydroboration of propene. Alternatively, the hydroboration product can rearrange and the BH₂ group can isomerise, forming the more stable 13a axial product starting from the equatorial 13b isomer. Once 13a forms an adduct with SMe₂ (or other electron donor molecules), the equatorial conformation is preferred. It is worth noting, that the formed RBH₂ species most likely exist as dimers, which contain B–H–B bridges providing substantial stabilisation; however, for simplicity all borane species depicted in the proposed mechanism are drawn with terminal B–H bonds.

Once hydroboration occurs, both the monohydroboration and dihydroboration species are much more reactive than the starting materials, conjugate diene 1 and borane. This was especially evident on account of the unreacted borane observed in solution after the consumption of all C=C bonds, entries 2–4 in Table 1. Additionally, monohydroboration of 1 leads to the formation of an isolated C=C bond, which was observed to be highly reactive (at least under our conditions) compared to the conjugated starting material 1, leading to a cascade of hydroboration reactions and concomitant formation of a cross-linked
polymeric network as the monohydroboration species continue to react preferentially.

In general terms, hydroboration on double bonds is known to follow a two-step process. The first and usually rate-limiting step is the activation of BH₃ (or substituted RBH₂ species) by breaking the solvent–borane adduct or the borane dimer. The second step is the addition of the BH₃ to the double bond and usually has a smaller barrier. Our calculations suggest that the formation of the solvent-free BH₃ intermediate is stabilized by short-lived intermediate complexes formed with the C=C bond containing reaction partner. We found that the barrier of the first step is reduced from +26.1 kcal mol⁻¹ to +14.6 kcal mol⁻¹ using BH₃-cyclohexene, to +15.0 kcal mol⁻¹ using 1,3-cyclohexadiene 1, and to +13.8 kcal mol⁻¹ using cyclohexene (see ESI S11, Table S1†). It was evident that the energy difference between mono and dihydroboration is very small and therefore, the determining factor for the preferred reaction pathway is most likely influenced by the experimental conditions. The barrier of the first step to form solvent-free boranes is also significantly decreased when substituted boranes (RBH₂) are used with electron-donating R groups, even when the free RBH₂ is not further stabilised by adduct formation with a solvent molecule or a C=C bond. With R = cyclohexyl (or cyclohexenyl), the barrier to generate a free BRH₂ is +13.3 kcal mol⁻¹ (or +13.1 kcal mol⁻¹), which is +12.7 kcal mol⁻¹ (or +13.0 kcal mol⁻¹) smaller than for the dissociation of the BH₃ Smes₂ complex (see ESI S11 Table S2†). As a result, the formed monohydroboration products are expected to react further.

Subsequent hydroboration of 13a or 13b can take place via several different pathways, depending on the reaction conditions. The newly formed, solvent-free monoalkylboranes (13a or 13b) can further react rapidly and hydroborate another cyclohexadiene molecule (ΔΔE = 1.0–2.2 kcal mol⁻¹, see ESI S11 Table S3†), or other monohydroboration of cyclohexadienyl (ΔΔE = 4.0–4.3 kcal mol⁻¹, see ESI S11 Table S3† leading to polymer formation. When excess borane is still available, BH₃ can also hydroborate the remaining double bond on 13a or 13b, although with a somewhat higher energy barrier. For example, the barrier for the hydroboration of 13a is 17.7–18.3 kcal mol⁻¹ (see ESI S11, Table S1†). Interestingly, this second hydroboration can also take place via an intramolecular mechanism through a RH₂BH₂ complex (ESI S11, Fig. S54†). The hydroboration reaction within this complex has some of the lowest barriers, 15.5 kcal mol⁻¹ to form the kinetically favoured cis-1,2-diborane cyclohexane isomer (or 18.0 kcal mol⁻¹ to form the thermodynamically favored cis-1,3-diborane cyclohexane, see ESI S11, Table S1†). The formed diboranes are further stabilised via B–H–B bridges. Potentially, this barrier is further reduced by forming a complex with another electron donating molecule, such as Smes₂, that facilitates the release of an active BH₃ (results are not shown). It is worth noting that the second hydroboration reaction can produce eight distinct diborane cyclohexane isomers in general if the chair-boat conformational change is not hindered, and many more in the conformationally restrained polymers. The formation of each isomer has different potential reaction mechanisms and corresponding rates. Interestingly, the intermolecular hydroboration, with the bridged cis-1,2-cyclohexane (see Fig. 6), is the kinetically favoured mechanism to form diborane over most of the other possibilities listed above (see ESI S11, Table S1†). The thermodynamically most stable product is the axial cis-1,3-cyclohexane, due to the favourable positions of the BH₂ groups of this isomer to form B–H–B bridges. This intermolecular mechanism may provide an explanation of the relative abundance of cyclohexanol after basic oxidation of these materials, assuming a potential subsequent elimination reaction from the bridged diborane species (see Fig. 6).

