Abstract

One in ten children and adolescents suffer with mental health difficulties at any given time, yet less than one third seek treatment. Untreated mental illness predisposes to longstanding individual difficulties and presents a great public health burden. Large scale initiatives to reduce stigmatization of mental illness, identified as a key deterrent to treatment, have been disappointing. This indicates the need for a clearer understanding of the stigmatizing processes faced by young people, so that more effective interventions are employed. A systematic review of the literature, assessing public stigma and self-stigma (i.e. internalized public stigma) specifically in children and adolescents with mental health difficulties (YP-MHD), was conducted. Forty-two studies were identified, confirming that stigmatization of YP-MHD is a universal and disabling problem, present amongst both children and adults. There was some variation by diagnosis and gender, and stigmatization was for the most part unaffected by labelling. Self-stigmatization led to more secrecy and an avoidance of interventions. The findings confirm that stigmatization of mental illness is poorly understood due to a lack of research and methodological discrepancies between existing studies. Implications for the findings are discussed, and suggestions made for future research.
1. Introduction

1.1. Mental health difficulties in children and adolescents

Mental health difficulties in children and young people are prevalent, estimated to affect 10%-20% of 5-18 year olds (Green et al., 2004; U.S. Public Health Service., 2000). Indeed, half of all lifetime cases of mental illness begin by age 14 (Sawyer at al., 2000; Kessler et al., 2005a; Kessler et al., 2005b). Untreated, they present a profound and longstanding impact on the individual and society (Patel et al., 2007; Jokela et al., 2009; Moses T., 2009a; Post et al., 2010). Having a mental health difficulty from a young age is associated with educational underachievement, family disruption, substance misuse and violence. Young sufferers experience poorer physical and sexual health than peers without mental health problems (Farina and Felner, 1973; Barkley, 2002; Donenberg and Pao, 2005), and have increased mortality rates from suicide and accidental injury (Gould et al., 2003; Aaron et al., 2004; Commission on Adolescence Suicide Prevention, 2005; Vijayakuma et al., 2005). On a societal level, public sector spending on untreated young sufferers presents a significant socioeconomic burden at £59,000 per child per year (Department of Health, 2001; Green et al., 2004) - 10 times higher than spending on unaffected peers (Scott et al. 2001; Romeo et al., 2006). For the purpose of this paper, YP (young persons) will be used to describe ‘children and adolescents without mental health difficulties’, and YP-MHD will be used to describe ‘children and adolescents under 18 with mental health difficulties’.

1.2. What is stigma?

Stigma has been defined as a deeply discrediting attribute associated with a given condition, directed towards those of considered lower social standing (Goffman, 1963). It consists of three key components: Stereotypes, prejudice and discrimination (Corrigan, 2005; Thornicroft, 2006). Stereotypes are learned, oversimplified and often negative attitudes embedded in society,
which allow individuals to generate quick impressions of specific subgroups (e.g. psychiatrists are eccentric), without necessarily believing in them (Jussim, 1995). Prejudices are endorsed stereotypes, meaning they are accompanied by negative emotional reactions. This inevitably leads to avoidance and social distancing, resulting in discrimination. Public stigma refers to the reaction of the general public towards stigmatized groups; it can be further differentiated into personal stigma (an individual’s own views of a stigmatized group) and perceived stigma (an individual’s perception of how others view a stigmatized group).

The extent to which a stigmatized individual is aware of public stigma has been termed stigma consciousness (Pinel, 1999; Thornicroft et al., 2007). The greater one’s stigma consciousness, the more likely they are to internalize public stigma, i.e. to self-stigmatize (Corrigan and Watson, 2002b). This makes them more likely to exhibit unfavorable behaviors in line with stereotypes (such as withdrawing from the general public), resulting in a perpetuating, negative cycle (Pinel, 1999). The result is one of impaired self-esteem and avoidance of treatment, leading to poorer long-term outcomes (Corrigan and Watson, 2002a).

1.3. Stigma in YP-MHD

It is increasingly evident that YP-MHD experience stigmatization, from both adults and children (Weiss, 1986; Adler and Wahl, 1998; Rose et al., 2007). Research has shown that YP-MHD are more stigmatized than children with physical illness or learning disability (Wilkins and Velicer, 1980) and that stigmatizing views and behaviors can develop from early childhood. Children as young as 6 appear to grasp everyday terms associated with mental illness and are well familiarized with cultural stereotypes by age 10, or even earlier if they themselves form part of a stigmatized group (Costello et al., 2006; Gale, 2007).

Stigmatizing views in YP are believed to develop as an assimilation of parent/carer views (Gale, 2007), media representation and cognitive development (Donenberg and Pao, 2005); and children are also more vulnerable to stigmatization due to their lower social status (Phares, 2003). There are key developmental considerations as to why understanding and targeting the stigmatization of YP-MHD, by both adults and children, is paramount. Firstly, the use of mental health services by YP-MHD is remarkably low (Sawyer et al., 2001; Essau, 2005; Zachrisson at al., 2006).
and stigma has been identified as an especially important barrier to help-seeking (Penn et al., 2005; Pescosolido et al., 2007b; Gulliver et al., 2010; Mukolo et al., 2010; Clement et al., 2014). Early intervention can result in long-term benefits (Barrett et al. 2001, Biederman, 2003; Hazell, 2007), which highlights the importance of accessing early effective care.

