Corticolimbic dysfunction during facial and prosodic emotional recognition in first-episode psychosis patients and individuals at ultra-high risk

Huai-Hsuan Tseng, MD, PhD,*, Jonathan P. Roiser, PhD, Gemma Modinos, PhD, Irina Falkenberg, MD, Carly Samson, BST, Philip McGuire, MD, PhD, Paul Allen, PhD

1. Introduction

Emotional processing deficits are widely reported in patients with chronic schizophrenia and first-episode psychosis (FEP), and has been linked to functional abnormalities of corticolimbic regions. However, corticolimbic dysfunction is less studied in people at ultra-high risk for psychosis (UHR), particularly during processing prosodic voices. We examined corticolimbic response during an emotion recognition task in 18 UHR participants and compared them with 18 FEP patients and 21 healthy controls (HC). Emotional recognition accuracy and corticolimbic response were measured during functional magnetic resonance imaging (fMRI) using emotional dynamic facial and prosodic voice stimuli. Relative to HC, both UHR and FEP groups showed impaired overall emotion recognition accuracy. Whilst during face trials, both UHR and FEP groups did not show significant differences in brain activation relative to HC, during voice trials, FEP patients showed reduced activation across corticolimbic networks including the amygdala. UHR participants showed a trend for increased response in the caudate nucleus during the processing of emotionally valenced prosodic voices relative to HC. The results indicate that corticolimbic dysfunction seen in FEP patients is also present, albeit to a lesser extent, in an UHR cohort, and may represent a neural substrate for emotional processing difficulties prior to the onset of florid psychosis.

amygdala, parahippocampal area, inferior frontal cortex) for evaluation. Neuroimaging findings in chronic schizophrenia and FEP patients suggest neural dysfunction is present at both stages of the putative model (Leitman et al., 2007; Li et al., 2010; Mitchell et al., 2004), i.e. in emotional perception and evaluation regions. Structural and functional abnormalities in these regions have also been reported in UHR populations (Broome et al., 2009; Fusar-Poli et al., 2011, 2007; Mechelli et al., 2011; Seiferth et al., 2008; Smieskova et al., 2010; Tognin et al., 2014). Furthermore, previous functional imaging studies in UHR cohorts examining emotional processing explicitly, using face stimuli, reported altered activation in primary sensory (i.e. lingual, fusiform, and middle occipital gyri) and in the prefrontal cortex relative to healthy controls, but not always in the amygdala (Seiferth et al., 2008; Wolf et al., 2015). These findings imply that emotional processing dysfunction in UHR participants may arise from the initial information decoding stage in sensory areas prior to engagement of the amygdala. However, so far the evidence is equivocal. The incentive salience hypothesis proposes that increased firing of dopaminergic neurons in the striatum enhances the salience of irrelevant stimuli in patients with schizophrenia, including emotion-laden stimuli (Heinz and Schlagenhauf, 2010; Howes et al., 2009; Kapur, 2003; Roiser et al., 2013). It has been repeatedly demonstrated that striatal dopaminergic activity, including dopamine synthesis capacity and stress-induced dopamine release, is increased in the early phase of the illness, including FEP (Bonoldi and Howes, 2013; Ellison-Wright et al., 2008; Mizrahi et al., 2012) and UHR stages (Egeront et al., 2013; Howes et al., 2009; Mizrahi et al., 2012) These alterations are mainly observed in the dorsal striatum. Furthermore, increased resting perfusion, a marker of neural activity (Allen et al., 2015), and altered connectivity (Dandash et al., 2014) have been reported in the dorsal striatum (especially the caudate) in UHR cohorts. Altered striatal function observed in FEP and UHR individuals may contribute to altered salience responses (Roiser et al., 2013), including responses to emotional-laden stimuli (Winton-Brown et al., 2014).

