The original main path derived without missing links and the adjusted main path obtained with the missing links supplemented are displayed together in Figure 4 using nodes and arcs of different styles for easier comparison. There are total 67 different nodes (patents) from both the original and adjusted main paths, and they are numbered from 1 to 67 in ascending order of their patent numbers and therefore their issued dates. A complete list of these 67 patents is provided in the Appendix.

There are 19 black nodes representing those patents present on both the original and adjusted main paths. There are 8 white nodes representing those appearing only on the original main path, and the 41 grey nodes are those present only on the adjusted main path. The solid grey arcs are direct citations, and the dashed black arcs are missing links.

The original main path involves 27 patents and is represented by the chain of black and white nodes connected by solid grey arcs (direct citations). The adjusted main path contains total 59 patents and is represented by the chain of black and grey nodes connected either by solid grey arcs (direct citations) or dashed black arcs (missing links).

As can be observed from Figure 4, the adjusted main path has captured two third (18) of the patents from the original main path. It seems fair to claim that both the original and adjusted main paths derive a substantially identical trajectory of knowledge flow in our case study, but the adjusted main path has offered significantly more information, as it provides additional 41 (=59-18) patents and additional 49 links in the adjusted main path. For the 49 newly added links, 6 of them are direct citations, whereas the other 43 are all supplemented missing links.

Based on where the newly included nodes and arcs occur, the adjusted main path may be partitioned into 4 sections, and their end nodes and span years (based on end patents’ issued years) are listed in Table 1. These 4 sections allow us to examine more closely the effect of missing links.

In Section 1, the original and adjusted main paths are completely identical. This is because a patent in an early stage of a technology field has fewer references. For example, the end nodes 1 (US3,977,845 issued in 1976) and 8 (US4,813,980 issued in 1989) have only 7 and 15 references. As we considered only BC pairs having BCS greater than 34, no BC pair within this stage would satisfy the threshold.

In Section 2, the end node 19 (US6,221,117 issued in 2001) has 140 references, indicating that there would be BC pairs satisfying the threshold and missing links are supplemented. These missing links help to identify and add new nodes 10, 11, and 18 to the adjusted main path, but these 3 nodes are all connected by direct citations, not missing links. The reason is that the supplemented missing links are few and dispersed, and they are not able to cooperatively thrust any one of them into a status as a major link of knowledge flow. However, they are able to strengthen some existing direct citations (i.e., 8→10→11→14, and 16→18→19) to become part of the adjusted main path.
In Section 3, the end node 60 (US8,057,575 issued in 2011) has 276 references, implying that there are more missing links incorporated into the APCN in this stage than in the previous stage. In contrast to what is observed from Section 2, these more numerous missing links are able to cascade together into a number of different path segments. We will talk more about Section 3 later.

Section 4 provides a different scenario as the original and adjusted main paths develop separately. We speculate that the development of the original and adjusted main paths is still in progress. It is possible that the original and adjusted main paths may merge at a future patent, just like what happens, for example, at node 25 that merges the original path segment 19→20→23→25 and the new path segment 19→21→22→24→25.

Table 1 also provides the minimum, maximum, and average BCS for the missing links in Sections 3 and 4, respectively. We can see that their BCS is not particularly strong, and actually none of the strongest 5% shown in Figure 1 has emerged as part of the adjusted main path. This
observation does not come as a surprise since, for a missing link to appear on the adjusted main path, it is determined by its topological location, not by its BCS.

Based on the above observation, we can see that there are some key patents denoted by nodes such as 19, 25, 29, 36, 38, 42, 52, and 60 of Section 3 providing a backbone of the knowledge flow as they are present on both the original and adjusted main paths. However, the adjusted main path suggests totally different path segments between these key patents involving completely different sets of patents connected almost entirely by the missing links. This seems to suggest that missing links may indeed deliver more topological significant relatedness than what is captured by the replaced direct citations.

To see that this phenomenon is not coincident, we conducted a number of experiments by manually multiplying the weights of all missing links by 0.5, 0.1, and 0.01 after all link weights are determined and before applying the global search method to determine the main path. In other words, we artificially and purposely reduced the weights of all missing links to one half, one tenth, and one hundredth of their original values. We found that the resulted main paths are exactly the same as the original one. This implies that the weights (i.e., traversal counts) of the 43 missing links on the adjusted main path are so strong that downplaying their importance to a great degree still wouldn’t produce any difference. Therefore, the 43 missing links indeed capture some topologically significant connections among patents.

In addition, please pay special attentions to nodes 25, 29, 36, 38, 42, 52, and 60 in Section 3. These patents are issued at close years 2003, 2003, 2004, 2005, 2006, 2010, and 2011, respectively (except the patents denoted by node 42 and 52 where they are issued at years 2006 and 2010). In the OPCN, they are sequentially cascaded by direction citations but, in the APCN, each of these direct citations is replaced by a series of missing links connecting a number of patents not on the original main path.

Taking nodes 52 and 60 as example, the arc in the original main path reflects the knowledge flow between the patents denoted by the two nodes. But with the help of the missing links, patents denoted by nodes 53 to 59 are manifested in the adjusted main path. As we already know, these are related patents occurring at close times (i.e., all issued between 2010 and 2011) and their relatedness may be overlooked by direct citations. Therefore, it seems that this series of intermediate and related patents may give us a more detailed picture regarding, for the original two patents denoted by nodes 52 and 60, how one evolves to the other.

As mentioned earlier, the main idea behind MPA is to use citations as proxies for knowledge flow. But missing links are not real citations, they are only simulations of real citations in the APCN. Therefore the adjusted main path derived from the APCN should not be considered as a better or more accurate path. The adjusted main path in this study is mainly used as a tool for observing the effect of missing links.

**Discussion and Conclusion**

Both direct citations and BC are valid tools in detecting similarity or relatedness, or in capturing knowledge flow among patents. Then, we were intrigued by a conflicting scenario that two patents lack direct citation but are strongly bibliographic-coupled.

Based on empirical data, we found that a significant portion of missing links have their patents’ filing or issued dates fall within one to two years. In other words, these patents are prosecuted
concurrently, and it would be difficult, if not impossible, for their applicants or examiners to become aware of and cite each other. Yet their relations may well be captured by missing links. Therefore, missing links seem to be useful in capturing the technology similarity or relatedness among these concurrent patents while direct citations among them are less likely to be established.

This study then applied MPA to a patent citation network involving 38,652 patents/publications, 188,721 direct citations, and 9,213 missing links. We then derived an original main path without the missing links added, and an adjusted main path with the missing links added to simulate real citations.

We found that some direct citations in the OPCN are replaced by a series of newly found patents connected by missing links in the adjusted main path. We verified that this is not coincident by manually downplaying the weights of the missing links to as low as one hundredth of their original values, and the adjusted main path is not affected at all.

On one hand, this observation suggests that missing links may indeed deliver, from the PCN and main path’s point of view, topologically more significant connections between patents.

More importantly, as a single direct citation of the OPCN is elaborated into a chain of newly found patents in the APCN, we found that these newly found patents not only may fill the gap left by direct citations as described above, but also may give us a more detailed picture regarding, for the two patents connected by the direct citation, how one evolves to the other.

This study may be challenged that an absolute BC threshold (34) is adopted in determining the missing links, and one may argue that a normalized or relative BC threshold should be more appropriate. By using an absolute threshold, indeed we may filter out some important BC pairs having fewer references (like what we observed in Section 1 of Figure 4), and may include some not-so-important BC pairs having more references (e.g., those added in Sections 3 and 4 of Figure 4). It is definitely interesting to see if the normalized or relative BC threshold would contribute any difference. We however were not so concerned in this study since MPA itself has an inherent tendency to filter out those irrelevant links.

This study may be extended along several directions. One extension is that, instead of adding the missing links, one can use BC to filter out irrelevant direct citations and see what difference may occur in the resulted main path. Another extension is that, similar to what Persson (2010) suggested, instead of using BC to determine latent connections, the similar and popular approach Co-citation (CC) may be applied to compare the two approaches.

Abstract
According to traditional co-citation analysis, co-citation frequency is mainly based on bibliographic references to calculate, which does not consider the multiple co-citation and the relative position of co-citation in a same academic publication. This study aims to thorough mining the essential characteristics of co-citation, in fact, co-citation position and distance, by constructing a position-based co-citation analysis framework and performing an empirical study. The results suggest that the distribution of citations in the text are extremely uneven, most of the citations are concentrated at the front of the article, as well as clustered, and also citation distribution is according to document types; the similarity of academic publications is not only concerned with citation frequency, but also concerned with co-citation level, the result of traditional co-citation analysis covers the effect of non-paragraph level; the co-citation probability in different level is decreasing with the increasing of co-citation frequency, co-citation frequency and the co-citation level have a negative linear relationship; the position-based co-citation analysis can enhance the co-citation clustering and benefit to deep research and evaluation.

1. Introduction
Co-citation analysis was respectively proposed by Small and Marshakov in 1973(Qiu and Ma, 2008), because of the objectivity of method, the validity of the data and the scientific principles of classification (Liu, 2005), co-citation analysis attracts the attention of the Scientometric community (Liu and Zhang, 2013). However, according to the traditional co-citation analysis, co-citation frequency is mainly based on bibliographic references to calculate (Leydesdorff, 2008). It does not consider the multiple co-citation and the relative position of co-citation in a same academic publication. Full text data of scientific literature contained the specific citations, such as the number of citations, citation position, and author's citation motivation. Therefore, co-citation analysis which based on the full text can explore the essence of co-citation. In recent years,
the continuous development and improvement of information structure technology, natural language processing technology and semi-structural information organization technology, bring new opportunities to rise and development of the full text co-citation analysis.

2. Related work
A review of the literature reveals that co-citation analysis has gradually increasing, including correlatively theoretical research (Small, 1980; Gmür, 2003), research progress (Wang and Leng, 2006), system design and development (Cui and Hu et al., 2000), comparative studies with other methods (Boyack and Klavans, 2010) and application research (White and Mccain, 1998). However, full text co-citation analysis research is very limited, and research on the relationship between the co-citation distance and the similarity of co-citation literature is still under theoretical level, lacking of empirical research and cases study.