Secondly, stigmatization of YP-MHD may influence personal identity and independence in the long-term, as adolescence in particular is a key stage in the development of autonomy (Hinshaw S.P., 2005). Positive peer relationships are important not only for promoting self-esteem, adjustment and resilience (Brown and Lohr, 1987; Parker et al., 1995; Azmitia, 2002), but also result in better outcomes in YP-MHD (Bagwell, et al., 1989). Hence, if YP-MHD are stigmatized by peers, they are more likely to avoid seeking support (Chandra and Minkovitz, 2006), and less likely to do well in the future.

1.4. The purpose of this study

Unfortunately, stigmatization of YP-MHD is under-researched and not well understood (Hinshaw, 2005; McKeague et al, 2015), yet children are not necessarily stigmatized as their adult counterparts, and stigma is likely to have different long-term implications based on a child’s development. This lack of a more specific understanding has resulted in expensive large scale national initiatives with predominantly disappointing results (Rickwood et al., 2004). A clearer understanding of the origins and constructs of the stigmatization of YP-MHD could better inform future stigma reduction policies and improve engagement, peer relationships and outcomes. This paper sets out to systematically review the literature examining the stigmatization of YP-MHD by adults and peers. Specifically, the objectives of the review were to identify how stigmatization of YP-MHD was affected by diagnosis, age and demographics and which key themes identified in the adult literature pertained to YP-MHD. We hypothesized, in line with the adult literature, that:

- Not all conditions would be stigmatised equally and that certain stigmatizing views would be more prominent in certain conditions e.g. dangerousness in psychosis.

- females and individuals of higher education attainment would be less stigmatising towards YP-MHD;

- Stigmatisation of YP-MHD would increase with increasing age of unaffected peers
Children and adolescents experience self-stigma and that this would have a detrimental effect on their emotional wellbeing.

2. Methods

Following PRISMA guidelines (Moher et al., 2009), Pubmed, PsycINFO, and the Cochrane Library were searched by 2 authors working collaboratively (AK and EK) for original research papers published between 1980 and 2015, examining stigmatization of YP-MHD. Search terms used were:

- Stigma: stigma, self-stigma, discrimination, prejudice, attitude, stereotype
- Mental illness: mental, psychiatric, psychological, AND illness OR disorder OR disturbance OR difficulty; Individual searches were also conducted for commonly diagnosed or significant conditions in childhood.
- Children and adolescents: adolescent* OR child* OR young person*.

For a full list of the individual searches conducted please refer to supplement 1.

Abstracts (and where necessary full reports) were screened independently by AK and EK. Only English language, original research papers, assessing adults' and YP stigmatizing views towards YP-MHD (specified age range 0-18) or self-stigma in YP-MHD were included in the review. Papers were excluded if:

- They did not address any component of mental health stigma
- They examined stigmatization towards individuals outside the 0-18 specified age range. If the papers concerned a wider age range but had extractable data for the 0-18 age group, these were included.
- They reviewed stigmatization following a stigma reducing intervention.
- The paper was a review article
- There was no extractable data
- They focused on stigmatization of mental health treatment, which we considered to be important enough to warrant a separate review.
Eligible papers were hand-searched for relevant references meeting the same criteria. Data was extracted using a predetermined data extraction sheet. Methodological quality was assessed using the Effective Public Health Practice Project “Quality Assessment Tool for Quantitative Studies (EPHPP), which gave ratings of either strong, moderate or weak quality. Qualitative studies were assessed using the Critical Appraisal Skills Programme (CASP) (Public Health Resource Unit, 2006), resulting in ratings of either good or weak methodological rigor. Data and quality were assessed independently by two of the authors (AK and MK) and discrepancies were discussed until a consensus was reached.

Qualitative data was analyzed using a thematic analysis approach (Liamputtong and Ezzy, 2005). An initial coding framework was manually created by AK, deduced from examination of this literature and background reading on stigma in mental health disorders. AK and MK then applied the coding template to the papers, revising the framework as was necessary until themes were identified.

3. Results

The database searches returned 5925 items after the removal of duplicates. Screening titles and abstracts identified 27 studies which met all 3 inclusion criteria (Fig. 1). A hand-search of reference lists resulted in a further 15 relevant studies, resulting in a total of 42 studies for the purpose of this review.

Thirty-two papers examined YPs’ stigmatizing views towards YP-MHD (Table 1) and 7 papers examined adults’ stigmatizing views towards YP-MHD (Table 2). Of these 39 papers, 31 reported on quantitative findings, ranging in quality from strong (10 studies), to moderate (15 studies) and weak (6 studies). Eight papers were qualitative in nature, and all of good methodological rigour, but one (Poster et al, 1986). Only 3 papers were found, by the same author, examining self-stigmatization. These were mixed methods papers of robust methodological means.

Studies were mainly conducted in the USA, followed by the United Kingdom, Ireland, Israel, Australia, Iran, Canada, Greece and Japan. Papers were published between 1985 and 2015 and participant numbers varied from 24 to 55,520. The age of participants in papers examining YP views was 6-18. Papers examining adults’ views did not all specify participants’ age range. All
studies but one (Harris et al., 1992) included male and female participants. The following results summarize the main findings.

