Article Type: Basic Science
ABSTRACT

BACKGROUND: Deterioration in bone health is a concern in managing pediatric inflammatory bowel diseases, but clear understanding of the independent contributions of disease and nutrition is lacking. This study aimed to ascertain whether bone health could be conserved during colitis by maintaining adequate nutritional intake in growing piglets.

METHODS: The effect of colitis on bone structure and strength was determined in piglets with dextran sulphate sodium-induced colitis. Piglets received either 100% macro/micronutrient requirements or 50% macro/100% micronutrient requirements. Femurs were analyzed for dual-energy x-ray absorptiometry, peripheral quantitative computed tomography, micro-computed tomography and 3-point bending tests.

RESULTS: Colitis, regardless of a well-nourished or malnourished diet, compromised areal bone mineral density (-17%) and volumetric bone mineral density (-20%) in cortical and trabecular bone. Structural integrity at mid-diaphysis was maintained during colitis; however, lower cortical area, trabecular area and bone mineral content resulted in lower energy to break.

CONCLUSION: Colitis compromises both bone structure and strength of long bones in piglets, independent of macronutrient intakes. Although confirmation of these findings in pediatric cohorts is needed, these data identify aspects of bone health that may be affected by inflammatory bowel disease.
INTRODUCTION

Inflammatory bowel disease (IBD) in children causes slowed growth, impaired bone growth and decreased stature (1-4). Children with IBD present with faltering linear growth and are often shorter (mean z-score -0.5) than expected for age compared to their parents and peers with up to 12.2% of this group being classified as stunted (<-2 z-score) (5). Similarly, dual-energy x-ray absorptiometry (DXA) imaging reveals that 75-89% have low areal bone mineral density (aBMD) during active disease states and 10-37% have low aBMD (z-score below -2.5) when in remission (6).

Long bones (e.g. femur, tibia) of children and adults are affected differently by IBD as pediatric populations usually present with slowed growth, while adults show signs of increased bone resorption (7). Abnormal bone development and skeletal morbidity may be multifactorial (8) or associated with inflammation (9), side-effects of medications (10) and/or inadequate nutrition (11). It has also been suggested that decreased physical activity and muscle strength may affect bone health in pediatric IBD (12).

Malnutrition is common among children with IBD and may be the result of reduced intake (13). Early studies demonstrated that bones of severely malnourished children are shorter and lighter than healthy children (14), and children with edematous malnutrition showed growth restriction, irregularly calcified epiphyses and diminished pattern of trabeculae in both femur and tibia (15). If bone resorption is elevated and bone formation reduced, bone modeling would be altered and reflected in bone geometry – ultimately, this would negatively affect bone strength. However, to date, such data in pediatric IBD is scarce (7).

Macronutrient under-nutrition, especially protein malnutrition, has been studied extensively in rats. Growing rats fed a protein-restricted diet (2.5% casein) for 16 weeks had decreased aBMD, bone mineral content (BMC), and bone strength in the lumbar spine, femur and tibia, along with lower
plasma insulin-like growth factor I (IGF-1) levels compared to rats fed a protein adequate diet (15% casein) (16). In a similar study, femurs of growing rats fed a 4% protein diet had lower linear dimension, weight and strength than controls receiving a 20% protein diet (17).

The dextran sulphate sodium (DSS) model of colitis is a well-established animal model of inflammation and mucosal injury similar to that of human ulcerative colitis (18,19). Our group has developed a piglet model of colitis (20-23) because the gastrointestinal physiology, morphology and pathology of the piglet more closely resembles that of humans (24). In this study we investigated how the structure and strength of femurs were affected by colitis and nutrition in growing piglets. Specifically, we used DXA, peripheral quantitative computed tomography (pQCT) and micro-computed tomography (μCT) in our analysis of long bone (whole, trabecular, and cortical) with respect to bone area, BMC, aBMD, volumetric bone mineral density (vBMD) and cortical thickness. We also used the 3-point flexure method to determine bone strength.