Elkiss(2008) used quantitative analysis found that citation summaries overlap to some extent with the abstracts of the papers and that they also differ from them in that they focus on different aspects of these papers than do the abstracts (Elkiss and Shen et al., 2008). Gipp and Joran (2009) under the assumption that closer citations are to each other in a document, the more likely it is that the cited documents are related, then they divided co-citation into 5 levels, citations listed in the(1) same sentence, (2) same paragraph, (3) same chapter, (4) same journal, (5) in different versions of the same journal, and define CPI (Citation Proximity Index) as 1, 1/2, 1/4, 1/8, 1/16 (Gipp and Beel, 2009). Liu and Chen (2012) use the proximity of co-citation to describe the co-citation documents’ references relative position distance, from four levels of sentences, paragraphs, chapters, articles, discussing the co-citation distance of the full text scientific publications, and statistics of 22 kinds of Open Access Journals of the co-citation frequency and co-citation position (Liu and Chen, 2012). Liu et al. (2015) proposed an improved algorithm based on citation context, co-citation document and document coupling (Liu and Yu et al., 2014). Boyack and his colleagues (2013) proposed to improve the accuracy of co-citation clustering through full-text data, they define co-citation distance as two co-citation position between the number of bytes the number of bytes representing percentage, divide co-citation hierarchy as (1) in the same position, (2) less than 5%, (3) 5% to 15%, (4) 15% to 25% and (5) above 25%, respectively, weight is set to 4, 3, 2, 1 and 0. Hu Zhigang, who distinguishes differences and connections between full-text based co-citation analysis based on the bibliographic data (Hu and Chen, 2013). Liu Shengbo, according to the position of two references cited in a document, co-citation relations can divide into sentence level, paragraph level, section level, and article level (Liu and Zhang, 2013).

Research object of position-based co-citation analysis is based on the full-text data of citing articles (Zhao and Zeng, 2014). Classifying and quantifying the individual co-citation strength on co-citation level from the citation position aspect, furthermore, it can reveal and measure the relevance of the co-citation relationship between documents. This study intends to build a position-based co-citation analysis method framework on the basis of previous studies, then through empirical analysis, and mining the relationship between the co-citation distance and co-citation document similarity, and comparing the validity difference between position-based co-citation analysis and traditional co-citation analysis.

3. Methodology
Before the construction of the method framework, we define the co-citation distance and co-citation intensity, co-citation distance refers to the relative distance of the co-citation document in...
the citing document; Co-citation strength is defined as the citation numbers of two articles which cited by other document, in fact frequency, in order to measure the relevance of co-citation documents.

Comparing to the traditional co-citation analysis, the contents and methods of analysis are different in position-based co-citation analysis, first we need to develop co-citation criteria level, the co-citation is divided into different levels respectively, and then analysis the distribution of co-citation position and co-citation level. Secondly, we need to assign the co-citation strength to different levels, and construct the co-citation matrix for the cluster analysis. Position-based co-citation analysis framework, as shown in Figure 1.

![Figure 1 Framework of Position-based Co-citation Analysis](image)

### 3.1 The division of co-citation levels

In a chapter, which has a chapter numbers, chapter title and other information; among the citation information, citation ID and citation context information; in the references section, document ID, title, authors, journals and other information.

Our study intends to use the method which proposed by Liu and Chen etc. (Liu and Chen, 2012; Liu and Zhang, 2013) and from the point of view of the structure of the article, this paper divides the co-citation level into four parts: the sentence level, the paragraph level, the chapter level and the article level.

### 3.2 Assignment of common cited distance

In the traditional co-citation analysis, as long as the two papers were cited at the same time (without considering the times of citation and position), their co-citation strength is 1. The analysis of the existing research illustrate that two articles were cited the closer their co-citation strength (relevance) is bigger, combining with existing research, and in order to facilitate of calculation, the co-citation distance of sentence, paragraph, section are assigned to 4 3, 2, 1. In addition, due to the normative documents, the same paragraphs or sections of the article are generally not the same sentence to express the same meaning of repetition, therefore in the same document in two or more than two times in the same sentence of the cited literature shows that they are in at least two aspects has correlation, the author that its relevance is higher than that of only a sentence level co-citation, so this is a separate named sentence layer two times cited and assigned to 8 (two sentences layers). For the shortest distance in the literature, which is referenced by many different levels in the same document, the shortest distance is taken as an assignment.

According to the above co-citation distance assignment method, select the article *The*
influence of missing publications the on the Hirsch index (Rousseau, 2007) as an example, table 1 is based on the XML data to extract the literature references in the text position, figure 2 is based on the data in Table 1 simplified reference position distribution map, figure 3 is the use of traditional methods and based on the position of the co-citation analysis method to get the co-citation matrix.

Figure 2. Single Citation Distribution Chart

Figure 3. Comparison of Traditional Methods (left) and Position-based (right) Matrix

3.3 Data sources and processing

The data of this paper comes from the full-text database of Elsever ConSyn, which provides the full text data of the structured XML format (Hu and Chen, 2012; Hu and Chao, 2013). Selecting the Journal of Informetrics (JOI) as a case study, the journal mainly publish information measurement of the related literature, literature metrology, involving the subject scope is relatively narrow, the relationship between the reference and citation network has a stronger, more conducive to analysis. In the database, the retrieval of all papers published in this journal, through
the "export" function of the database will retrieve the full text of the XML format data, then
download and import EXCEL, extract citation information.

We plan to analysis position-based co-citation from the following two aspects, firstly
statistical analysis of the distribution of co-citation in scientific literature in term of sentence,
paragraph, section, and article; on the other hand, using the above co-citation distance assignment
a citation for single assignment, then two kinds of co-citation matrix for clustering analysis,
comparison of the traditional co-citation and co-citation validity position difference based on the
way.

4. Results and discussions
4.1Position-based co-citation distribution analysis

4.1.1 Reference position distribution

Generally speaking, the scientific paper mainly includes introduction, method, analysis results,
conclusion and discussion. Generally, JOI paper contains 4-6 chapters, including the number of
four chapters, five chapters and six chapters of three papers about the total number of papers 3/4,
we will mainly base on the structure of these three kinds of scientific literature data analysis.

The distribution of citations in each chapter of scientific literature is not uniform, and the
distribution of the number of citations in each chapter is shown in table 2. In the four chapter
structure of the thesis, the first section contains 1285 references, higher than second, section three
or four of the reference number 776, 796 and 271, in the five and six chapters in the paper also
has the same structure characteristics. It can be seen that the reference is mostly distributed in the
front part of the scientific literature, mainly in the first and second sections, accounting for 61.36%
of the total citations.

By analyzing the data of XML full text of each article, we found that there are the following
characteristics in the distribution of references: 1. References are mainly concentrated in the first
section (usually the introduction part). Foreign literature at the beginning of the study need to
have an overview of the background of the study, the previous studies have been summarized and
analyzed, so in the first section of the literature will be relatively more.

Almost all literatures are cited in the first chapter, more than 90% of the references are cited
in the second and third chapters, and in the four or five and six chapters are relatively small. The
two or three chapter will introduce the research methods, the 456 chapter is usually results,
conclusions and discussion part, this part explains in the introduction and reference method is
necessary, scientific research is established on the basis of previous studies, the theory and method
of using the former must be reflected in the article. And in the conclusion and discussion part is
more should reflect their own research results and ideas, the reference is not necessary. （3）The
quote is no single, scholars clustering references in reference, this type of literature is usually the
topic or group by the methods of the same. The clustering cited more persuasive than single quotes,
quoted from the side can explain the different point of view. The different types of distribution of
different reference literature. Review of the citation distribution is relatively uniform, wide range, full text various chapters are basic references, and the method in the methods section of Citation Distribution of the most intensive, ordinary paper in the first part of "Introduction" refers to the most densely distributed. Therefore, we can classify the scientific literature according to the distribution of references, and then study the different types of documents.

4.1.2 Co-citation level distribution analysis

To analyze the references of co-citation distributions, you need to establish a reference of the co-citation relations foundation, marking each co-citation of co-citation level, this process is very complicated, so the data selected from 32 papers published in JOI journals in 2007 as the analysis object. At first, all the references of the 32 literatures were extracted and the weight of these 1138 references were obtained, and 78 references were cited. The cited frequency was greater than or equal to 2. The statistics were 78 references in each document in the co-citation and co-citation level, get the total cited 1699 times (the same as the literature on multiple co-citation count). In which the article layer 569 times, the section level 571 times, paragraph 515 times, the sentence layer 33 times, two times and above the sentence level 11 times. They are accounted for in table 3.

As can be seen from the data in Table 3, the sentence, paragraph and section of the total cited 66.51% of the total citation. Because the data set is based on more than 2 times cited references, the results and analysis of all references based on the results there are some errors in this ratio will be reduced, but it is certain that the sentence level, paragraphs and chapters layer co-citation amount is very large, visible division co-citation of different levels the level of co-citation analysis is necessary to distinguish. The traditional co-citation analysis will be considered as the level of the article, and the results of the analysis cover up the effect of the non-article level.

4.2 The relationship between the frequency of co-citation and co-citation

According to the traditional method of citation analysis, the statistics of each literature on the total citation frequency, found data maximum co-citation frequency was 9, so the author for each citation frequency (1-9) statistic of the hierarchical distribution of Co-citation respectively, see table 4.

</table>
As can be seen from the table two, in the same literature more than 11 times a total of 2 references were cited in the sentence level, of which 8 were cited in accordance with the conventional method of co-citation analysis. In the same literature, more than two times of the total cited in the sentence level of the literature on, intuitive, is very similar, but in accordance with the traditional way of analysis of the results, the similarity is relatively weak. In addition, table 4 of the cited frequency was 1, 2 and 3 of the literature accounted for more than 90% of the total, while only about 1/3 of the total citation is in the layer, if the traditional method to calculate the total citation frequency measure co-citation strength, while greatly weakening the similarity between documents. In the co-citation analysis, the similarity of the literature is not only related to the co-citation frequency, but also with the co-citation level.