The dorsal striatum, especially the caudate nucleus, has been shown to modulate frontolimbic connections during valence-specific emotional processing (Dwadkar et al., 2012; Kotz et al., 2015), particularly in response to unpleasant stimuli (Carretie et al., 2009). Misattribution of emotionally salient stimuli has been reported in patients with schizophrenia during emotional processing (Cohen and Minor, 2010). Together, these findings implicate that altered striatal function in psychosis contributes to the valence misattribution of emotional-laden stimuli. It is not clear, however, if altered striatal function impacts on emotional valence judgment in UHR and FEP individuals.

We investigated the neural correlates of emotion recognition in UHR and FEP subjects using both dynamic facial and prosodic voice stimuli. In addition to the emotional face stimuli used in previous studies in UHR populations (Dwadkar et al., 2012; Seiferth et al., 2008), we additionally included prosodic voice stimuli; as impaired capability to extract non-verbal emotional information from language is widely reported in schizophrenia (Bach et al., 2009; Edwards et al., 2002, 2001; Kucharska-Pietura et al., 2005; Leitman et al., 2007) and high-risk populations (Addington et al., 2012; Amminger et al., 2012a, 2012b). We predicted that (1) relative to HC, FEP patients would show reduced recognition accuracy for both facial and prosodic voice stimuli across emotions, and that this would be associated with decreased activation throughout corticolimbic regions involved in both sensory (i.e. FG, STG) and higher order emotional processes (i.e. amygdala and prefrontal cortex). We additionally predicted (2) that relative to HC, UHR participants would show reduced recognition accuracy and functional alterations in this corticolimbic network, particularly in cortical sensory regions (i.e. FG and STG), but to a lesser extent than that seen in FEP patients. Finally, given the role of the caudate nucleus in the processing of negative emotional stimuli (Carretie et al., 2009), we explored bilateral caudate regions and predicted that (3) UHR and FEP participants would show increased activation in this region relative to HC during emotional valence judgment.

### 2. Methods

#### 2.1. Participants

All participants were between 18 and 40 years of age. Eighteen UHR participants were recruited from Outreach and Support in South London (OASIS) (Broome et al., 2005). The UHR state was defined according to the Personal Assessment and Crisis Evaluation (PACE) criteria (Yung et al., 1998) and confirmed using the Comprehensive Assessment of At Risk Mental States (CAARMS) scale (Yung et al., 2008). In brief, UHR participants met at least one of the following criteria: a) attenuated psychotic symptoms; b) brief limited intermittent psychosis; or c) a significant decline in cognitive and social functioning over the past year, together with either schizotypal personality disorder or a first degree relative with a psychotic disorder. One of the UHR participants was taking atypical antipsychotic medication (the chlorpromazine equivalent was 100 mg/day).

Eighteen FEP patients were recruited to the study through South London and Maudsley early intervention clinics (http://www.slam.nhs.uk). FEP was operationally defined as ‘first treatment contact’ plus an ICD-10 diagnosis of psychosis (codes F20–F29 and F30–F33) (World Health Organization, 1992a). The clinical diagnosis was validated by administering the Schedules for Clinical Assessment in Neuropsychiatry (SCAN, World Health Organization, 1992b), and the clinical states were in partial remission. Ten of the FEP participants were taking atypical antipsychotic medication (all using second generation antipsychotics, the chlorpromazine equivalent in those FEP participants who were taking antipsychotic medications was 186.66 ± 118.84 mg/day).

Twenty-one gender-matched healthy control (HC) participants were recruited via advertisements from the same geographical areas as UHR/FEP participants. No HC participants met criteria for a DSM-IV-TR psychiatric disorder, fulfilled the PACE criteria for prodromal symptoms, or had a first-degree family history of psychiatric disorders. One HC was excluded due to incomplete data collection.

Exclusion criteria for all subjects included a history of neurological disorder, prior head trauma resulting in loss of consciousness and/or hospitalisation, or any contraindications to exposure to a magnetic field (e.g. metal implants, or pregnancy). Any participants reporting excessive use of alcohol (>21 units per week for men and >14 units per week for women) or recent recreational drug use (use of cannabis, stimulants, hallucinogens, or opiates in the two weeks prior to the fMRI scan) were excluded. None of the participants had received a DSM-IV-TR diagnosis for substance abuse or dependence.