The aim of this study was to ascertain whether bone structure and strength could be maintained during colitis by providing adequate macronutrient intake. Specifically, we hypothesized that: 1) malnourished piglets with colitis would have decreased bone area, BMD, BMC, cortical thickness and bone strength compared to healthy, well-nourished piglets, and that 2) well-nourished piglets with colitis would maintain bone health similar to well-nourished piglets without colitis.
RESULTS

As previously described by Harding and colleagues, colitis was confirmed by the presence of fecal occult blood by day 9 of the 14-day study and colon histology was characterized using a 6-point scale with 4 sub-classifications (higher histological damage scores were demonstrated in piglets with colitis than health controls) (21). Well-nourished piglets with colitis (WN-C) demonstrated lower increases from Day 1 in chest circumference (-33%) and snout-to-rump length (-22%) compared to healthy piglets without colitis (WN-Healthy). Malnourished piglets with colitis (MN-C) demonstrated lower gains in average daily weight (-63%) and lower increases from Day 1 in chest circumference (-77%) and snout-to-rump length (-29%) compared to healthy piglets (22). In the present study, results are presented in graphical form, while data tables can be found in supplemental materials. In addition, an analytical model of the left femur was created to clearly portray our methodology and gain a visual appreciation of the level of detail captured by DXA, pQCT and μCT (Figure 1).

Linear Dimensions

Femur length was not different among the three groups (7.11 ± 0.14 cm). Neither widths (1.14 ± 0.03 cm) nor cortical thicknesses (0.10 ± 0.01 cm) at mid-diaphysis was different among groups (Supplemental Table S1 (online)).

Whole Bone Analysis

Femur aBMD was affected by both colitis and macronutrient intake (Figure 2). The DXA analysis confirmed lower whole bone aBMD of femur in WN-Colitis (0.242 g/cm²) by 16% (p < 0.05) and MN-Colitis (0.239 g/cm²) by 17% (p < 0.05) compared to WN-Healthy (0.287 g/cm²). Whole bone area and BMC were not different among groups, whereas μCT analysis demonstrated no difference in whole bone volume, BMC and vBMD among groups (Supplemental Table S2 (online)).
**Bone Geometry Analyzed by pQCT**

The pQCT analysis of femurs 4% from the growth plate revealed lower vBMD (total, trabecular and cortical) in WN-Colitis (189, 173 and 219 mg/cm³ respectively) by 20% (p<0.05) compared to WN-Healthy (243, 230 and 276 mg/cm³ respectively); however, area (total, trabecular and cortical) was not different (Figure 3). Similar patterns of change were seen 8% and 12% from the growth plate. At the 40% site, lower cortical area in WN-Colitis (27 mm²) by 21% (p<0.05) and MN-Colitis (27 mm²) by 21% (p<0.05) was observed compared to WN-Healthy (34 mm²); however, cortical vBMD was not different. Neither cortical area nor vBMD were different 50% from the growth plate (Supplemental Table S3 (online)).

**Bone Geometry at Mid-Diaphysis by μCT**

Femur area at mid-diaphysis was uniquely affected by colitis and nutritional status (Figure 4). Cortical and trabecular area of femur at mid-diaphysis were lower in WN-Colitis (0.28 and 0.10 cm² respectively) by 20% (p<0.05) and MN-Colitis (0.28 and 0.09 cm² respectively) by 40% (p<0.05) compared to WN-Healthy (0.35 and 0.17 cm² respectively); there was no difference in total area. Cortical volume at mid-diaphysis was lower in WN-Colitis (0.005 cm³) by 30% (p<0.05) and MN-Colitis (0.005 cm³) by 30% (p<0.05) compared to WN-Healthy (0.007 cm³); there was no difference in total or trabecular volume. BMC at mid-diaphysis (total, trabecular and cortical) was lower by 22%, 15% and 55% (respectively; p<0.05) in both WN-Colitis (4.7, 0.5 and 3.9 mg respectively) and MN-Colitis (4.7, 0.5 and 4.3 mg respectively) compared to WN-Healthy (6.0, 1.1 and 4.7 mg respectively). vBMD at mid-diaphysis (total, trabecular and cortical) was not different among the three groups (Supplemental Table S4 (online)).
**Bone Strength**