We use SPSS statistical analysis software to carry out contingency table analysis, and analyzes whether there is a certain correlation between the co-citation frequency and the co-citation level. Column variable contingency table for total citation frequency, variable as co-citation level, which is defined as "1 sentence 2 times", 2 "3" sentence "paragraph layer", 4 ", 5" chapters "in this layer, resulting in Table 5.

After the table 5 is compiled, we use the method of chi square test to analyze whether there is a connection between the co-citation frequency and the co-citation level. In this paper, the original hypothesis of chi square test is that the co-citation frequency and the co-citation level are independent of each other. The chi square test results are shown in Table 6, and the cluster bar graph is shown in Figure 4.

![Figure 4. Cluster Bar Chart](image)

Table 6 shows that the chi square statistic (Chi-Square Pearson) value is 234.539, the corresponding p value is 0. If the significance level alpha is set to 0.01, the probability of P chi square value is less than alpha, so we should reject the null hypothesis, that the co-citation and co-citation levels are related, and the linear by linear association (Linear-by-Linear Association) the probability of P is smaller than that of alpha, total cited frequency and co-citation level linear. From table 4, figure 4 shows that the co-citation level total citation frequency is mainly 2 and 1, with the increase of frequency, the level of co-citation presenting the possibility of a decreasing trend, the total citation frequency can be determined with the co-citation level co-citation is
negatively linear correlation.

4.3 Comparison of cluster analysis

According to the traditional co-citation analysis method and the position based co-citation analysis method, we establish the co-citation matrix of these 78 documents, and then introduce the matrix into SPSS software to compare the cluster analysis. Firstly, the clustering results of the two methods are obtained by using the system clustering method, as shown in Figure 5.

![Figure 5. Traditional (left) and Position-based (right) Co-citation Analysis](image)

According to figure two, the clustering results of the 5 methods are found to be more precise than the traditional methods based on the consistency of the clustering results, as shown in Figure 5. Secondly, the clustering effect index is introduced, and the clustering results of the two methods are compared and evaluated.

Results the best clustering should make the similarity class of internal documents as large as possible, the class similarity between documents is as small as possible, according to this standard,
and the author uses the clustering quality evaluation comparison of the two methods of clustering results (Han and Zhao, 2009). The indicators are defined as follows:

\[
S_{ter}(C) = \frac{\sum_{i=1}^{K} S_{tera}(C_i)}{K} \quad (1)
\]

\[
S_{tra}(C) = \frac{k}{1 + \sum_{j=1}^{k} \text{dist}(\text{Centroid}_j, \text{Centroid}_i^2)} \quad (2)
\]

\[
CF = \frac{2S_{tera}(C) / S_{tra}(C)}{S_{tera}(C) + 1 / S_{tra}(C)} \quad (3)
\]

Among them, clustering results within class similarity, poly class number, is a subset of the results in class; the similarity clustering results, is the center of the J class, is the center of all points. Therefore, the larger the value, the better the clustering effect.

In this study, a total of 78 articles are involved in clustering, at least can be clustered into 1 categories, up to 78 categories, the number of clusters is too small to lose the significance of clustering, according to the sample data to be classified. Figure 5 analysis can be found, re adjust the distance of 25 is a critical value, when the distance is slightly less than 25, two methods are clustered into 6 categories; when re adjust the distance of 15, based on the position of the traditional co-citation analysis and cluster number were 18, 16, two methods were 11 Article 8, article alone into classes, accounted for the total number of class 61% and 50%; when re adjust the distance of 10, based on the position of the traditional co-citation analysis and cluster number were 29, 25, the two methods were 18 articles, 16 articles and 62% separate categories, accounting for 64% the total number of classes; when re adjust the distance of 5, a single article into a single cluster ratio of more than 80%. In conclusion, the author thinks that 78 articles should not be more than 18 the number of clusters. Continue to use SPSS software, K-means cluster analysis, and calculate the number of fixed class in a number of two methods of clustering results of the quality of the results, in order to compare. Table 7 lists the 6 class to 18 class together, the corresponding position clustering results with the traditional co-citation analysis method based on quality.

<table>
<thead>
<tr>
<th>Cluster</th>
<th>CF_{position}</th>
<th>CF_{tradition}</th>
</tr>
</thead>
<tbody>
<tr>
<td>6</td>
<td>0.83</td>
<td>1.25</td>
</tr>
<tr>
<td>7</td>
<td>0.99</td>
<td>1.32</td>
</tr>
<tr>
<td>8</td>
<td>1.11</td>
<td>1.25</td>
</tr>
<tr>
<td>9</td>
<td>1.38</td>
<td>1.31</td>
</tr>
<tr>
<td>10</td>
<td>1.43</td>
<td>1.36</td>
</tr>
<tr>
<td>11</td>
<td>1.48</td>
<td>1.30</td>
</tr>
<tr>
<td>12</td>
<td>1.39</td>
<td>1.27</td>
</tr>
</tbody>
</table>

Table 7 analysis illustrate that when clustered into 11 classes, the position of the co-citation analysis method to achieve the best clustering result based on the position value is 1.48, the traditional value is only 1.30; when clustered into 10 classes, the traditional co-citation analysis method to achieve the best clustering effect, the traditional value is 1.36, and the position value 1.43; when the cluster number is less than 9, the traditional co-citation clustering analysis method
is better than the quality of the clustering results of co-citation method based on position of quality, but the two methods have not yet reached the best clustering results, clustering number is not desirable; when the cluster number is not less than 9, clustering the results of co-citation clustering results the position of quality is superior to the traditional co-citation analysis method based on quality. Therefore, with the traditional co-citation analysis method, the position of the co-citation analysis methods to enhance the co-citation clustering results based on the analysis of the relationship between the clustering (or more weak) more literature from the formation of small separation categories, the similarity of the internal documents (more), class the similarity between the literature (smaller). Based on the position of the co-citation clustering method for more accurate clustering of scientific literature, it is conducive to the in-depth study and evaluation.

5. Discussion and Conclusions

This paper constructs the position of co-citation analysis method based on the framework, the co-citation analysis is divided into four levels and the differences between the assignment respectively; secondly, in the empirical analysis through the analysis of the citation frequency of each chapter of the position information can be found according to the citation, Citation Distribution classification on the scientific literature; third, through the co-citation analysis hierarchical distribution, that accounts for about 66% of the total citation is at the sentence level, paragraphs and chapters layer, the traditional co-citation analysis results cover the non-article level effect; fourth, the relationship between the level and cited by analyzing references find the co-citation frequency and a negative linear correlation between the co-citation co-citation level; fifth, the use of SPSS to two kinds of co-citation matrix clustering comparison, found that the position is based on The cited analysis method improves the validity of co-citation clustering.

Although the research made some achievements, but there are two problems: first is that the data is imitated in sample size and coverage, the research conclusions in other disciplines are founded, has yet to be verified; second is lacking of co-citation distance assignment f, four layer co-citation represents co-citation strength gap is equal, still needs to confirm the specific method of calculation.

In general, the position of the co-citation analysis method compared with the traditional co-citation clustering analysis method has a better effect on, although not confirmed the rationality of valuation gap, but the new method can help to improve the co-citation analysis, based on the position of the visible co-citation analysis has a very important value and the significance the development of co-citation analysis.

Abstract
Judah Folkman is considered the father of angiogenesis research. However, his hypothesis on tumor angiogenesis met a lot of skepticism at the beginning. Scientific resistance has been described in sociology of science, and leads to delayed recognition of pioneer work. In bibliometrics, it is characterized by papers, called sleeping beauties, that do not achieve recognition in terms of citations until a few years after their original publication. The present paper explores to what extent the phenomenon of delayed recognition have affected Folkman’s scientific production and the citation life of his publications. Citation analysis show that Folkman’s landmark paper published in 1971 is a sleeping beauty. The scientometric analysis is associated with a qualitative analysis in order to shed a light on the reasons behind the delayed recognition, and the awakening of “Sleeping Beauty” by a “Prince”, attracting a lot of attention in terms of citations. Interestingly, the fact that Judah Folkman was one of the co-authors of the Prince paper challenges the common practice of excluding self-citations and review while conducting such bibliometric analyses.

Conference Topic
Studies on the level of individual scientists

Introduction
Judah Folkman’s scientific production
The field of angiogenesis research began in the late 1960s with an attempt to delineate the role of neovascularization in tumor growth (Folkman, 1963). Over the past 50 years, angiogenesis research has become a very active and broad field of biomedicine. This new field of biology was initiated and pioneered by the American medical scientist Judah Folkman (1933-2008), who is unanimously considered the father of angiogenesis (Ribatti, 2008). Folkman introduced the concept of “anti-angiogenesis” as a potential novel anticancer therapy and his discovery is considered as a paradigm shift in cancer therapy (Cao, 2008). As a result, more than 1.2 million patients worldwide are now receiving antiangiogenic therapy (Bischoff, 2008).
Folkman received more than 150 awards from 11 nations. He was also elected to the National Academy of Sciences, to the Institute of Medicine and appointed to the President’s Cancer Advisory Board (Klagsbrun, 2008). Yet, during the first 20 years of his career, his ideas were met with a lot of skepticism, criticism and rejection (Folkman, 2008a). Folkman liked to reflect on the resistance he faced from his pairs by saying: “If your idea succeeds, everybody says you’re persistent, if it doesn’t succeed you’re stubborn” (Oranski, 2008).
Delayed recognition in scientific literature

The early rejection of Folkman’s ideas by the scientific community leads to the hypothesis that his work suffered from “delayed recognition”. Delayed recognition is a phenomenon where papers do not achieve recognition in terms of citations until a few years after their publication (Garfield, 1989a, 1989b, 1990; Glänzel, 2003; Van Calster, 2012). It also refers to terms such as “resisted discoveries” (Barber, 1961), “premature discoveries” (Merton, 1988), “late-bloomers” (Stent, 1972), “Mendel syndrome” (Costas, 2011). In scientometrics, it is called “sleeping beauty” (SB) (Van Raan, 2004), a publication that goes unnoticed for a long time, and then, awakened suddenly by a ‘prince’ (PR), attracting a lot of attention in terms of citations.