Boron containing polymer formation from dienes has been reported previously by Brown et al. during the hydroboration of 1,3-butadiene. However, these polymers were found to
form via cyclic hydroboration, which is not expected in the case of cyclic diene 1, as this would require the initial formation of highly unfavoured ring-in-ring structures (see ESI S8, Fig. S48†). As a result, cyclic hydroboration mechanisms and their products are not considered here.

2.3 Dihydroboration of other cyclic dienes

Intrigued by the results of our study on 1,3-cyclohexadiene, we expanded the substrate scope to include a range of different cyclic dienes including: α-terpinene, 1,3-cycloheptadiene, 1,3-cyclooctadiene, 1,3,5,5-tetramethyl-1,3-cyclohexadiene, γ-terpinene, 1,4-cyclohexadiene, 1,2,4,5-tetramethyl-1,4-cyclohexadiene, 1,5-cyclooctadiene and the acyclic 2,3-dimethyl-1,3-buta diene as a control and direct comparison to the reported polymer structures (see ESI S9, Fig. S49†). In a similar fashion to our observation with 1, all of the dienes listed above, including the acyclic diene, were susceptible to dihydroboration. Not all dienes above led to the formation of crosslinked polymeric networks, several resulted in a clear solution, which contained a mixture of boron hydride species and unreacted borane (see ESI S9, Fig. S50 and S51†). A clear pattern, however, was observed with simple cyclic dienes, such as 1, 1,3-cycloheptadiene, 1,3-cyclooctadiene, and 1,4-cyclohexadiene leading to the formation of the boron-containing crosslinked polymers whereas more sterically demanding dienes such as α-terpinene yielded a clear solution. Interestingly, γ-terpinene also led to the formation of a cross-linked material. Following this trend, dihydroboration of 1,2,4,5-tetramethyl-1,4-cyclohexadiene yielded clear solutions while the reaction with 1,3,5,5-tetramethyl-1,3-cyclohexadiene first produced a clear solution, but observation of an insoluble material occurred after 2 h. Despite the absence of sterically demanding substituents, hydroboration of 1,3-cyclooctadiene resulted in a clear solution, yielding the commonly used reagent 9-BBN on account of the formation of a stable 6-member boron-containing cyclic structure. Finally, when acyclic diene, 2,3-dimethyl-1,3-buta diene was used in the reaction, a clear solution was obtained as previously reported.27-29 Therefore, it was clear that the position of the C=C bond, in relation to the sterically demanding group, was crucial in the formation of these materials, which were not limited by ring size.

3 Conclusions

To conclude, boron containing polymers form when cyclic 1,3- or 1,4-dienes, free of sterically demanding groups are fully hydroborated, irrespective of the cyclic diene size, borane equivalents and mode of addition. When steric hindrance is present or cyclic borane species are favourably formed, as for example when straight chain of 1,5-dienes are utilised, clear solutions are observed. These materials were characterised by solid state FT-IR and NMR and were found to consist of boron hydride bridged species due to stabilisation reasons and the synthetic time scale utilised. Further supported by oxidation analysis, it was clear that hydroboration proceeds further than the monosubstituted borane adducts to form higher substituted, more stable, bridged borane species. Therefore, our results are in disagreement with the published conclusions on the study of dihydroboration of cyclic dienes by H. C. Brown et al.24,25 as we observed that dihydroboration of cyclic rings proceeds quantitatively irrespective of ring size or structure.