Femur strength was uniquely affected by both colitis and nutritional status (Figure 5). Energy at break was lower in WN-Colitis (956 mJ) by 26% (p<0.05) and in MN-Colitis (895 mJ) by 31% (p<0.05) compared to WN-Healthy (1295 mJ). Young’s Modulus, stress, strain, work to failure and modulus of toughness were not different among the three groups (Supplemental Table S5 (online)).
DISCUSSION

This study presents a comprehensive analysis of bone in the growing piglet as a model for the growing child using precise imaging techniques. Using pQCT technology, we found lower vBMD (total, trabecular and cortical) but similar area of femurs in piglets with colitis compared to healthy controls at all three regions analyzed (4%, 8% and 12% from the growth plate). Analysis by μCT at mid-diaphysis found that trabecular and cortical area of femur were comprised by colitis, whilst vBMD remained the same. These data suggest that short-term colitis may compromise the mineralization of newly formed bone below the growth plate. Conversely, colitis may not alter density of bone at mid-diaphysis formed prior to administration of DSS, though further bone growth (i.e. bone area) seemed to be compromised. This notion may also be supported by the bone strength data. Femoral intrinsic strength was maintained (i.e. Young’s Modulus and Modulus of Toughness), while the extrinsic property (i.e. energy at break) was lower in piglets with colitis. This suggests that piglets with colitis may be more sensitive to breaks when pressure is applied directly at mid-diaphysis where bone area is smaller (despite unaltered vBMD).

Our results are similar to previous work demonstrating 2 weeks of DSS administration in 9-week old mice resulted in decreased trabecular bone volume and trabeculae number in distal metaphysis in mice with colitis compared to controls (19). Similarly, children newly diagnosed with Crohn’s disease had significantly lower trabecular vBMD at tibial metaphysis compared to healthy controls, with significant improvement within the first 6 months of treatment (25). However, it is unclear if the low vBMD in children is due to the inflammatory effects of colitis or altered nutrient metabolism that would limit mineralization of newer bone under the growth plate (26). In contrast to our work, others have suggested that children with IBD are not more likely to have increased fracture risk than healthy controls in the same age and gender category (26), while the prevalence of long bone
fractures, as reported by parents in a survey, was also no different between children with IBD and their healthy siblings (27).

In our study, piglets were maintained on liquid formula diets delivered by intragastric feeding tube. Exclusive enteral nutrition has recently been used as the therapy of choice to induce remission in patients with Crohn’s disease with about 80% of patients entering remission after 8 weeks (28). Enteral feeds and steroids have similar efficacy in promoting remission (29) and patients receiving nutritional therapy showed less reduction in BMD than those receiving corticosteroids (30). Recently, after eight weeks of exclusive enteral nutrition, markers of bone resorption and bone formation normalized to control levels, suggesting that adequate nutrition or nutritional therapy may normalize bone turnover by reducing inflammation (31).

We demonstrated that the superimposition of moderate protein energy malnutrition in piglets with short-term colitis did not compromise geometry of long bones. We cannot be certain if malnutrition had an effect, since all piglets were constantly fed an enteral formula consisting of high quality proteins with calcium, high vitamin D, and adequate micronutrients. Therefore, our model of moderate protein energy malnutrition may not completely parallel the human scenario. It is interesting to note that despite constant enteral feeds, bone geometry was compromised in piglets with colitis compared to their healthy controls, suggesting that the inflammatory response itself may have a greater short-term effect on bone than nutrition.

An important contribution of this study was to establish the conditions for comprehensive imaging with multiple platforms (DXA, pQCT and μCT). We found that aBMD (as analyzed by DXA) was lower in piglets with colitis than healthy controls, but vBMD of the whole femur (as analyzed by μCT) was not different. Conversely, in children with IBD, there was no change in aBMD of the femoral neck (as determined by DXA); however, volumetric interpretation of the DXA data
demonstrated low vBMD (9) after calculating bone mineral apparent density from a formula developed by Kroger and colleagues (32). This rationale stems from the idea that calculating vBMD using DXA analysis alone may not always reflect true vBMD – the area being measured is two-dimensional and does not include the depth and thickness of the bone, which is necessary for determining true bone mineral content since minerals are spread throughout the entire bone (33). Based on our analysis, we found that pQCT and μCT are more precise in analyzing BMD compared to DXA, providing a volumetric analysis instead of a two-dimensional areal analysis. Additionally, we found that both pQCT and μCT are similarly precise in their analyses of total, cortical and trabecular area, BMC and vBMD.