3.1. Key themes in the relationship between mental illness and stigma in YP-MHD

All 42 identified studies examining adults’ and YPs’ views evidenced that YP-MHD experienced stigmatization (Table 1). Most identified papers measured personal stigma. Regardless of assigned quality ratings, YP-MHD were consistently more stigmatized than unaffected peers (Peterson et al., 1985; Poster et al., 1986; Harris et al., 1992; Friedrich et al., 1996; Brook et al., 2000; Brook and Geva, 2001; Campbell et al., 2004.; Corrigan et al, 2005.; Ghanizadeh et al., 2006; Pescosolido et al., 2007a; Mukolo and Heflinger, 2011; O’Driscoll et al., 2012; Ohan et al., 2013; Swaim and Morgan, 2001; Bellanca and Pote, 2013). They were more stigmatized than peers with learning difficulties (Brook and Geva, 2001; Bellanca and Pote, 2013) and peers with physical health conditions and disability (Corrigan et al., 2005; Martin et al., 2007; Pescosolido et al., 2007a; Walker et al., 2008; Mukolo and Heflinger, 2011). The only condition more stigmatizing than mental health difficulties was alcohol misuse (Corrigan et al., 2005).

Interestingly, the only study that compared the same mental health condition in adults and children reported childhood depression to be considered more severe than adult depression (Perry et al., 2007). The key, identified themes related to stigmatization were consistent with findings in the adult literature. These were as follows:

3.1.1. Blame and responsibility

Ten studies commented on the role of ‘blame/responsibility’ on stigmatization. Seven examined YP views (Peterson et al., 1985; Corrigan et al., 2005; Coleman et al., 2009; Swords et al., 2011; O’Driscoll et al., 2012; Dixon et al., 2013; Dolphin and Hennessy, 2014; O’Driscoll et al., 2015) and two examined adults’ views (Martin et al., 2007; Mukolo and Heflinger, 2011). The degree of blame varied by diagnosis (e.g. Corrigan et al., 2005). High caliber qualitative and quantitative means found that where causal attributions were identified as beyond the child’s control, YP-MHD were not blamed (Peterson et al., 1985; Dolphin and Hennessy, 2014; O’Driscoll et al., 2015).

3.1.2. Behavioral Intentions and Social Distance
Eighteen studies, of varying scientific rigor, examined social distance/behavioral intentions, making it the most frequently assessed construct of stigmatization (Table 1). Blaming views were associated with a desire for greater social distance (Corrigan et al., 2005; Coleman et al., 2009; Dixon et al., 2013). The desire for social distance was also reliably related to diagnosis (Martin et al., 2007; Walker et al., 2008; Mukolo and Heflinger, 2011; Ohan et al., 2013); ethnicity (Mukolo and Heflinger, 2011); participant age (Martin et al., 2007) and identification with YP-MHD (Secker et al., 1999). Negative beliefs and attitudes were mirrored with negative behavioral responses (Harris et al., 1992; Moses T., 2010b). Positively, negative emotions and attitudes were not always predictive of peer exclusion (Friedrich et al., 1996; Swaim and Morgan, 2001; Campbell et al., 2004; O’Driscoll et al., 2012; Washington et al., 2012; Dolphin and Hennessy, 2014; Mavropoulou and Sideridis, 2014). Being white, female, and educated resulted in less social distance (Martin et al., 2007).

3.1.3. Dangerousness

Dangerousness was endorsed more frequently in YP-MHD than in YP with physical disorders or normal troubles (Pescosolido et al., 2007a). Participants rated female mental health sufferers as less dangerous than their male counterparts, and fourteen year olds as less dangerous than eight year olds (Poster et al., 1986). ‘Dangerousness’ was most often, but not always (O’Driscoll et al., 2012), associated with psychotic or behavioral disorders (Secker et al., 1999; Yoshioka et al., 2013), though it was also identified as a stigmatizing belief in depression (Reavley and Jorm, 2011). Children aged 12-13 more commonly reported perceptions of dangerousness than children aged 6-7 (Spitzer and Cameron, 1995). Surprisingly, greater familiarity increased perceptions of dangerousness in some YP-MHD (Corrigan et al., 2005). Adult studies mirrored the above findings (Martin et al., 2007; Pescosolido et al., 2007a) with some adults believing depressed children to be more dangerous than depressed adults (Perry et al., 2007).

3.1.4. Familiarity

Six studies commented on the role of familiarity (i.e. experiencing or knowing someone with a mental illness) in shaping attitudes towards YP-MHD (Secker et al., 1999; Corrigan et al., 2005; Law et al., 2007; Martin et al., 2007; Bellanca and Pote, 2013; Mavropoulou and Sideridis, 2014). Results were inconsistent: familiarity was identified as decreasing (Bellanca and Pote,
2013; Mavropoulou and Sideridis, 2014; Secker et al., 1999), increasing (Corrigan et al., 2005) or not affecting stigmatizing attitudes (Law et al., 2007). These differences could not be explained based on quality ratings. Amongst adult participants, personal contact with YP-MHD only reduced stigmatization if this contact was rated as positive (Martin et al., 2007).