Written informed consent was obtained from all participants after detailed explanation of the study protocol. Ethical approval for the study was granted by the UK National Research Ethics Service Committee London – Bromley (reference number: 11/LO/0623).

#### 2.2. Clinical and neurocognitive assessment

Participants’ demographic and clinical data and estimated IQ scores are presented in Table 1. IQ was assessed using the Wide Range Achievement Test Revised (WRAT-R) (Jastak and Wilkinson, 1984). Symptoms in UHR and FEP participants were assessed with the Positive and Negative Syndrome Scale (PANSS) (Kay et al., 1987). The Clinical Assessment of At Risk Mental State (CAARMS) (Yung et al., 2005) was administered to UHR and HC participants (Table 1). Lifetime cannabis use experience was determined by self-report frequency and classified into four levels: 1-experimental, 2-occasional, 3-moderate, and 4-severe use, while non-users were coded as 0.

#### 2.3. MRI acquisition and processing

Functional images were acquired using a 1.5T MRI scanner (Sigma, LX-GE, Milwaukee, USA) at the Institute of Psychiatry, King’s College London, UK, using the following parameters: TR = 3000 ms, TE =
40 ms, flip angle = 90°, slice thickness = 2.5 mm with 0.5 mm gap, field of view = 24 cm × 24 cm and a 64 × 64 matrix. In total, 46 axial slices parallel to the anterior commissure-posterior commissure (AC-PC) line were collected for each participant. Four hundred and seventeen-sequence images were acquired during the task in each participant. Structural data were acquired using a three-dimensional T1-weighted FSPGR sequence (voxel size: 1 × 1 × 1 mm³, field of view: 280, 146 slices, TR = 11.092 ms, TE = 4.87 ms, TI = 300 ms, α = 18°) for coregistration purposes.

2.4. Emotional recognition paradigm

We used emotional stimuli with dynamic and continuous change in facial geometric configuration (Platt et al., 2010) and with vocal prosodic characteristics (Nowicki and Duke, 1994) validated in previous studies. The details for both facial and prosodic tasks are described in the Supplementary materials. There were 96 dynamic face trials (happy, sad, fearful and neutral) and 96 high-intensity voice trials (happy, sad, fearful and their low-intensity comparisons) of variable duration (the mean trial duration was 4.2 ± 1.37 s). Dynamic emotional stimuli were created with Abrosoft Fantamorph software (version 4.0). Photographs were morphed from neutral to the target emotion with increasing intensity within 25 frames during the ‘morph’. A one-second inter-stimulus interval in which a fixation-cross was presented in the centre of the screen followed each stimulus. During the emotion recognition task, face and voice trials were presented interspersed in a pseudo-random order and arranged into two sessions. Face stimuli were presented on a projection screen. A fixation cross was presented during the voice trials. Participants were instructed to choose between four emotional categories (happy, sad, fearful, neutral) via a button box as quickly as possible before the voice and/or video clips ended. After the morphing face and voices stopped a black screen with fixation cross was presented until the end of the trial. During the task, participants’ response accuracy was recorded.

3. Data analysis

3.1. Behavioural data analyses

Clinical and demographic data were analysed using chi-square tests (gender, handedness) and analyses of variance (ANOVA) (other demographic and clinical data) in IBM SPSS 19. Separate analyses were performed for the face trials and the voice trials. Accuracy scores were analysed using repeated measures analyses of covariance (RM-ANCOVAs) with age included as a covariate of no interest. Emotional category (happy, sad, fearful, neutral) was entered as the within-subjects variable. Diagnostic group was entered as the between-subjects variable. In addition, we explored the frequency of valence misrecognition between groups i.e. positive emotion (happy dynamic faces and prosodic voices trials) misrecognised as negative emotion (sad or fearful dynamic faces and prosodic voices trials). Following the detection of significant main effects or interactions, post-hoc t-tests or F-tests were employed and inferences were made at p < 0.05.