Quantitative criteria for studying delayed recognition can be summarized as being of three kinds: average-based criteria, quartile-based criteria and parameter-free criteria. One example of average-based criteria is van Raan’s (2004). Van Raan defined three variables for SB (a) depth of sleep (cs), that is, average citations per year received in the sleeping period since publication, with cs< = 1 standing for deep sleep and 1<cs< =2 for less deep sleep; (b) length of sleep (ns), that is, duration of sleeping period, often lasting between 5 and 10 years; and (c) awake intensity (Cw), amounting for instance to 20 citations per year over a period of 4 years. The quartile-based criteria were presented by Costas and colleagues’ measure (2010). They are able to describe three categories of publications by identifying the “Year 50%” as the year in which an article received for the first time at least 50% of its citations. SB are papers that have not received 50% of their citations when 75% of other documents in their fields have already received 50% of their citations.

A parameter-free index was proposed by Ke et al. (2015): “The Beauty coefficient (B)”. It quantifies the extent to which a paper could be considered a SB by adding up differentials between the citation curve of the publication and a reference line calculated between the year of publication and the year of maximum citations. Applying their criteria to their database, they consider as “top sleeping beauties” the 1000 papers with the highest “Beauty coefficient”, which corresponds to papers with B>=317.93.

Like in the fairy tale, a “Sleeping Beauty” must be awoken by a Prince. The Prince is usually the author of the first citing paper, but Du and Wu propose that candidates for "prince" should fulfill additional criteria such as: (i) the PR should be published at the time when the SB began to be highly cited; (ii) the PR should be highly cited papers themselves; and (iii) PR should be co-cited with the SB (Du, 2016).

The quantitative criteria that scientometrics offer for studying delayed recognition can be very useful to understand the dynamics of scientific change. However, such analysis must be examined critically by qualitative approaches such as historical or sociological analyses.

Aim

Sleeping beauties are relatively rare (<0.1%) (Ke, 2015) but they have been identified in numerous medical or research fields such as chemistry (Van Raan, 2004), metallurgy (Van Raan, 2004), ophthalmology (Ohba, 2012), pediatrics (Zavrsnik, 2016), psychology (Ho, 2017), or radiology (Gorry, 2016), and popularized among the wider scientific community (Cressey, 2015). The reasons for the SB pattern of citations may be linked to a paradigm shift in the research field (Van Raan, 2004) or social recognition through a Nobel Prize, for example (Du, 2016). However, the explanations for sleeping beauties are under explored.

The study of delayed recognition is necessary to understand scientific knowledge better. The present work aims to study the extent to which the phenomenon of delayed recognition affected Folkman’s body of work. We analyzed Folkman’s scientific production and the citation life of his publications looking for sleeping beauties. Then, we attempted to identify the relevant
prince, and tried to understand the reason for delayed recognition and the awakening mechanisms.

**Methods**

A collection of 510 publications authored by Judah Folkman were extracted with metadata, as well as a corpus of 116,703 citations from Scopus® database through 31 December 2015. Descriptive statistics were conducted using the Scopus® built-in functions and exported in CSV format to Excel, which was employed for further calculation. Using Ke at al.’s criteria (2015), the “Beauty coefficient” (B) was calculated for all of Folkman’s papers in order to identify top sleeping beauties. B quantifies the extent to which a paper may be considered a SB. For a given paper, they defined $c_t$ as the number of citations received in the $t^{th}$ year after publication, and $t$ as the age of the paper. The paper receives its maximum number $c_{tm}$ of yearly citations at time $t_m$. Straight line, $L_t$ connects the points $(0, c_0)$ and $(t_m, c_{tm})$ in the time-citation plane. The beauty coefficient B is then calculated using the Ke et al.’s equation. Ke et al. offer also a simple method for identifying the awakening time $t_a$ which is defined as the time $t$ at which the distance $d_t$ between the point $(t, c_t)$ and the reference line $L_t$ reaches its maximum.

Following Costas et al. (2011), we also calculated the quartile-based criteria “Year 50%” for all articles of the same year of publication, organized them in ascending order in terms of their percentiles, and recorded those falling on percentiles 25 as “P25” and those falling on percentiles 75 as “P75”.

The SCImago® journal rank measure was directly retrieved from Scopus®. The numbers of co-citations between the SB paper and each candidate Prince paper were calculated using Gephi® an open-source network analysis software package (https://gephi.org/). Each citation is represented by a unique Scopus identifier (EID). The number of co-citations was equal to the number of citation duplicates detected by Gephi®.

Finally, all the bibliometrics analysis were complemented by a historical approach of the Folkman biography and history of angiogenesis using sources with criticism.

**Results**

*Judah Folkman’s scientific production*

Folkman published his first paper in 1953 while he was enrolled at Harvard Medical School in 1957. In 1967, he was appointed Surgeon-in-Chief at Children’s Hospital, and the year after Professor of Pediatric Surgery at Harvard Medical school, at the unprecedented age of 36. He stepped down from that position in 1981 in order to work exclusively on angiogenesis research. During the 41 years that he worked at the Boston Children Hospital, he was the author of 396 articles, 41 reviews, and some 76 monographs. He published on the average 9.658 papers/year with a maximum of 23 papers in 1998 (Fig.1; grey box; right y-axis: publications number).

All along his scientific career, he published in various disciplines (multidisciplinary, medicine, surgery, oncology, pathology, biochemistry) in more than 160 different journals. About one-quarter of his research publications was published in the best medical and biology journals (Table 1). He also collaborated with a large number of researchers (more than 150) during his prolific and long career. His main collaborators were his fellows or technician, Yueng Shing, Evelyn Flynn, Robert D’Amato, and Michael O’Reilly.

Folkman’s scientific work was rapidly recognized in the academic community (675 total citations in 1970 for 26 publications); until 2015, his work was cited more than 116,700 times (Fig. 1; dashed line: cumulative citations for all Folkman’s publications by year, left y-axis).

Regarding his main research interest, he published his first paper on tumor growth in 1963, and published in 1971 his first two paper untitled angiogenesis (Fig. 1: black box).

delayed paper has a B coefficient well above the threshold (B>=317.93) used by Ke et al. (2015) unlike the following ones (Table 2). This paper entitled “Tumor Angiogenesis: Therapeutic implications” was a review which was published in 1971, in a top journal (99th percentile rank): the New England Journal of Medicine (Folkman, 1971). This landmark paper has averaged 139.53 citations per annum, amounting to 6,279 citations up to the 31st December 2015.

Figure 2. Citation history of Folkman’s sleeping beauty, candidate prince papers and angiogenesis publication trends.

During its first 23 years, however, the paper was cited only 113 times. This suddenly rose to 18 citations in 1995, 33 citations in 1996, and 65 citations in 1997 (Fig. 2; black line: number of citations per year for Sleeping Beauty, left y-axis). Since 1995, the paper has averaged 293.6 citations per annum. This clearly exemplifies a sleeping beauty, although it does not fit exactly into Van Raan’s definition. With its 4.7 citations per year during the sleeping period, the paper qualifies as a “light sleep” (Van Raan, 2004; 25); it slept for 23 years instead of five to ten. Also, the average number of citations over the four years following its awakening was 51 per
annum, which is a very high awake intensity by considering Van Raan’s definition (minimum of 20 citations per year for a 4-year period). In addition, using Costas et al.’s criteria (2011), Year50% = 39 (which corresponds to the year 2009), while P75 = 34.5. This means that Folkman’s paper is classified as a paper with delayed recognition.

**Identifying the Prince**

In order to determine the Prince paper, the year of the awakening was calculated using Ke et al.’s equation (2016) and was revealed to be 1994. Based on the awakening year, the investigation was narrowed down to the period of time between 1992 and 1996 in which the top publications citing Folkman’s main paper were identified. The Prince paper was likely to have been published in a top rank journal, to be among the first highly cited citing articles, and to share the largest number of co-citations with the SB paper during the awakening period 1993-97 (Table 3). The citation curve of Prince should match the citation awakening of the SB paper.

**Table 3. Top candidate Prince publications citing Folkman’s Sleeping Beauty around the awaking year (1993-1997).**

The most cited article citing Folkman’s paper is a publication untitled “Angiostatin: A novel angiogenesis inhibitor that mediates the suppression of metastases by a Lewis lung carcinoma”, published in 1994 in Cell. The first author is Michael O’Reilly’s, a post-doctoral fellow at that time in Folkman’s laboratory, who was one of the co-authors (O’Reilly, 1994) (Fig. 2; black dotted line: candidate Prince paper #1, left y-axis). This article also shares the highest number of co-citations with the landmark paper (505 co-citations) (Table 3). Our Prince is therefore this paper with Michael O’Reilly. Beside the citation of Folkman’s main paper by the Prince, the awakening can be attributed by the discovery of his pioneering work by a whole research community. It is worthy of note that the awakening citations of Folkman’s paper matched with the annual rate of publications entitled or indexed (abstract, keywords) for the keyword angiogenesis (Fig. 2: black dashed line, right y-axis).