3.2. Stigmatization varies by mental health diagnosis

In order to examine the first hypothesis, the authors searched the identified literature for stigmatizing views related to specific disorders. Eleven papers, of predominantly robust methodological means, looked at stigmatization by diagnosis (Table 1 & Table 2). Nine papers looked at depression (Poster et al., 1986; Secker et al., 1999; Walker et al., 2008; Coleman et al., 2009; Swords et al., 2011; O’Driscoll et al., 2012; Bellanca and Pote, 2013; Dixon et al., 2013; Ohan et al., 2013); 6 papers examined Attention deficit and hyperactivity disorder (ADHD) (Walker et al., 2008; Coleman et al., 2009; Swords et al., 2011; O’Driscoll et al., 2012; Bellanca and Pote, 2013; Ohan et al., 2013); 3 papers examined anxiety (Poster et al., 1986; Dixon et al., 2013; Yoshioka et al., 2013), 3 papers examined schizophrenia (Poster E., 1992; Secker et al., 1999; Yoshioka et al., 2013) 1 paper examined anorexia (Secker et al., 1999) and 1 paper studied Borderline personality disorder (Catthoor et al., 2015).

It is unclear whether ADHD or depression in children is more stigmatized by YP (Walker et al., 2008; Coleman et al., 2009; Swords et al., 2011; O’Driscoll et al., 2012; Bellanca and Pote, 2013). Adults appear to stigmatize depression more than ADHD (Ohan et al., 2013). Children with anxiety were favored over children with depression (Dixon et al., 2013). YP generally recognized schizophrenia as a mental illness (Poster E., 1992; Secker et al., 1999; Yoshioka et al., 2013), but were less clear about anorexia (Secker et al., 1999) and social phobia (Yoshioka et al., 2013). In Catthoor et al. (2015), borderline personality disorder was the highest rated condition with regards to stigmatizing experiences.

3.2.1. A mental health label does not necessarily increase stigma, but a negative behavioral description does.

Six studies looked at the interaction between mental health labels and actual/described behavior on stigmatizing attitudes towards YP-MHD; 4 studies examining YPs’ views (Harris et al., 1992;
Friedrich et al., 1996; Swaim and Morgan, 2001; Law et al., 2007) and 2 studies looked at adults (Martin et al., 2007; Ohan et al., 2013). The 4 studies examining YPs views found that the addition of a diagnostic label did not increase stigmatization but rather that participants were reacting to the behaviors present or described in the target children. This finding was consistent, despite varying methodological considerations. In the 2 carefully considered adult studies, despite using different quantitative tools, the addition of a mental health label or the recognition of the child as “mentally ill” did result in an increase in stigmatization. Although there appears to be a difference in the way adults and YP responded to the addition of a label, overall it is the delivery of a negative description and actual behavior that results in the most discrimination.

3.3. The impact of demographic factors on stigmatization

3.3.1. Age

The authors hypothesized that stigmatization of YP-MHD would increase with increasing age. Looking at the evidence, 15 papers studied the relationship between participants’ age and stigmatizing attitudes (Table 1). Despite different quality ratings, knowledge of mental health difficulties improved with increasing age, (Poster, 1992; Spitzer and Cameron, 1995; Brook and Geva, 2001). However, knowledge did not equate to acceptance. A number of high quality studies, predominantly comparing primary school children of 2 different ages, identified younger children to be more accepting than older children (Peterson et al., 1985; Swaim et al., 2001; Campbell et al., 2004; Bellanca and Pote, 2013; McKeague et al, 2015). This contrasted with the carefully considered work of Swords et al (2011), who found that adolescents aged 14-18 were more positive than children aged under 12, towards peers with ADHD and depression. Some studies found no differences in beliefs about YP-MHD (O’Driscoll et al., 2015).

Amongst adult participants, participant age did not impact on endorsed beliefs (Mukolo and Heflinger, 2011). In other studies the observed relationships were much more complex and dependent on other variables (O’Driscoll et al., 2012; Mavropoulou and Sideridis, 2014;). In two studies, attitudes were similar across grades, with subtle differences depending on the specific construct being measured (Mavropoulou and Sideridis, 2014). A comparison of 13-17 year olds with 18-24 year olds found that adolescents and their families had greater difficulty with disclosure and
acceptance than the older age group and their families (Elkington et al., 2012). Identifying with the character based on age was helpful in reducing stigma (Secker et al., 1999).

3.3.2. Gender

The relationship between gender and stigmatization was examined in twenty-three papers. As predicted in the hypothesis and identified in many studies of adults’ views, several robust studies identified more positive attitudes amongst female participants (Peterson et al., 1985; Martin et al., 2007; Reavley and Jorm, 2011; Swords et al., 2011; O’Driscoll et al., 2012; Dolphin and Hennessy, 2014; Yoshioka et al., 2014). At the same time, two well executed experiments, looking at Tourette Syndrome and Autism, found male participants to be more positive than females on certain measures of stigma (Friedrich et al., 1996; Swaim and Morgan, 2001) and a third study found boys to be better at recognizing deviant behavior (Spitzer and Cameron, 1995). Females were more likely to endorse stress as a causal factor for mental illness (Swaim and Morgan, 2001) and children were more likely to draw a “crazy person” as male, particularly if they were female (Poster et al., 1986). In some cases, participant gender had no impact on attitudes (Corrigan et al., 1995; Law et al., 2007; Mukolo and Heflinger, 2011; Washington et al., 2012; O’Driscoll et al., 2015) or findings were mixed (Mavropoulou and Sideridis, 2014). Being of the same sex as the child increased identification and reduced stigmatization (Secker et al., 1999). Boys reported more perceived peer stigmatization (Moses T., 2010b). There was some suggestion that children of both genders more often identified a child with psychological difficulties to be male, whereas children with physical difficulties were more often thought of as female (Roberts et al., 1981; Roberts et al., 1984).