3.2. Functional MRI analyses

Functional images were pre-processed using SPM8 software (http://www.fil.ion.ucl.ac.uk/spm) running under Matlab 7.1 (Math Works, Natick, MA, USA). The full preprocessing procedures are detailed in Supplementary materials.

Images of both sessions were realigned to the obtained structural image. The remaining images were then realigned to the first image of their respective session and resliced with sinc interpolation. Movement parameters were calculated and images with excessive movement (>1.5 mm of translation and 1 degree of rotation in any axis) and the adjacent images were examined and removed if the image was corrupted. Interpolation between the images adjacent to the corrupted images was performed to replace the removed images. Subjects who had >10% of data corrupted were considered as having excessive movements and were excluded from the subsequent analyses. One UHR participant and one FEP participant were thus excluded. Images were segmented and spatially normalized (Friston et al., 1995) to a standard MNI-305 template using nonlinear-basis functions and spatially smoothed with a Gaussian kernel 8-mm full width at half maximum isotropic. A standard event-related first-level analysis of regional responses was performed; onset times (i.e. of the onset of the facial expressions or voice clips) and associated durations were convolved with a canonical haemodynamic response function. To exclude low frequency drifts a high-pass filter was applied using a set of discrete cosine basis functions with a cutoff of 128 s, and an AR(1) model was applied to account for temporal auto-correlation intrinsic to the fMRI time-series. The movement parameters were entered as separate regressors of no-interest in the first level analyses.

For first level statistical analysis, ten experimental regressors were defined: 1) Happy Face 2); Sad Face; 3) Fearful Face; 4) Neutral Face; 5) High-intensity Happy Voice; 6) Low-intensity Happy Voice; 7) High-intensity Sad Voice; 8) Low-intensity Sad Voice; 9) High-intensity Fearful Voice; and 10) Low-intensity Fearful Voice. Five first level contrasts of interest were then computed for dynamic face and prosodic voice stimuli: 1) Happy – Comparison; 2) Sad – Comparison; 3) Fearful – Comparison; 4) All emotions – Comparison; and 5) Positive emotion (Happy) – negative emotion (Fearful + Sad). For dynamic faco
contrasts, neutral faces acted as the comparison condition. For prosodic voice trials, since the validated stimulus set (DANVA-2-AP) did not contain neutral voice stimuli, low-intensity voice trials served as the comparison condition (i.e. high versus low intensity for the same prosodic emotion).

Second-level analyses were performed using two approaches: whole brain voxel-wise analyses for exploration of the effect of emotional processing, and region of interest (ROI) analyses (Li et al., 2010; Wittman et al., 2012) based on a visual and auditory emotional processing model in schizophrenia (Tseng et al., 2015). Whole brain analysis was performed using ANCOVA and independent samples t-tests (conducted within the SPM ANCOVA framework) with age as a covariate of no interest. Other confounding factors (i.e. IQ, cannabis use and antipsychotics use) were not included in the analyses as supplementary correlational analyses between these factors and peak activation in all ROIs were non-significant within each group of participants. Statistical inferences were made at p < 0.05 after FWE cluster-level correction for multiple comparisons. When the group comparison omnibus F-contrast did not reach significance, additional exploratory pair-wise analyses were performed to compare FEP versus HC, UHR versus HC and FEP versus UHR, with a corrected threshold at p = 0.017 (Bonferroni corrections for 3 contrasts), except for the exploratory hypothesis examining bilateral caudate regions during emotional valence judgment. For ROI analyses, a search sphere with a radius of 16 mm (twice the smoothing kernel) was applied to the centre of each ROI using the small volume correction function in SPM8 (described below). Coordinates were described according to the standard Montreal Neurological Institute (MINI) system.