**Discussion**

*Delayed recognition of the angiogenesis-dependent tumor growth hypothesis*

Despite the fact that Judah Folkman is recognized today as the father of angiogenesis research, his landmark paper suffered from delayed recognition. Folkman’s SB paper first presented the hypothesis that “tumor growth is angiogenesis-dependent” (Folkman, 1971). In this rather
theoretical article, Folkman showed preliminary evidence that tumors could not enlarge beyond a microscopic size of 1-2 mm$^3$ without recruiting new capillary blood vessels. Folkman also introduced the term “angiogenesis” to mean the prevention of new vessel sprouts from being recruited by a tumor, reported the isolation of a tumor angiogenesis factor (TAF) and speculated that antiangiogenesis may provide a form of cancer therapy with an antibody against TAF. Many skeptics challenged Folkman’s hypothesis (Kerbel, 2000), and many scientists argued that the search for an angiogenesis inhibitor was a “fruitless exercise” (Folkman, 2008b). However, the 1980s witnessed the discovery of the first molecules that mediated angiogenesis such as acidic and basic fibroblast growth factor (Shing, 1984) and vascular endothelial growth factor (Ferrara, 1989). In addition, the first angiogenesis inhibitor, interferon α, was discovered by Brouty-Boyé & Zetter (1980). By 1988, daily low dose interferon α was successfully used to treat cancer. All those experimental and clinical advances throughout the 80s were not sufficient to trigger the awakening of Folkman’s paper. It was until the mid-90s that it received the attention and recognition it deserved.

The Prince’s kiss of life
Since the late 1970s, Folkman’s laboratory conducted a long-term effort to prove the existence of angiogenesis inhibitors. This effort was fruitful in that the laboratory reported eleven molecules between 1980 and 2005 (Folkman, 2008). In 1991, Michael O’Reilly came to Folkman’s laboratory as a postdoctoral fellow (Folkman, 1996). His mission was to attempt to uncover the mechanism of suppression of metastatic growth by a primary tumor. Folkman developed an alternative hypothesis after reading Noel Bouck’s report in 1989 that the emergence of tumor angiogenesis was the result of a shift in balance between positive and negative regulators of angiogenesis in a tumor (Rastinejad, 1989). All these findings suggested to Folkman that a primary tumor might suppress growth of its distant metastases by releasing an angiogenesis inhibitor into the circulation.

Indeed, the discovery of angio statin came as a result of an attempt to test this hypothesis (O’Reilly, 1994). The discovery and publication of angio statin in 1994 resulted in a fundamental evolution in the field of angiogenesis (Soff, 2000). The characteristics of Angio statin listed above made the scientific community finally appreciate the real importance and relevance of endogenous angiogenesis inhibitors (Folkman, 2004), and consequently recognize the major importance of Folkman’s 1971 founding paper. This late recognition was immediately translated by the subsequent awakening of Folkman’s sleeping beauty.

Conclusion
This paper has attempted to apply methodology of citation analysis to explore if Judah Folkman’s scientific work suffered from delayed recognition, and sustain the author feeling about scientific resistance to his tumor angiogenesis hypothesis (Bikfalvi, 2016). It has shown that Folkman’s landmark paper is indeed a sleeping beauty based on the calculation of the B coefficient and according to Costas’ criteria. If, it does not fulfil Van Raan’s sleeping beauty publication criteria, it is due to the arbitrary thresholds on the sleeping period and on awakening intensity (Gorry, 2016; Li, 2016). However, the idea that papers with delayed recognition show the highest impact in their fields is supported by our case study (Costas, 2010).

However, Folkman’s SB paper is categorized as a “review” paper, and, there is no consensus so far to the inclusion or exclusion of this type of document in citation analysis. Although the definition of a review might vary across fields, journals and time, it usually presents an overview of recent research advances and highlights results inconsistencies. Folkman’s review hypothesizing that “tumor growth was angiogenesis-dependent led to a profound paradigm shift in oncology” (Cao, 2008). Therefore, it is tempting to refer to Kuhn’s scientific revolution
(Kuhn, 1970), and consider that Folkman’s sleeping beauty is probably the paper that initiated the field of angiogenesis research.

Folkman’s SB paper slept for more than twenty years until the discovery of angiostatin in 1994 (Soff, 2000). The most obvious explanation is that the scientific community was skeptical, waiting for sound experimental evidence before changing in paradigm, according to Popper’s cumulative process (Popper, 1961). Alternatively, scientific controversy might explain delayed recognition of the SB (Gorry, 2016). Folkman’s landmark paper might have suffered from controversies surrounding the financing of his lab and its partnership with Monsanto during that sleeping period (Hess, 2006). However, the controversy born of the difficulties of replicating Folkman’s results by other laboratories did not affected the awakening of his landmark paper by the Prince paper. Angiogenesis research started to spread to many laboratories and became a burgeoning field with hundreds of papers per year.

Interestingly, the fact that Judah Folkman was one of the co-authors of the Prince paper challenges the common practice of excluding self-citations when conducting such bibliometric analyses. Self-citation is defined as a citation in which the citing and the cited paper share at least one author in common. If self-citation is believed to sustain self-promotion, it may be justified by the cumulative nature of science, when authors refer to previous hypotheses, methods or results (Popper, 1961). The fact that Folkman kept citing his own paper after all those years demonstrates his phenomenal persistence and belief in the importance of his theory. It should certainly not be seen as means to artificially inflating citation rates in order to strengthen his position in the community (Glänzel, 2008). During the sleeping period, the NIH turned down Folkman’s grant proposal, and he was able to continue his research program by securing founding with private companies (Hess, 2006). Constancy and continuity in a research field are important components that ensure the development of new research subject area (Price, 1976).

**Acknowledgment**

This work was supported by an internship to Adil El Aichouchi granted by the Bordeaux’ University consortium on vascular aging (ATT-VIVA). We would like to thank Pascal Duris for his support and Andreas Bikfalvi for his comments on the biology of angiogenesis.

Abstract
In this paper, we report distributions of in-text citations in full text articles from two large databases – the PubMed Central Open Access Subset and Elsevier journals – as functions of time and textual progression. Using over five million articles from these two databases, we show that the numbers of in-text citations (i.e., mentions) per reference have remained nearly constant over time, and that the number of mentions per reference decreases with reference age. The data also show that mentions are concentrated at the beginning and near the end of articles, but that the distribution changes with the number of mentions per reference. References ages peak on average at around the 30% point in an article, and decrease thereafter. Citation counts for references also peak at around the 30% point, suggesting that methods papers are more highly cited than other types of papers. Citation counts are also a function of mentions – those references mentioned only once are much more highly cited than those mentioned many times, which correlates with the notion of perfunctory references being mentioned less often than those references that are more central to a citing article.

Analysis of full text

Introduction
The increasing availability of full text from scientific articles in electronic format is a development with the potential to greatly impact citation analytics and the ability to accurately model the structure of science. Full text contains information not only on the exact locations of in-text citations within articles, but also the context in which a citation to previous work is made. Specific problems that can be addressed using full text data include classification of in-text citations by type and function, and improving measures of impact by weighting of citations based on polarity, typology, function, citing location, and perhaps other features as well. Weighting of citations also has the potential to impact our knowledge of the structure of science, in that document clustering (and the resulting maps) could be based on a more accurate measure of the relatedness between documents. These applications, although beyond the scope of this paper, motivate the current work, which characterizes the distributions of in-text citations (and associated features) in two large full text databases. A solid understanding of these distributions is required before advanced applications of full text data, such as those mentioned, can be most fruitfully pursued.

Study of in-text citations and related text from scientific documents using full text sources has a long history. Although both syntactic (the location of references) and semantic (the meaning of references) studies have been pursued (Ding, Liu, Guo, & Cronin, 2013), here we focus primarily on the syntactic aspect. The terminology used in previous studies of in-text citations is not consistent. Thus, to avoid confusion, we define our terminology here. A reference is an
item in the bibliography or reference list of a document. An in-text citation is a mention of a reference within the full text of a document. A reference can be mentioned one or more times in a document. Each mention is an in-text citation. We use the terms in-text citation and mention interchangeably in this article.

Over the years, many studies of the location or position of in-text citations have sought to identify the relative value of citations as a function of the position or the number of mentions. Implicit among many of these studies is the assumption that references that are more related to the citing article are the more valuable or essential references for that article. In reviewing prior work we focus on those studies that explicitly include mention location in their analysis. Early studies were necessarily done by hand with small datasets. In one of the first studies, Voos & Dagaev (1976) examined citations to a set of four highly cited articles, two from biology, one from medicine and one from physics. Despite their very small sample, their findings suggested that a) most mentions come from introduction sections, b) the location and the number of mentions – which early studies often referred to as op. cit. – were both important in determining the value of a citation, c) time was important, and d) different disciplines had different citation patterns.

Cano (1989) sought to study citation function and utility while also examining position. Using 344 references that were coded by function and utility by their authors, they found that references that were mentioned in a perfunctory and negational way were most often peripheral or of low utility. They also found that references classified as organic, conceptual, operational or evolutionary were more typically essential or of higher utility, and that mentions were more concentrated in the first 15% of an article. Maričić et al. (1998) examined citation contexts as well as locations using 11% of the mentions to a set of 357 articles, and suggested that references should be valued differently based on the section of the citing article in which they appear. They found references with relatively low “meaning” (or value) to be mentioned predominantly in the introduction, while those mentioned in other sections had higher meaning.

Bornmann & Daniel (2008) examined a set of 350 in-text citations to a set of articles written by grant applicants. Using the IMRaD (introduction, methods, results and discussion) structure, they found that while more mentions appeared in the introduction and discussion sections of citing articles, methods and results sections were slightly enriched with mentions to articles with higher citation counts. In perhaps the most detailed comparison with ground truth data available, Tang & Safer (2008) surveyed authors of 49 articles in biology and 50 articles in psychology who assessed the mentions in their articles for importance, reason for citation, and relationship to the cited author. They found that reference importance increased with numbers of mentions and more detailed discussion. In addition, the authors considered references mentioned in the methods and results sections to be most important, while those mentioned in the introduction section only were less important than those in other sections.

Several recent works have also focused on the distribution of in-text citations within full text. Hu, Chen & Liu (2013) counted the number of mentions per section for 350 articles from Journal of Informetrics, finding that half of the mentions are in the first 30% of the text. They graphically represented distributions of mentions for articles with four, five and six sections. The six-section representation showed the greatest differentiation in the number of mentions per section, with counts decreasing (per kilo-words) through the first four sections, then increasing for the fifth section, and decreasing again for the last section. Ding et al. (2013) also counted mentions by section for 866 JASIST articles, finding that the literature review
section had the largest numbers, and that the most highly cited articles were referenced in the introduction and literature review sections.