3.3.3. Ethnicity

Few studies examined the role of ethnicity in this age group and findings are not comparable due to the quality of the studies and different ethnicities considered (Martin et al., 2007; Walker et al., 2008; Coleman et al., 2009; Moses T., 2010b; Mukolo and Heflinger, 2011; Elkington et al., 2012). There may be a trend towards ethnic minority groups holding more stigmatizing views but this requires further exploration.

3.3.4. Socioeconomic status
Despite hypothesizing that the evidence would find less stigmatizing attitudes amongst individuals of higher educational attainment, only 2 moderately rated papers (Roberts et al., 1984; McKeague et al., 2015) specifically examined the role of socio-economic status in children’s perceptions of psychological disturbance. These did not find significant differences between the beliefs of participants in high and low socioeconomic groups.

3.4. Self-Stigma

Only 3 studies were identified to examine the effects of self-stigma on emotional wellbeing in YP-MHD. These were all moderately rated and are summarized in Table 3 (Moses, 2009a; 2009b; 2010a). They looked at the same sample of sixty 12-18 year old YP-MHD. Self-labelling resulted in increased levels of self-stigma and depression and a trend towards a lower sense of self-mastery, but no impact on self-esteem (Moses, 2009a). Self-labelling practices were also more prominent in those with greater perceived public stigma, younger age at initiation of treatment and a higher socio-economic status. Older adolescents; lower age at treatment onset; and being of white ethnicity were linked to higher self-stigma. Less self-stigmatization was noted in those with externalizing disorders e.g. conduct disorder. Parental factors were also of relevance, in that parental optimism and a greater faith in the child’s ability to control behavior was protective against self-stigmatization, whereas parental secrecy increased self-stigma (Moses, 2010a), resulting in greater personal rejection and shame.

Correlations were also identified between adolescents understanding/perceptions of mental illness and self-stigma (Moses T., 2010a). Self-stigma increased in adolescents who perceived less control over their mental health difficulties and believed their problems to be life-long. Perceived causal explanations for illness that correlated with increased self-stigmatization were social problems, family problems, trauma, personality/way of thinking, and biological causes. The more causal factors identified per patient, the higher their self-stigma rating. Perceived economic difficulties as a causal factor were not correlated to self-stigmatizing beliefs. Parental secrecy regarding a child’s mental health problems also increased self-stigmatization among adolescents.

3.5. Perceived Stigma

Several reliable lines of evidence suggest that perceived stigma is greater than personal stigma (Friedrich et al., 1996; Moses T., 2010b; Elkington et al., 2012; Yoshioka et al., 2014). Girls
and participants aged 12 (as compared to participants aged 9) gave lower ratings for their classmates’ behavioral intentions (i.e. perceived stigma) towards a peer with autism than their own (personal stigma) (Swaim and Morgan, 2001). Greater peer stigmatization was also perceived by Whites, males, those receiving treatment from a younger age and youth with at least one mood disorder (Moses T., 2010b). A study examining whether children with ADHD viewed their behaviors as stigmatizing found that diagnosed children reported more perceived stigmatization on all fronts—teachers, parents and peers (Wiener et al., 2012), which had knock on effects on their global self-worth.

4. Discussion

4.1 Summary of findings

This paper is, to the best of the authors’ knowledge, the first systematic review examining stigma specifically towards YP-MHD. With this in mind, the authors investigated a number of predetermined hypotheses guided by the adult literature, and conducted a thematic analysis to start to build a picture of stigmatization in this age group.

Most notably, the evidence for stigmatization in YP-MHD was found to be significant, universal and multifaceted, with levels of stigmatization varying depending on the characteristics of both the stigmatizers and the stigmatized. There were several parallel themes between stigmatization of YP-MHD and adult patients. Specifically, YP-MHD, like their adult counterparts, suffered more discrimination than peers with other health needs; and themes such as familiarity and blame/responsibility had discreet effects on the degree of stigmatization individuals experienced. Consistent with the adult literature (Chandra and Minkovitz, 2006; Burke et al., 2008; Andersson et al., 2010) and our hypothesis, males were both more stigmatized and more stigmatizing than females, possibly as a result of the same widely held belief that males should be self-sufficient at managing mental health difficulties, leading to a lower uptake of treatment by male children. Also consistent with the hypotheses, there was evidence of variation in stigmatizing views based on participants’ diagnosis; and stigmatizing beliefs for the most part appeared to increase with age, possibly as children’s awareness of mental health difficulties increased. It was not felt possible to
comment on the impact of socioeconomic status and ethnicity, as studies were too few and varied in their methodology.