Four ROIs, identified in a meta-analysis (Li et al., 2010) of facial emotion recognition studies, were used to examine group effects during dynamic face trials. These were the bilateral FG (left, −39, −65, −13; right, 40, −52, −14), left amygdala (−21, −7, −8) and right lentiform gyrus (22, −3, −5). For the prosodic voice trials, primary facial decoding areas (bilateral FG) were replaced by primary prosodic decoding areas (bilateral STG: left, −62, −22, 1; right, 49, −23, 6); coordinates were selected from the meta-analysis by Wittman et al. (2012). To test our valence-specific hypothesis an ROI in the caudate nucleus (Carretie et al., 2009), was chosen in the left (−18, −2, 24) and right caudate body (16, 4, 18) (Carretie et al., 2009). Spheres were then constructed in MarsBaR toolbox for SPM (Brett et al., 2002). A single inclusive mask containing all ROIs was applied, and statistical inferences were made at p < 0.05 with FWE correction for multiple comparisons at the voxel-level after applying small volume correction (SVC).

4. Results

4.1. Demographic and clinical data

Demographic and clinical data for each group are reported in Table 1. There were significant age differences (F = 5.86, df = (2, 54), p < 0.005) with FEP patients being older than HC. There were significant estimated IQ differences (F = 8.47, df = (2, 54), p = 0.001) with HC showing higher IQ scores than UHR and FEP. There were also significant differences in cannabis use (F = 10.10, df = (2, 54), p < 0.005) with HC having more cannabis use experience than HC and FEP.

4.2. Dynamic face trials

4.2.1. Recognition accuracy

Mean accuracy scores are shown in Fig. 1(A). There was a significant main effect of emotional category (F = 14.86, df = (3, 159), p < 0.001). Across all participants, recognition accuracy was greatest for happy relative to sad (t = 8.22, df = 56, p < 0.001) and fearful trials (t = 6.62, df = 56, p < 0.001). There was a trend towards an effect of diagnostic group (F = 2.65, df = (2, 53), p = 0.08) with HC showing greater accuracy than FEP patients across all emotional conditions (post-hoc pairwise comparison: HC > FEP, F = 5.74, df = (1, 36), p = 0.022). The group × emotional category interaction was non-significant (F = 0.42, df = (6, 159), p = 0.87).

The effect of diagnostic group for misrecognition of positive emotional faces (i.e. happy) as negative (i.e. sad or fearful) was also non-significant (F = 1.49, df = (2, 53), p = 0.24).

4.2.2. Functional MRI

The main effect of task (emotional > comparison trials) is reported in the Supplementary material. The main effect of group (emotional > neutral trials) was non-significant for both whole-brain and ROI analyses (Table 2). However, exploratory pair-wise group tests (conducted within the SPM ANCOVA framework) revealed trends towards significance in the right FG. In this region both FEP (t = 3.62, df = 51, p = 0.04 SVC) and UHR groups (t = 3.62, df = 51, p = 0.04 SVC) were performed to compare FEP versus HC, UHR versus HC and FEP versus UHR, with a corrected threshold at p = 0.017. In the supplementary hypothesis an ROI in the caudate showed reduced activation during emotional face trials relative to HC. However, the effects did not survive after correction for multiple comparisons (corrected threshold p < 0.017). The difference between UHR and FEP groups did not approach significance. The group × valence (positive vs. negative emotions) interaction was non-significant in the caudate ROI.

4.3. Prosodic voice trials

4.3.1. Recognition accuracy

Mean accuracy scores for prosodic voice trials are shown in Fig. 2(A). The main effect of emotional category was non-significant (F = 1.028, df = (3, 159), p = 0.38). The main effect of diagnostic group was significant (F = 7.96, df = (3, 159), p = 0.001) across all emotional categories, driven by greater overall accuracy in HC relative to UHR (F = 4.30, df = (1, 36), p = 0.045) and FEP (F = 23.69, df = (1, 36), p < 0.001) groups. The group × emotional category interaction (F = 1.035, df = (6, 159), p = 0.41) and group × valence interaction for misrecognition were non-significant (F = 2.22, df = (2, 53), p = 0.11).