There are several limitations to this study that must be addressed. Firstly, investigation of osteoblast/osteoclast activity, IGF-I levels and RANKL/OPG expression would have greatly completed the bone structure and strength outcomes to give a better understanding of bone development and integrity. Second, the sample size was small, ranging from N=6 to N=8 piglets; however, statistically significant data was homogenous and normally distributed. Lastly, the mechanism of how DSS induces colitis is not well described in literature and may not exactly represent how ulcerative colitis actually affects bone development in humans.

In conclusion, we were able to use complementary imaging techniques to analyze bone geometry in a growing piglet model of DSS-induced-colitis. We have shown that short-term colitis compromises bone structure and bone strength of piglet femurs, independent of protein and energy malnutrition. Using DXA, we found that colitis decreased whole bone aBMD. Analysis with pQCT determined that colitis compromised vBMD of newly formed cortical and trabecular bone near the growth plate. The use of μCT at mid-diaphysis found that structural integrity of bone was maintained during colitis but lower area resulted in lower energy to break. Future investigations of
osteoblast/osteoclast activity and expression of inflammatory mediators, bone growth factors would greatly complement the outcomes of our study and give a better understanding of bone development and metabolism. Inflammation plays a key role in the pathogenesis of bone loss in pediatric IBD and warrants further investigation towards therapies that may prevent and reverse the loss of bone.
MATERIALS AND METHODS

Animals and Study Protocol

Piglets (N=16; 5-7 days old; Yorkshire x Landrace) were randomized to 3 treatment groups for the 14-day study as previously described by Harding and colleagues (21,22). Catheters were implanted in femoral and jugular veins (for blood sampling) and stomach (for diet and DSS administration) on day 1, using isoflurane (MTC Pharmaceuticals, Ontario, Canada) anesthesia (20). Constant intragastric feedings began 2 hours after surgery and infused daily over 16 hours, reaching full feeding of 300 mL/kg by day 3 and adjusted daily based on weight. On day 4, two groups received DSS 1 g/kg/d to induce colitis and, after 5 days of DSS, the presence of occult blood by Hemoccult (Beckman Coulter, ON, Canada) confirmed colitis.

Liquid diets were prepared in our laboratory using an egg albumin and whey protein base (21) to achieve nutritionally adequate energy intakes as per National Research Council (NRC) recommendations (34). Well-nourished groups received 100% of macro- and micronutrient requirements (WN-Healthy and WN-Colitis) and the malnourished group (MN-Colitis) received 50% of macronutrient requirements to achieve energy intakes of 925 kJ/kg/d and 461 kJ/kg/d, respectively. However, the MN-Colitis group received >100% of the micronutrient requirements. Of particular interest to this study, vitamin D was supplied at 120% of NRC recommendation in all three groups.

The right hind leg from each piglet was removed at necropsy. Femurs were excised, cleaned of soft tissue, wrapped in saline soaked gauze and stored at -20°C. All animal procedures and protocols were reviewed and approved by the McGill University Animal Care Committee in accordance with the Canadian Council on Animal Care guidelines (35).
**DXA Analysis**

Each bone was scanned *ex-vivo* using a QDR 4500A v11 bone densitometer and analyzed using the “small animal” software (Hologic Inc, Massachusetts, USA). Quality control was performed using a spine phantom, yielding a coefficient of variation (CV%) for BMC and aBMD of < 0.5%. Before positioning the femur, the length and width (at midpoint) was measured with a Fisherbrand traceable digital caliper (Fisher Scientific). Each bone was scanned supine in a water bath where the water was 1 cm above the most prominent part of the bone. Data collected included bone area (BA; cm²), bone mineral content (BMC; g) and areal bone mineral density (aBMD; g/cm²). All bones were scanned once, with the exception of the first bone, which was scanned three times.