At a rate of 25%, Moses (2009a) found the prevalence of self-stigmatizing attitudes to be lower than adult self-stigmatization figures. The strongest evidence for stigmatization due to ‘labeling’ was also amongst adults. Today’s youth may be more open and supportive of YP-MHD, and the media’s role in normalizing MHD may be filtering through to YP-MHD such that they no longer feel as “singled out”. Although encouraging, this leaves much room for improvement for the 25% who will suffer self-stigmatizing attitudes, resulting in secrecy, denial and possible poorer outcomes (Moses T., 2010b).

4.2. Limitations

Whilst this review represents a promising start to our understanding of stigma towards YP-MHD, it has some limitations. Firstly, although 42 papers were identified, the rich variation in methodology, sample size and subsequent quality presented a challenge in comparing the data, as the concepts being investigated were not always like-for-like. This is in part due to the absence of standardized, validated tools, to compare experiences of stigma in YP-MHD, until recently (McKeague et al, 2015). Hence, this made it difficult to both draw comparisons between groups, and also investigate change over time. Secondly, the studies only reviewed a limited number of stigma components. Thirdly, due to the specific age range reviewed for the purposes of this paper, recent studies which overlapped with our age range but from which we could not readily extract child-specific data were excluded. Fourthly, most studies also looked at self-reporting of stigmatizing attitudes and this may not reflect true behavioral intentions. Finally, evidence regarding self-stigmatization came from only one sample of YP-MHD.

4.3. Future directions

It was very positive to identify that YP may present as more accepting than adults of YP-MHD. YP reacted to the behaviors displayed by their peers rather than any labels attached,
which suggests that naming the concern, so that appropriate interventions can be sought, may not have such a negative impact on YPs' attitudes.

Future studies will need to further investigate sex-related aspects of stigmatizing attitudes and in particular why females have less stigmatizing views than males, and at what point self-stigmatization develops in both sexes. It is also important to understand why familiarity and knowledge do not necessarily equate to a reduction in stigmatizing views, as this may often be an assumption when designing projects to reduce stigmatization. There is a need to replicate the above work to ensure findings are reproducible and more widely applicable, and to invest in longitudinal studies to understand how stigma evolves across the developmental trajectory of children and adolescents.

Based on our findings, future investment should aim at

• Targeting gender differences with special emphasis on males e.g. working with boys’ schools and providing better pastoral care.

• Targeting worries associated with specific diagnoses e.g. dangerousness in psychosis.

• Offering tailored psychoeducation following diagnosis to YP-MHD and their family. The evidence has shown that those with a greater sense of responsibility for their illness have a higher level of self-stigma, so specific psychoeducation programs around this may reduce the impact of this false notion.

• Offering family orientated interventions. Unless stigma is addressed within families, transgenerational transmission of stigmatizing attitudes will continue to affect access to services and appropriate treatment of YP with mental health problems. Families in lower socioeconomic groups may be in greater need of intervention of this kind.

• Setting up anti-stigma campaigns led by individuals with an understanding of the wider cultural context. A ‘one size fits all’ approach is likely to fail in an ethnically diverse society, as different cultural beliefs come into play from childhood, influencing attitudes and discrimination.

ACKNOWLEDGMENTS
The Stigma of Mental Illness in Children and Adolescents: A Systematic Review

We would like to thank Gillene Thomas and Sandra Fewings for their assistance in the identification of studies included in the revised versions of the manuscript.

<td>8-18</td>
<td>926 F (48.7%)</td>
<td>51.2% White, 14.8% African American, 11.0% Hispanic, 3.0% Asian</td>
<td>To investigate: 1. differences in stigmatization between mental and physical health conditions; 2. the effect of causal attributions and beliefs about dangerousness on discriminatory behaviors.</td>
<td>Children were randomly assigned vignettes depicting a child with one of: ADHD, depression, or a physical condition. Children responded to an online survey.</td>
<td>Stigmatization by diagnosis: Depression was more stigmatized than ADHD. Blame/Responsibility: See below. Causal attributions, Blame/Responsibility and Social distance: Poor parenting, substance misuse and low effort resulted in a more blaming view and an increased desire for social distance. Endorsed beliefs of stress, poor parenting, substance misuse and low effort were most commonly endorsed for the depression vignette. Genetic and brain differences were identified as causal attributions in all vignettes equally. Genetics, brain differences and God's will were not associated with social distance. Ethnicity: Differences were identified by ethnic background. Gender: Girls were significantly more likely to endorse stress as a causal factor. Self-stigma: Those who reported a diagnosis of depression or ADHD were more likely to endorse parenting, low effort and substance misuse causes (moralistic causal beliefs). Social distance: See Causal attributions above.</td>
</tr>
<tr>
<td>6</td>
<td>2005</td>
<td>USA</td>
<td>3 years</td>
<td>189 F (55%)</td>
<td>16.6% White, 16.6% Black, 9.5% Hispanic, 2.1% Native American</td>
<td>To investigate: 1. differences in stigmatization between mental and physical health conditions; 2. the effect of causal attributions and beliefs about dangerousness on discriminatory behaviors.</td>
<td>Adolescents were presented with one of 4 vignettes: peer with mental illness; peer with mental illness and a brain tumor; peer with alcohol misuse; peer with leukaemia.</td>
<td>Stigmatization of YP-MHD: Alcohol misuse was the most stigmatized of the conditions (statistically significant). Mental illness was more stigmatized than leukaemia on measures of pity, dangerousness, fear, help and avoidance. Dangerousness: Greater familiarity resulted in stronger attributions of dangerousness but with a small effect size (R² = 0.05). Ethnicity &amp; Gender: No associations were identified between demographics of participants and familiarity. Familiarity &amp; Blame/Responsibility: Greater familiarity resulted in greater responsibility being attributed to people for their mental illness. Social distance: Willingness to help was associated with pity and inversely associated with anger. Danger was positively correlated with fear (R² = 0.53) and which was in turn positively correlated with avoidance (R² = 0.26). Note: Some students had been exposed to the anti-stigma campaign so some responses may be post an anti-stigma intervention and such studies were generally excluded from the paper.</td>