4.3.2. Functional MRI

The main effect of task (high intensity prosodic voices > low intensity prosodic voices) is reported in Supplementary material. Whole-brain analysis revealed a trend towards a significant group effect in the left amygdala extending to left insula (Table 3, Fig. 2(B)). Pair-wise group comparisons revealed reduced activation in FEP patients relative to HC in the left amygdala, medial orbital frontal gyrus, lingual gyrus and left angular gyrus (whole brain corrected, cluster-level) (Table 3). The difference between UHR and FEP groups was non-significant. ROI analyses confirmed the group effect in left amygdala (F = 15.08, df = (2, 51), p = 0.009; SVC) and in the left STG (F = 12.79, df = (2, 51), p = 0.03 SVC; see Table 3 and Fig. 2(C)). Pair-wise group tests also showed that the FEP patients had significantly lower activation than the HC group in the left amygdala (t = 5.46, df = 51, p = 0.002 SVC) and left STG (t = 5.05, df = 51, p = 0.003 SVC; see Table 3).

The group × valence interaction were non-significant (F = 9.31, df = (2, 51), p = 0.17) in the caudate ROI. Pair-wise group comparison showed a trend group × valence interaction between HC and UHR in the left dorsal caudate. In this region, HC showed greater activation for negative relative to positive emotions but the opposite pattern was seen in UHR participants (positive > negative) (t = 4.31, df = 51, p = 0.02; see Fig. 3). However, this did not survive a Bonferroni corrected threshold of p < 0.017. The group × valence interactions between FEP and HC groups, and between FEP and UHR groups in the caudate ROI were non-significant (Table 4).

5. Discussions

We investigated the neural correlates of emotional processing in response to emotional stimuli in two sensory modalities (visual, auditory)
in FEP patients, UHR and HC individuals. In line with our hypothesis, FEP patients showed reduced recognition accuracy compared to HC during dynamic face and prosodic voice trials. During dynamic face trials, overall recognition accuracy for UHR participants was intermediate to HC and FEP patients but did not differ significantly from either group. During prosodic voice trials, however, UHR participants showed significantly reduced recognition accuracy relative to HC, while significantly reduced accuracy for fearful voice trials in UHR was observed (Fig. 2(A)). Of note, the vocal fear recognition rate was relatively low, which might reflect its higher ambiguity (i.e. lower accuracy and longer reaction times, see Edwards et al., 2002; Tseng et al., 2013) and thus susceptible to both time-urgent design (requiring participant to respond as soon as possible before the clip ended) and the background noise during image acquisition. Nevertheless, these factors affected all three groups and the results remain consistent with previous studies (Amminger et al., 2012a; Hoekert et al., 2007; Kohler et al., 2010; Thompson et al., 2012) that show impaired emotion recognition in people at clinical high-risk for schizophrenia before the full expression of psychotic illness.

The majority of previous studies in schizophrenia (Lee et al., 2002; Li et al., 2010; Pinkham et al., 2005; Reske et al., 2009) report reduced amygdala activity in patients with schizophrenia. However, contrary to previous findings and our hypotheses, we did not find a significant group difference in brain activation during dynamic face trials. Using a relatively low magnetic field scanner (1.5T rather than 3T) may have contributed to the lack of differences in activation between groups.

All \( p \)-values reported for ROI analyses are FWE corrected at the voxel level.
We used a low-field scanner to mitigate the loud noise generated by high-field scanners, which may interfere with the processing of acoustic stimuli. Nevertheless, the lack of activation differences in response to emotional face stimuli is consistent with a small number of previous studies that did not find clear amygdala activation differences in schizophrenia relative to healthy controls (Sachs et al., 2012; Swart et al., 2013). Our findings may suggest that relatively intact facial emotional processing is also seen in early and prodromal stages of psychosis.