**pQCT Analysis**

Each femur was scanned *ex-vivo* using a Stratec XCT 2000 scanning unit (Stratec Inc, Pforzeim, Germany). A tube made of #2 plastic with the following dimensions was used: 15.5 cm x 8.5 cm x 0.5 mm. The standard phantom was scanned with and without the plastic tube to rule out x-ray interference. Femurs were scanned in the supine position. The reference line was set before each scan using a scout view (SV) and placing the line at the lowermost point of the top of the distal epiphyseal plate. Gantry diameter was set to 60 mm and voxel size was 0.2 mm. Cross sectional slices (1 mm thick) were made at each of five different sites: 4%, 8%, 12%, 40% and 50% from the reference line (NB- the reference line is placed 10% the length of the bone; therefore, the 40% site represents mid-diaphysis). The SV speed was set to 30 mm per second and the CT speed to 10 mm per second. To measure trabecular bone, a threshold of 107 mg/cm³ was used with a trabecular area of 65%. To measure cortical bone a threshold of 524 mg/cm³ was used. For the three trabecular sites (4%, 8% and 12%), area and volumetric BMD were calculate for total, trabecular and cortical bone. For the two
cortical sites (40% and 50%) cortical area and cortical density were calculated. Area is expressed in mm² and density in mg/cm³.

μCT Analysis

Each bone was scanned *ex-vivo* using a Latheta LCT-200 X-ray CT scanning unit and analyzed using the standard analysis software (Hitachi-Aloka Medical Ltd., Tokyo, Japan). Each bone was placed in a lucite holder which was 60 mm in diameter. Positioning was standardized in the supine position, with the distal end of the bone facing the opening of the unit (specimen position was determined as “face down and head front”). Scan conditions were set as follows: pixel size 60 μm, slice thickness 120 μm, number of slices 450, pitch 180 μm, rotation angle 360 degrees. Each bone was scanned once with the exception of the first bone scanned on each day, which was scanned three times. The mid-diaphysis slice was then analyzed to provide parameters that were then used for the bone’s moment of inertia, namely x, x’, y and y’ as per Ferretti and colleagues (36). Parameters measured where: cortical thickness, planar volume (total, cortical, trabecular), BMC (total, cortical, trabecular) and vBMD (total, cortical, trabecular). Area is expressed in cm², volume in cm³, BMC in mg and volumetric vBMD in mg/cm³. All bones were scanned once, with the exception of the first bone, which was scanned three times.

Bone Strength

Biomechanical strength of each bone was tested *ex-vivo* by the 3-point flexure method using an Instron v5544 (Instron, Massachusetts, USA). Fulcrum span-length was set at 22.68 mm. Bones were balanced between the 2 fixed supports in the supine position so that the load descends in the anterior to posterior direction. Mid-diaphysis was determined by dividing the length of the bone by two. A test speed of 2 mm/min was used and bones were loaded until failure. The time to break was on average 2.3 minutes. Load extension curves (N vs. mm) were constructed for each bone using Bluehill© software
version 3. Extrinsic parameters measured were: energy at break, ultimate force, ultimate displacement and work to failure. Intrinsic parameters measured were: stress, strain, Young’s modulus and modulus of toughness.

Statistical Analysis

All data was analyzed as one-way unbalanced ANOVA using the proc glm procedure of SAS Version 9.3. Least square means were calculated with pooled standard error. Levene’s test confirmed homogeneity of variance and the Anderson-Darling test confirmed normality. Tukey-Kramer test was used to determine statistical significance. A p-value of < 0.05 was considered statistically significant. Data that were not homogenous or normally distributed were power transformed.

ACKNOWLEDGEMENTS

We would like to thank Paula Lavery for her invaluable assistance in training and calibration of the DXA, μCT and INSTRON v5544.

AUTHORSHIP

P.V. designed and carried out the research, analyzed the data, performed the statistical analysis and wrote the first complete draft of the manuscript; S.V.H. designed the original piglet research, carried out the piglet study and wrote the manuscript; T.J.H. designed and carried out the pQCT protocol and helped write the manuscript; H.A.W. designed the research and wrote the manuscript; L.J.W. conceived the study, carried out the piglet study, wrote the manuscript and had primary responsibility for the final content. All authors read and approved the final manuscript.