</table>

- **Age & Gender:** There were positive changes for both boys and girls, with gender differences based on the specific construct being measured. Subtle differences in the strength of positive findings were noted between gender and grades.
- **Familiarity:** Children who had had actual classroom contact with peers with ASD held more positive attitudes and behavioral intentions and were more empathic than children who hadn’t had classroom contact. This difference was maintained at 3 months. **Social Distance/behavioral intentions:** See above.

**Studies:**
- **Views of Young People**
- **Country**
- **No. Participants**
- **Age**
- **Gender**
- **Ethnicity**
- **Purpose**
- **Methods**
- **Outcome Measures**

**Notes:**
- **Quality:** Strong
- **Quality:** Moderate
- **Quality:** Good

**PMHSS:** The PMHSS showed good validity and reliability. Stigmatization of YP-MHD: YP were able to distinguish between personal stigma (their own stigmatizing views) and societal stigma (other peoples' stigmatizing views) towards YP-MHD.

**Socioeconomic status (SES):** Did not show any differences in stigmatizing views.

**Age:** Older participants were more stigmatizing of YP-MHD than younger children.

**Explicit attitudes:**
- **Gender:** Males reported more peer stigmatization. No difference found in family stigmatization based on demographic factors.

**Stigmatization by diagnosis:**
- **Social distance & Perceived stigmatization in YP-MHD:** 62% participants described stigma in peer relationships amounting to friendship loss. Those who did not report difficulties were more secretive or to socialise with others with similar difficulties. 46% described stigmatization from family and 35% described stigma from school staff. 22% described a different but positive treatment from others as a result of their difficulties. 3 adolescents felt ‘over-protected’ by family members. Those who reported stigmatization in one domain were likely to report stigmatization in another domain. Youth with at least 1 affective disorder reported more perceived stigma from peers.
| Study | Authors | Country | Sample Size | Age | Gender | Ethnicity | Purpose | Methods | Outcome Measures |
|-------|---------|---------|-------------|-----|--------|-----------|---------|---------|-----------------
| 17    | O'Driscoll et al 2015b | Ireland | 148 | 10-11 years (n = 72) and 15-16 years (n = 76) | 80F 54% | White | To explore adolescents’ beliefs about fairness of excluding peers with ADHD or depression | Qualitative group study consisting of same-sex groups of 3-5 participants interviewed in school. Participants were randomly assigned to either the depression or ADHD groups and read to age and sex matched vignettes | Thematic analysis of YP-MHD: This was the only study in the review which sought to explore YP views of excluding peers with a mental illness. The participants appeared to recognize the pros and cons of exclusion for YP-MHD. They appeared to respond that justification for excluding peers would depend on an extent to their relationship with the YP-MHD. They also recognized the benefits of positive peer relationships for YP-MHD but were concerned with the social costs for themselves of including them.

| 18    | O'Driscoll et al 2015b | Ireland | 148 | 10-11 years (n = 72) and 15-16 years (n = 76) | 80F 54% | White | To provide a detailed understanding of the nature and function of discriminatory behavior ours in YP without mental health problems (social exclusion) towards YP-MHD. | Qualitative group study consisting of same-sex groups of 3-5 participants interviewed in school. Participants were randomly assigned to either the depression or ADHD groups and read to age and sex matched vignettes | Thematic analysis of YP-MHD: Two main reasons were given to justify social exclusion (discrimination) of YP-MHD by peers:
- Failure to engage in a reciprocal social interaction, which participants felt would result in a very one sided or boring interaction. They were also concerned with the YP-MHD not liking them.
- Risk: Concerns about the impact that engaging with the YP-MHD would have on the participants own mental state, and the risk of disciplinary or social consequences of associating with them.

| 19    | Peterson et al | USA | 163 | 8-17 and 11-16 | 93F 57% | Predominantly boys | Children were shown one of 4 SAT or SDS | Stigmatization of YP-MHD: Children rated the depressed child less favorably compared to the non-depressed child.