Despite the group comparison of brain activation during dynamic face trials did not reach statistical significance, exploratory pairwise ROI analysis of functional MRI data showed a non-significant trend of reduced right FG activation in FEP patients relative to HC. During prosodic voice trials, a more widespread pattern of reduced activation was apparent in FEP patients relative to HC, involving both sensory (STG) and emotional processing regions (amygdala and medial orbital prefrontal cortex), and also left temporal-parietal-limbic regions, including left MTG, left insula, and left thalamus. Dysfunction in cortical and limbic brain regions that are involved in sensory (i.e. FG, STG), information relaying and modulation (i.e. basal ganglia/caudate), and higher order emotional processes (i.e. amygdala and prefrontal cortex) in patients with schizophrenia has been established robustly (Lee et al., 2002; Li et al., 2010; Tian et al., 2011). Our findings complement those of schizophrenia studies, and confirm previous studies reporting functional changes in these corticolimbic regions, involved in both early decoding and emotional recognition/interpretation, in FEP population (Reske et al., 2009, 2007).

In FEP patients the deactivation (negative contrast estimates) indicate greater activation to neutral rather than emotional stimuli in corticolimbic regions (Figs. 1(C) and 2(C)), and could be interpreted as hyperactivation to neutral or subtle emotional stimuli as previously reported in schizophrenia populations (Aleman and Kahn, 2005; Hall et al., 2008; Modinos et al., 2015; Seifert et al., 2008). This functional change would be consistent with the notion that non-emotional information is more salient in FEP and at-risk states. Such abnormalities are thought to contribute to the social cognition and social functioning deficits apparent in emerging psychotic disorders (Amminger et al., 2012b).

Relative to HC, despite a showing a non-significant trend for reduced activation in the sensory cortex (right FG) during emotional versus neutral dynamic face trials, UHR participants did not show significant difference in either face or voice modalities. Similarly, intermediate BOLD response between HC and FEP was observed in UHR participants in those areas showing decreased activation in the FEP group during prosodic voice trials, albeit the difference between HC and UHR did not reach statistical significance. This task-related subtle functional changes in the brain in the UHR participants is consistent with previous studies (Dutt et al., 2015). We speculate that these trends may reflect early subtle changes in primary sensory emotional processing regions, which may manifest in vulnerability states before the full-blown onset of psychosis. However, this requires testing in a larger sample.

Interestingly, although the majority of studies in patients with schizophrenia report corticolimbic dysfunction during the presentation of emotional face stimuli, our findings in FEP patients suggest dysfunction that is more evident during the presentation of prosodic voice stimuli instead of facial stimuli. The reasons for this are not entirely clear but it is possible that as the emotional information carried in prosodic voices delivers more subtle interpersonal social cues than faces, voice stimuli may provide a more sensitive method to investigate functional alterations related to emotional recognition deficits in FEP and UHR cohorts. Our results support the findings of previous studies that reported reduced accuracy for prosodic emotional recognition in FEP and UHR groups (Amminger et al., 2012a) and suggest that prosodic emotional, rather than facial, stimuli may be better able to reveal the subtle emotional processing deficits associated with early psychosis and vulnerability states.

The FG and the STG have been hypothesized to extract facial features and acoustic properties from visual and speech input, respectively, during stage 1 of the model proposed by Wildgruber et al. (2009). Although the current findings do not unequivocally support an impairment in these primary sensory processing areas in UHR, early subtle changes may have presented at the initial perceptual stage and impact on emotion recognition accuracy. By contrast, during both dynamic face and prosodic voice trials, activation in cortical regions (i.e. amygdala and OFC) involved in emotional recognition and interpretation was not significantly reduced in UHR participants relative to HC. This supports the view that corticolimbic hypoactivation (particularly in the amygdala) during the processing of emotion is related to the disease, rather than vulnerability states (Rasetti et al., 2009) and is constant with previous...
greater for negative relative to positive valence trials, consistent with a trend towards an interaction in the caudate nucleus relative to HC when comparing UHR populations has been reported previously during a salience processing task during emotional processing. Altered striatal activation in UHR participants suggesting altered caudate function during emotional processing. Altered striatal activation in UHR populations has been reported previously during a salience processing task (Roiser et al., 2013) and may be related to elevated dopamine synthesis capacity in the associative striatum (Howes et al., 2009). Inappropriate activation in the caudate during the presentation of emotional stimuli could result in confusion regarding the salience and/or valence of emotional stimuli, although this was not seen at a behavioural level in UHR participants.