The largest study of in-text citation distributions, and the most similar to our work, is the recent study by Bertin et al. (2016), who showed distributions of mentions and reference ages as a function of text progression from 45,000 scientific articles published in PLOS journals. Given that the PLOS documents have relatively consistent styles by journal and have very well tagged section headers, they were able to characterize these distributions in terms of the IMRaD document style. Specific documents that have sections not in IMRaD order were reordered to IMRaD order, leading to the observation that mentions are most highly concentrated in the introductions of articles, followed by the discussion section. They also showed that reference ages (i.e., time between the publication years of a citing publication and a cited publication) are highest at the beginning of the introduction and in the methods section, decreasing at the end of the introduction and in the results and discussion sections. The fact that these distributions are very similar across PLOS journals led them to characterize these as “invariant” distributions.

Finally, Zhao, Cappello & Johnston (2017) coded 1473 in-text citations from 14 JASIST articles by citation function, using three categories that were considered influential and two categories that were considered non-essential. To limit references to those that are influential for the purposes of citation analysis, they suggest that “removing all citation occurrences in the Background and Literature Review sections and uni-citations in the Introduction section appears to provide a good balance between filtration and error rates.”

In summary, regarding distributions of in-text citations, there is a consensus among previous studies that mentions tend to be more concentrated at the beginnings (e.g., introduction and related work) and endings (e.g., discussion and conclusion) of articles than in the middle sections. There is also a rough consensus that references that are mentioned outside the introductory sections are perhaps the most valuable.

Our work expands specifically on Bertin et al. (2016) by examining in-text citation distributions for two much larger full text datasets – the PubMed Central (PMC) Open Access subset and a large portion of the Elsevier full text corpus. Using these much larger and disciplinarily broader data, we will show that there are significant variations in the distributions that were not seen in the strongly biomedical PLOS corpus. We also report citation count distributions as a function of text progression. The paper proceeds as follows. We first review relevant literature and then describe our datasets and analysis methods. Results are then reported along with key observations. The paper concludes with a summary and suggestions for additional work.

Data and Methods
We have obtained access to two large sources of full text scientific articles that are available in machine readable form – the PubMed Central Open Access Subset (PMCOA) and full text from Elsevier (ELS) journals. Elsevier content is also available in their ScienceDirect product. PMCOA contains roughly 36% of the articles from PubMed Central, and is comprised of a) articles from open access journals and b) articles that are required to be made publicly available under the National Institutes of Health (NIH) public access policy and legislative mandates. Given publisher embargos, inclusion of the latter type of articles is typically delayed 12 months after publication. Nearly all PMCOA articles are also indexed in PubMed. ELS contains articles from nearly 3,000 Elsevier journals. Given that Elsevier is the largest
publisher of journals in the world, ELS is the single largest source of full text scientific articles currently available, and covers most scientific and technical fields.

Each full text source was obtained and processed independently, at different times, by different institutions, and using different code, as will be explained below. Despite these differences, the same basic steps were applied to each source: downloading, filtering, parsing, database creation, reference matching, and analysis.

**PubMed Central Open Access Subset**

The PubMed Central Open Access Subset was downloaded in XML format and processed by SciTech Strategies in October 2015. The subset included data through mid-2015 and contained 1,113,891 individual records, of which 945,279 had an associated PubMed ID (PMID) and at least one reference. Most of the records without PMID were conference abstracts that are not indexed in PubMed. We further limited the data to articles that were classified in PubMed as either a ‘journal article’ or a ‘review’, that were published in 1998 or later, and that had at least one reference with a reasonable reference year (defined as being between 1900 and 2015 and where the publication year was no earlier than one year prior to the reference year).

Each XML record was parsed such that individual sections, paragraphs and sentences were identified and numbered. While sections and paragraphs were delimited using XML tags, sentences were delimited and split using the NLTK (http://www.nltk.org/) pre-trained Punkt tokenizer for English. References, along with their bibliographic metadata (including PMID in many cases) were also extracted. In-text citations and their exact positions in the text (in terms of character offsets and text progression centiles within the article) were identified in the sentence level data using reference tags. Multiple in-text citations in the same bracket, whether using author/date or numbered formats, were given the same position in the text, regardless of which reference was listed first. Figure and table captions and footnotes were not considered. Parsed data were loaded into a MySQL database for further processing.

In addition to its centile position within the text, other data were added to each mention including the number of mentions (for the citing article and reference combination), reference age, the CWTS Leiden Ranking field to which the citing article belongs, and the Scopus citation counts to the reference as of the publication year of the citing article. Citation counts were obtained in a two-step process. First, Scopus article IDs were identified for each reference where possible by 1) using the listed PMID for the reference and looking up the corresponding Scopus ID from our matching table, or 2) matching the reference metadata to publication metadata from Scopus. Scopus IDs were identified for nearly 90% of the mentions. Citation counts to each reference were then from our Scopus data tables and added to the data. We note that citation counts are incomplete for references published prior to 1996 since Scopus records only contain references from 1996 onward. Leiden Ranking fields were added using a DOI lookup table provided by CWTS; only 593,224 articles could be matched to a field given the incompleteness of DOI data.

**Elsevier Full Text**

The Elsevier full text data were obtained in January 2017 and thus included a nearly complete 2016 publication year. Data were downloaded and filtered by CWTS using the following steps. First, the CrossRef REST API was used to identify all publications in Elsevier journals, numbering 8,437,487. Other types of publications, for instance publications in book series or conference proceedings, were not considered. Second, the Elsevier ScienceDirect API (Article
Retrieval API) was used to download these publications in XML format. Downloading was possible only for the 7,862,859 publications to which Leiden University has access via subscription. For some of these publications, the XML included only metadata rather than full text. Publications without full text were discarded, leaving 6,179,750 XML records. In particular, all publications that appeared before 1998 were discarded, because for almost all of these publications XML formatted full text was not available. Finally, the data were limited to those records that were English-language publications specifically labeled as full-length article, short communication, or review article, leaving a total of 4,821,774 full text records for analysis.

Each XML full text record was parsed to create sections, paragraphs, and sentences. This is important to properly locate each in-text citation. Sections and paragraphs were identified directly using XML tags. Only main sections were taken into account while subsections were ignored. Sentences could not be identified using XML tags. To identify sentences, we used a modified version of the sentence splitting algorithm provided in the BreakIterator class in the Java API. In-text citations and their exact positions in the text (in terms of character offsets and text progression centiles within the article) were identified in the sentence level data using the CWTS parsing algorithms. In addition, we also identified in-text citations occurring at various special locations in the full text of a publication, such as in footnotes and in the captions of tables and figures. Given that these mentions may perform a somewhat different function than mentions in the text body, we have not included them in the analysis that follows.

Publications in the ELS database were matched with publications in the Web of Science database. Publications were first matched based on DOI. If no DOI-based match was obtained, publications were matched based on the combination of the last name with first initial of the first author, publication year, volume number, and first page number, which together form a relatively unique key for each article. A match was required for all four fields. Of the publications retained for analysis, 4,503,790 could be matched with a publication in the Web of Science database. References in the full text publications were also linked to the five broad fields of science distinguished in the 2016 edition of the CWTS Leiden Ranking. Publications from 2016 were excluded in this step since the 2016 Leiden Ranking includes only publications through 2015. The number of publications that could be linked to one of the five fields is 3,892,083.

Descriptive Statistics
Numbers of articles, references and in-text citations for both datasets are given in Table 1, along with other characteristics of the data. Roughly 3% of the references were not included in the PMCOA analysis because they were missing a reference year or did not have a reasonable reference year. Although the average article in the ELS dataset is somewhat smaller than the average article in the PMCOA dataset (e.g., in numbers of paragraphs, sentences, characters, etc.), the average numbers of mentions per reference (1.573 and 1.572 for PMCOA and ELS, respectively) and percentage of sentences with mentions (19.91% and 19.77%) are very similar. The most substantial difference shown in Table 1 is in the numbers
of sections; this difference is explained by the fact that major sections and subsections were counted for PMCOA while only major sections were counted for ELS.

Results

In-text citations from full text articles can be characterized in a number of ways. For this paper, we choose to characterize distributions in terms of time and text progression.

Temporal Distributions

PMCOA and ELS have very different temporal distributions. PMCOA contains less than 1% of the articles indexed in PubMed prior to 2004, but has rapidly expanded since then to where it contains 19% of PubMed articles in 2014 (see Figure 1). In contrast, ELS contained over 100,000 articles in 1998, and while the number of full text articles has grown consistently, coverage (as compared with the total number of articles and reviews in Scopus) has stabilized at roughly 18% since 2004. Thus, PMCOA is highly skewed to recent content, while ELS contains a roughly consistent slice of the scientific literature over the past 12 years. Note that while we had fewer PMCOA articles in 2015 than in 2014 due to the timing of our data acquisition, full year values are shown for 2015 and 2016 (based on a recent query) as the dashed line in Figure 1.

Average numbers of references and mentions per article have increased in both databases over the years; however, the increase has been more pronounced for ELS than for PMCOA (see Figure 2). Despite the absolute differences, the average numbers of mentions per reference are very similar for the two databases and are nearly constant over time, decreasing only very slightly from 1.59 in 2001 to 1.57 in 2015. This constancy suggests that, despite changes in numbers of articles and references, the way in which references are mentioned has not changed recently.

A different type of temporal distribution can be examined by basing the data on citation interval (i.e., reference age). Figure 3 shows average numbers of references, mentions, and mentions per reference as a function of citation interval. Peak values occur for references and mentions for two-year old references; numbers then decrease steadily with increasing age. Most interestingly, the youngest references are mentioned more often than older references. While references aged two years or less are mentioned on average over 1.7 times, references older than 20 years are mentioned only 1.39 and 1.44 times each (PMCOA and ELS,
respectively). The differences between the tails in the PMCOA and ELS data likely stem from the fact that ELS covers all fields while PMCOA is focused on biomedical literature. Field-level differences will be investigated in future work.