<td>White 52%</td>
<td>The study had 3 main goals, only one of which was related to stigma as follows: Do children with ADHD or depression have autistic behaviors and disorder as stigmatizing?</td>
<td>Children recruited from primary and secondary schools, community centers and libraries. They completed a battery of questionnaires</td>
<td>AAQ (Attributions of ADHD Questionnaire)</td>
<td>Perceived stigmatization was linked to lower self esteem. The findings suggested that children with ADHD are vulnerable to self-stigmatization and greater perceived stigma. Self-stigma: Children with ADHD perceived the most problematic ADHD behaviors as more stigmatizing (i.e., more troublesome to others, more embarrassing) than children without ADHD. They reported more stigmatization from parents, teachers and peers.</td>

- Items about dangerousness in schizophrenia were most likely to be endorsed.
- Items relating to social phobia being a personal weakness were most likely to be endorsed.
- Items relating to 'not telling anyone' about depression were most likely to be endorsed.

**Dangerousness:** Beliefs about dangerousness were more commonly held about schizophrenia.

**Gender:** Males were more stigmatizing than females for all scales (statistically significant difference)

**Perceived stigma:** Personal stigma was lower than perceived stigma for all disorders.

<td>46</td>
<td>30-50</td>
<td>40 F (87%)</td>
<td>To investigate teachers' knowledge and attitudes towards ADHD and LD.</td>
<td>An author designed questionnaire of 54 questions in total, assessed, amongst other things, teachers' attitudes towards pupils with ADHD</td>
<td>Newly piloted questionnaire of demographics and teacher knowledge &amp; attitudes about ADHD &amp; LD (learning difficulties)</td>
<td>Stigmatization of YP-MHD: 1/2 teachers responded that pupils with ADHD should be taught in a special setting and 1/2 favoured mainstream education. Most teachers believed that students with ADHD have similar IQs to students without ADHD. 87% felt that children with ADHD required psychological support; and 85% would be more lenient towards students with ADHD. Teachers wanted to be informed if a child had ADHD: 15% thought that pupils with ADHD were less likely to be less successful in the future. 1/2 believed that children with ADHD would continue to struggle with peer relations and family life in the future. In summary, the authors reported that attitudes and understanding of ADHD were relatively poor.</td>

</tr>
</tbody>
</table>
| Personal stigma | Quality: Moderate | See methods Martin et al | | | | Descriptive analysis & logistic regression used to account for the emergence and persistence of negative attitudes | Blame/Responsibility: Child blame was endorsed as a causal attribution in over 70% of children depicted in the ADHD or depression vignette, which was higher than for asthma (43%) and normal troubles (65%). ADHD was the only one of the 4 conditions significantly positively associated with all four causal attributions. Higher educational achievement resulted in increased beliefs of environmental stress factors and less apportioning of blame to the child. 
Social distance/Behavioral intentions: Desire for social distance was significantly higher for children in the ADHD and depression vignettes than for asthma. ADHD had the highest mean desire for social distance, and parent blame was endorsed more frequently than biology. Gender, Age, race and income had no statistically significant difference with endorsed attributions. 
Ethnicity: black respondents preferred greater social distance from the child. |
| Ohan et al 2013 | Australia | 225 | 39.17 +/- 5.42 | 200 F (89%) | Australian 92% Other 8% | To examine the impact of labeling on children with ADHD or depression | Parents answered questions on a vignette of a M/F child with either: no mental health difficulty; symptoms of depression or ADHD but no label; symptoms of either ADHD or depression with an attached diagnostic label | Stereotypes subscale, Prejudice subscale, Social distance subscale | Stigmatization of YP-MHD: Parents were significantly more stigmatizing (more stereotypes and prejudices held) towards children with symptoms of ADHD or depression than without. There was a further small significant increase in stigmatizing views when a label was attached. 
Stigmatization by diagnosis: ADHD was more stigmatized than depression on measures of prejudice and Social distance. Social distance As above |

<td>Perry et al 2007</td>
<td>USA</td>
<td>505</td>
<td>Adults 18-89 years</td>
<td>302 (60%)</td>
<td>13-15% African American</td>
<td>To compare public attributions and attitudes of the general population towards children and adults with depression, with a focus on causality, perceptions of violence and the use of coercion</td>
<td>Participants responded to questions assessing the described construct, following a vignette description of either a child or adults with depression</td>
<td>Descriptive &amp; bivariate logistic analysis of 5 sets of binary variables, comparing public attitudes and attributions toward child/adult depression</td>
<td>Stigmatization of YP-MHD: Childhood depression was perceived as more serious than adult depression (83% v 51%). Causal attributions: Both adult and childhood depression were attributed to stress. More people recognized childhood depression as a genetic condition, a chemical imbalance or a consequence of child rearing. Dangerousness: Respondents believed children with depression to be more dangerous than adults with depression (40% v 30%). They perceived the 2 groups to be of equal risk to themselves. In summary, authors concluded that children with depression may be more vulnerable to stigmatization than adults with the same condition.</td>

**Highlights**

- Stigmatization of young people with mental health difficulties is widespread and starts from childhood.

- Young people seemed to be more accepting than adults’ of children and adolescents with mental health difficulties.

- Current evidence suggests that young people may be reacting more to the behaviours displayed in peers with mental health difficulties, rather than to mental health labels.

- More research, and validated instruments measuring stigma, are needed to better understand stigma and self-stigma, so that it can be targeted effectively in the future.