### 6. Limitations

The main limitation of the present study is the relatively small sample size: our findings will need to be replicated in larger FEP and UHR cohorts. The age difference between HC and FEP was another limitation. However, we included age as a covariate in all analyses to address this issue.

Several potential confounding factors needs further discussion. First, the three groups were not matched for estimated pre-morbid IQ and our experimental task required explicit emotion recognition under a time constraint which may have been cognitively demanding (Phan et al., 2002). However, to our knowledge, although performance of emotion recognition may be associated with specific cognitive deficits (Bryson et al., 1997), there is no evidence that general intelligence significantly affects emotional processing (Coan and Allen, 2007). Furthermore, we chose not to control for IQ in the main analysis since this may remove important variance (Edwards et al., 2002) between groups, as low IQ is a phenotypic characteristic of psychosis (Mesholam-Gately et al., 2009). A supplementary correlation analyses showed that the peak activation in all ROIs did not correlate with IQ within any of the groups, suggesting that IQ was not a major confounding factor for emotional processing.

A further limitation is that one UHR participant and a number of FEP patients that participated in the study were taking low doses of antipsychotic medication. Although most studies in patients with schizophrenia suggest that medication is not a major confounding influence on emotional recognition accuracy (Fusar-Poli et al., 2007; Navari and Dazzan, 2009), the influence of antipsychotic medication on hemodynamic responses during emotional processing remains unclear. Nevertheless, supplementary correlation analyses showed that the peak activation in all ROIs did not correlate with chlorpromazine equivalent dose in our FEP participants. Likewise, the higher lifetime experience of cannabis use in the UHR cohort, relative to both FEP and HC groups is also a potential confounder, given that chronic heavy cannabis use may affect emotional recognition accuracy (Hindocha et al., 2014; Platt et al., 2010). However, none of our UHR cohort reported concurrent heavy cannabis use nor met the DSM-IV diagnostic criteria for neither cannabis abuse nor dependence. A supplementary correlation analyses showed that the peak activation in all ROIs did not correlate with cannabis use within any of the groups, supporting the view that cannabis use did not affect the results.

Another potential limitation is using low-intensity emotional prosodic stimuli as the contrast instead of neutral ones. It is arguable that the contrast of high versus low intensity for voice stimuli may reflect an intensity or arousal effect rather than emotion itself. In our study design it would not be possible to differentiate these two effects. However, as intensity is an important dimension of emotional information, these contrasts should still evoke the neural correlates of emotional processing, independent of their low-level acoustic properties (Ethofer et al., 2006).

### 7. Conclusions

In summary, FEP patients showed emotional recognition deficits and functional alterations in corticolimbic regions consistent with deficits across a multi-stage emotional processing model, mainly in the voice modality. By contrast, while UHR participants also showed emotional recognition deficits behaviourally, we only observed a trend towards an interaction in the neural processing of emotional stimuli in caudate nucleus, with a non-significant decrease of activation in early sensory
processing regions. Our results highlight the need to investigate behavioural and neural vulnerability biomarkers in psychosis-prone high-risk populations in larger samples, and to expand the etiological understanding of psychosis and consequently provide insights for preventive strategies. Future longitudinal studies are needed to fully understand the chronology of emotional and corticolimbic dysfunction in the development of psychosis.

Financial disclosure

This work was supported by a Brain & Behavior Research Foundation NARSAD Independent Investigator Grant to PA, and a NARSAD Young Investigator Grant to GM (#21200, G.M., Lieber Investigator). IF was supported by the G.A. Lienert Foundation, Adolf-Schmidtmann-Foundation, FAZIT-Foundation and the German Academic Exchange Service.

The funding agencies did not have any role in the design and conduct of the study; collection management, analysis, and interpretation of the data; and preparation, review, or approval of the manuscript.

Declaration of interests