![Graph showing full text coverage by year.]

Figure 2. Average numbers of references, mentions, and mentions per reference by year.

![Graph showing average numbers by year.]

Distributions by Text Progression

While several other studies have aimed to characterize distributions of in-text citations in terms of the IMRaD structure, our study simply characterizes these distributions as a function of text progression. We did not assign mentions to sections due to the lack of uniformity in section naming and ordering across journals. For example, while the ordering implied by IMRaD likely holds for a significant share of all journals, for other journals it is conventional for the methods section to be at the end of the article rather than after the introduction.
Figure 3. Average numbers of references, mentions, and mentions per reference by reference age. Bubble areas (right) denote relative fractions of mentions.

Figure 4 shows the distribution of mentions for three databases as a function of text progression using five-percentile bins. The reference distribution for the 66,227 articles in PLOS journals through 2012 that are available in PMCOA, approximating the results of Bertin et al. (2016) for the PLOS corpus, is included for comparison purposes. The three databases are similar in that the percentage of mentions for each is highest at the beginning of the paper (typically corresponding to the introduction), followed by a decay to a level that is relatively flat at around 3.5% of the references in each 5% bin. Each curve also then increases to a secondary peak nearer the end of the paper before tapering off to a very low level at the end.

In addition to these similarities, there are also subtle differences. PMCOA and PLOS have similar characteristics through the first 40% of articles, but the secondary peak occurs earlier (70% vs. 80%) and is a bit lower and broader for the PLOS curve than for the PMCOA curve.
despite the fact that both databases are primarily biomedical in nature. Bertin et al. (2016) showed that PLOS journals with the discussion section at the end have their secondary peak at the 90% point, while those with the methods section at the end have their secondary peak at the 60% point. PLOS ONE, with roughly half of each type, had a much shallower and broader peak at around the 70% point. The fact that the secondary peak in the PMCOA curve is shifted to the right of that in the PLOS curve suggests that PMCOA has proportionally more articles with their discussion section at the end. The ELS curve shows even more significant differences. The decay after the introduction is more gradual than that of the PMCOA curve and the secondary peak is much lower and occurs later, at the 85% point. These differences could easily be due to field-level differences. However, verification of this hypothesis will need to wait for future analysis. Regardless of the reasons for the differences, these results show that the distribution of in-text citations in scientific articles are perhaps not quite as invariant as previously reported.

Figure 5 shows distributions of mentions for the PMCOA and ELS databases as a function of number of mentions. The patterns are similar for both databases; the distributions of mentions flatten as the number of mentions increases. References mentioned only once are more prominent in the introduction sections of articles than are references mentioned many times.

We have also investigated citation interval as a function of text progression. Figure 6 shows results for PMCOA, ELS, and the PLOS subset. The three curves are similar in nature, with a slight decrease in reference age immediately after the first five-percentile bin, followed by an increase to a peak value and then a gentle decay to the end of the article. PMCOA reference ages are roughly one year older than those for PLOS articles. Given that both databases are largely biomedical, this suggests that the immediacy of PLOS articles is somewhat higher than those of biomedical articles in general. The ELS curve varies between one and two years higher than the PMCOA curve. Once again, we suspect that this difference is due to field-level effects.
Figure 6. Distribution of citation intervals (reference ages) associated with mentions for three databases.

Figure 7 shows distributions of citation intervals of mentions for the PMCOA and ELS databases as a function of number of mentions. The patterns are similar for both databases; the reference ages decrease as the number of mentions increases. References mentioned only once are substantially older than those mentioned many times, and are particularly so at the peak around the 25-35% point, likely corresponding in most cases to methods sections. This correlates well with the results of Figure 3, which showed that younger papers are mentioned more than older papers, but also shows that this holds true in all parts of an article.

Figure 7. Distribution of citation intervals associated with mentions as a function of number of mentions for PMCOA (left) and ELS (right).

Finally, we show the average citation counts for references mentioned as a function of text progression. Figure 8 shows that the PMCOA and ELS curves are similar in nature. References cited at the beginning of the article are more highly cited than those appearing later in the introduction. Citation counts then rise substantially to a peak at the 30% point, followed by a decrease, and then another increase toward the end of the paper. This final
increase is much more pronounced for PMCOA than for ELS, and may be specific to biomedicine.

![Figure 8. Distribution of citation counts associated with mentions for PMCOA and ELS (left), and average citation counts of references as a function of number of mentions (right). Bubble areas denote relative fractions of mentions (left) or references (right).](image)

Interestingly, the citation counts for references in PMCOA articles are much higher than those in ELS articles. We suspect that this difference is due to three reasons, but cannot do more than conjecture at this time. First, articles in biomedicine are often more highly cited than those in science as a whole due to citation cultures and database coverages. Second, PMCOA is mostly comprised of papers funded by NIH (due to the NIH OA mandate), and NIH funded papers have substantially higher counts than the typical biomedical paper (Boyack & Jordan, 2011). Even though we are measuring the citation counts of references rather than the citing papers, it is not unreasonable to suspect that articles that are highly cited also preferentially cite other highly cited articles. Third, Scopus citation counts are higher than citation counts from the Web of Science (WoS) for the same paper since Scopus coverage is broader than WoS coverage.

Figure 8 (right) also shows that the most highly cited references are typically mentioned less often than references that are less highly cited. Average citation counts for references mentioned only once are three times as high as for references mentioned eight or more times. References mentioned only once are also likely to be accompanied by less explanation than those mentioned multiple times (Zhao et al., 2017). This suggests that references mentioned only once are more likely to be perfunctory than those mentioned multiple times.

**Conclusions**

In this paper, we have analysed the in-text citations from over five million articles from two large databases – the PubMed Central Open Access Subset and Elsevier journals. Using these two databases, we have shown that the numbers of mentions per reference have remained nearly constant over time, and that the number of mentions per reference decreases with reference age. The data also show that mentions are concentrated at the beginning and near the end of articles, but that the distribution changes with the number of mentions per reference. References ages peak on average at around the 30% point in an article, and decrease thereafter. Citation counts for references also peak at around the 30% point, suggesting that papers cited in methods sections (which are typically other methods papers) are more highly cited than other papers. This contradicts the finding of Ding et al. (2013) that the most highly cited papers are mentioned in the introduction and literature sections. Citation counts are also a function of mentions – references mentioned only once are much more
highly cited than references mentioned many times, which correlates with the notion of perfunctory references being mentioned less often than those references that are more central to a citing article.

Differences exist between distributions from the PMCOA and ELS databases that cannot yet be explained. We suspect that these differences are primarily due to field-level differences. Immediate future work will thus focus on analysing these data using a field-level classification to identify the nature and magnitude of these differences, if any exist.

Acknowledgments
We thank Mike Patek for extraction and fielding of the full text from PubMed Central. Colavizza is funded by Swiss National Fund grant number P1ELP2_168489.

Abstract
This paper explores the position of Preprint in scholarly communication through bibliometric and empirical analysis of the arXiv-deposited papers in Information science & library science field and Robotics field, and focuses on four aspects, including “increasing trend”, “time gap”, “citation advantage” and “citation trend” in these two fields to demonstrate the effect of Preprint. The results show that the amount of preprints is increasing, most authors prefer to publish a pre-print in a journal or submit a post-preprint to arXiv within two years, the preprints have an obvious citation advantage compared with the papers only published in journals, and the citation increases rapidly after submitting the post-prints to arXiv.

Conference Topic
Journals, databases and electronic publications; Science communication

Introduction
Preprint, or Open Access (OA) shows an increasingly prosperous trend, and is widely supported by the government, research institutions and researchers all over the world. However, the progress of this emerging scholarly communication channel has been far slower in China compared with the world because of the academic evaluation and the academic journal issue system in China. Any promising thing will eventually break through the obstacles and move forward, the first Chinese preprint system, ChinaXiv was established on June in 2016 eventually. There emerged many preprint systems in 2016, such as engrXiv, SocArXiv, ChemRxiv and PsyArXiv. Especially, in the same year, the first preprint platform arXiv announced that 250-300 million dollars would be invested to promote its modernization and CrossRef announced to include the Preprint.

The emergence of a number of preprint platforms is challenging to the scientific journals. Scientific journals have been long dominant in the scholarly communication system through the printed papers by peer-review. The rejection and the delay due to lengthy journal review processes and manuscript backlogs, or no publish because of the payment, the block of access papers because of the economic burden as pay for the publisher, all of these problems in the scholarly communication systems would be partly solved by Preprint, due to the three main features of Preprint: “free academic publish”, “publish before print”, and “even publish no print”.

Bernal JD, the father of Science of Science, had promoted some insightful thought on scholarly communication as early as 1930s. He predicted that the rapid growth of science would lead to science journals actually abolished finally in his foundation work The Social Function of Science (1939), and expressed this opinion in The Transmission of Scientific Information: A User's Analysis (1959). He proposed to take each individual paper as the unit
of scholarly communication instead of journals, to promote scholarly communication directly using advanced electronic computers for scientific information collection, filtering and classification, to establish a central scientific literature system for scientists to transmit their research, as well as to retrieve and have access to all scientific literature. Scholarly communication is changing and will continue to change in future although the Bernal’s prediction is considered to be bold and exaggerated.

Preprints, as the name implies, initially referred to authors’ manuscripts submitted to an internet platform before published in journals. With the development of Preprint, such as arXiv, Coprints, RePEc, etc., the term “preprints” refers to all the papers deposited in preprint platforms at present, including both pre-prints (as submitted to a journal for peer review), working papers, post-prints (as a final copy of the peer-reviewed edited full text) or accepted manuscripts articles. Preprints—“temporary documents whose function is to bridge the time-gap created by publication delays” (Goldschmidt, 2002)—present a well-established mechanism for the exchange of scientific information.

Lawrence (2001) studied the correlation between articles freely available online (also called OA articles in some papers) firstly. He analysed 119,924 conference articles in computer science and related disciplines from DBLP (dblp.uni-trier.de), the results showed that freely available online articles were cited more often than ‘offline’ articles published in the same venue. Subsequently, many researches on the citation advantage of OA articles have emerged (Anderson, 2001; Craig, Plume & Mcveigh, 2007; Swan, 2010; Wagner, 2010; Ingwersen & Elleby, 2011; Gargouri & Lariviè re, 2012). The citation impact of Preprint varies by field. Brown (2003) explored the role of the Chemistry Preprint Server (CPS) in Chemical communication, and suggested that though it appeared unlikely that the CPS would replace the traditional chemistry journal in the near future, the CPS was utilized, appreciated, and valued by a wide variety of chemists to enrich their scholarly discourse and these extraordinary systems were likely to ultimately become the conventional scientific mode of information dissemination of the future. Brody & Harnad (2004) focused on the citation advantage analysis on pre-print manuscripts in physics and mathematics, and found that articles with a corresponding pre-print version deposited in arXiv would be more cited than those do not. Antelman (2004) studied the preprint in four subjects, Philosophy, Political Science, Electrical and Electronic Engineering and Mathematics, and found the proportion of preprints varied by disciplines from 17% to 69%, but across all these four disciplines, the preprints did have greater impact. Schwarz (2004), Metcalf (2005) and Henneken & Kurtz (2006) all found that papers with a matching pre-print version deposited in arXiv are both cited more than non-posted papers by examining the average citation rate of preprints in the Astrophysical Journal. In Solar Physics, there was also a significant citation advantage of preprints posted to arXiv or Montana State University (MSU) archive, which had citation rates 2.6 times and 1.7 times higher than the average of similar papers that are not posted as preprints respectively (Metcalf, 2006).

Some researchers explored the possible causes of citation impact of preprints. Kurtz (2005) proposed three possible explanations: “Early Access (EA)”, “Self-selection Preference (SP)” and “Open Access (OA)”, and found there is no OA effect in astrophysics. Hajjem (2005) suggested that the SP was unlikely the merely or mostly factor for citation advantage of preprints, because that though the proportion of preprints in physics was much higher (and
even approaches 100% in some subfields), the citation advantage of them was still obvious. Moed (2007) found that in the field of condensed matter physics, the EA and SP factors were the main causes for the citation advantages of arXiv-deposited articles, and which was also supported by Kurtz (2007). All the studies discussed above are only directly applicable to a certain discipline, but less universal across all research fields, as citation behaviour and author attitudes to Preprint are cultural factors that differ across different fields (Brown, 2003; Zitt, 2005; Alma & Brown, 2005). Many researchers have repeatedly confirmed the citation advantage of arXiv-deposited papers in many disciplines (Davis, 2007; Moed, 2007; Mine, 2009; Xin Shuai, 2012; Larivière et al., 2014), but few researchers do it in the field of LIS or Robotics, and analyse the “drive” factor for authors submitting a post-preprint to arXiv by comparing the citation trend before and after being submitted to arXiv.

In order to explore the position of Preprint in scholarly communication, this paper makes a bibliometric and empirical analysis of the arXiv-deposited papers in LIS field and Robotics field, and focuses on the four aspects: the usage trend of arXiv; the time gap between submission time and publication time; mean citation frequency of arXiv-deposited papers and WoS papers and their citation trend by year in these two fields.

**Data source**

Information science & library science (LIS) and Robotics are selected for this exploring research. In the LIS field, there are 43 journals listed in the Q1 and Q2 JIF quartiles in the LIS category in JCR (2015), and 20 of them are deposited in arXiv. According to the amount of arXiv e-prints (Tab.1), the top 6 journals (the total amount account for over 92%) are selected for our research.

In the Robotics field, the journals (proceedings) are selected to research is on the base of robotics articles because there is no such an exact category in JCR. Top 10 journals are listed according to the amount of articles based on 58,799 robotics articles, which are retrieved by the query “WC=ROBOTICS” in WoS (2010-2017) (Tab.2), and the top 5 journals (proceedings) with large amount of preprints in arXiv (the total amount account for over 95% of all) are finally selected.

Results and Analysis

The increasing trend of arXiv-deposited papers

The proportion of arXiv-deposited papers in WoS is 2.17% and 0.27% in LIS and Robotics field respectively, which is much lower than the proportion of 18.7% in the physics field (Gentil-Beccot, 2010) and almost 100% in high-energy physics (Brody, 2006). This difference is understandable, because arXiv initiated in physics field (Brody, 2006). The amount of the arXiv-deposited papers is increasing generally in LIS and Robotics fields (Fig.1). The figure shows that the history of arXiv-deposited papers in Robotics is longer than in LIS, and the increasing trend of arXix-deposited papers in Robotics is more obvious than in LIS.
**Figure 1. The trend of submission time of arXiv-deposited papers**

*Time gap between arXiv submission year and journal publication year*

Most papers are submitted to arXiv and printed in journal in the same year in the two fields (Fig. 2). The preprints are divided into pre-prints and post-prints according to the order of submitted to arXiv and published in journal. In Fig. 2, the X-axis means the time gap between arXiv submission year and journal publication year and the Y-axis means the amount of Preprint papers. The result shows that the proportion of pre-prints and post-prints is 57.3% and 36.5% respectively in the LIS field and 47.4% and 41.4% respectively in the Robotics field. Most authors prefer to publish a pre-print in a journal or submit a post-preprint to arXiv within two years.

**Figure 2. Distribution of the time gap between arXiv submission and publication year**

a. the LIS field

b. the Robotics field
It should be noted that the amount of the preprints maybe underestimated because some article titles changed significantly enough to not be discoverable between their preprints and journal papers. In our research, the same articles are identified by matching on title, key words and abstract technically.

**Citation advantage of arXiv-deposited papers**

The potential impact advantage of the preprints has been a part of the wider Open Access debate (Harnad, 2004; Antelman, 2004; Metcalfe, 2004). The citation frequency per paper for arXiv-deposited papers and non-arXiv-deposited papers in WoS is counted respectively in LIS and Robotics field (Fig.3), which shows that the arXiv-deposited papers have the absolute citation advantage comparative to the non-arXiv-deposited papers. The citation advantage of arXiv–deposited papers in each journal is showed in Tab.3.

*Citation advantage= \((\text{citation frequency per arXiv-deposited} – \text{citation frequency per non-arXiv-deposited}) / \text{citation frequency per non-arXiv-deposited}\)"

**Citation trend of arXiv-deposited papers and WoS papers**

The citation trend of pre-prints, post-prints, highly-cited papers and WoS papers in the selected journals is showed respectively for LIS and Robotics field in Fig.4. Top 2% highly-cited LIS papers and top 1% highly-cited Robotics papers in each year are selected according to the proportion of preprints in these two fields. The X-axis represents the years after journal publication, and the Y-axis represents the citation frequency per paper in the corresponding year (the right Y-axis represents the mean citation frequency for the highly-cited papers).

![Citation trend in LIS and in Robotics](image)

**Figure 4.** Citation trend in LIS and in Robotics (wos-: all WoS papers in the selected journals; pre-: all pre-prints; post-: all post-prints; high-: highly-cited papers in the selected journals)
The citation trend of WoS papers shows upward in the first 3-4 years after journal publication, and then declines slowly in both the two fields. Comparatively, the citation trend of highly-cited papers shows a longer upward period and a quicker increase speed. The trends of pre-prints and post-prints are between the WoS papers and highly-cited papers, and fluctuating range of their citation curves is greater, which shows that preprints are more possible to be hot topics, which could attract more attention in a short time period. Comparing the citation trend of pre-prints with post-prints, in LIS, the pre-prints tend to be more cited than post-prints in general, while in Robotics, the situation is opposite in the first 3-5 years after journal publication, which could explain that why the proportion of pre-prints is larger than the post-prints in LIS, but opposite in Robotics to some extent.

It can be explained easier that authors submit a pre-print to arXiv before its journal publication, because pre-prints can give a longer period to be read and cited (Kurtz, 2005), and form citation advantage further. While, why the authors submit a post-print to arXiv? The relationship between the time period and the citation frequency of post-prints is benefit to this question. We set the arXiv submit time as the time division point, that is the ‘0’ on the X-axis, and investigate the citation trend of post-prints before and after they are submitted to arXiv respectively (Fig.5).

![Figure 5. The relationship between the citation and the interval time of post-prints](image)

In Figure 5, the X-axis represents the interval time between publishing a post-print in journal and submitting it to arXiv. For example, ‘-5’ means that the 5th years before submitting it to arXiv, and ‘1’ means the 1st year after submitting it to arXiv. The Y-axis represents the mean citation frequency per paper.

During the period that the authors haven’t submitted their journal papers to arXiv, the citation frequency of the post-prints increases at the rate of 0.186 and 0.063 in the field of LIS and Robotics respectively. However, it is clear that the citation frequency per paper increases faster at the rate of 0.253 and 0.457 after being submitted to arXiv respectively in the two fields. The results support that the arXiv platform could improve the citation frequency of the papers deposited in it, so some authors would still submit their journal papers to arXiv.
Conclusion and Discussion

There are different using patterns on the arXiv platform in the LIS field and Robotics field. The history of arXiv-deposited paper in Robotics is longer than in LIS, and the increasing trend of preprints in Robotics is more obvious than in LIS. The time gap distribution curves show that most authors prefer to publish a pre-print in a journal or submit a post-preprint to arXiv within two years.

In both fields, the citation advantage of arXiv-deposited papers is obvious. The citation trends of four kinds of papers—WoS papers, highly-cited papers, pre-prints and post-prints—show that the trends of pre-prints and post-prints are between the WoS papers and highly-cited papers, and fluctuating range of their citation curves is greater, indicating that preprints are more possible to be hot topics, which could attract more attention in a short time period.

The pre-prints tend to be more cited than post-prints in general in the LIS field, while the situation is opposite in the first 3-5 years after journal publication in the Robotics field, which could explain the proportion of pre-prints (57.3%) larger than the post-prints(36.5%) in LIS, but opposite in Robotics. The relationship between the time period and the citation frequency of post-prints represents that the mean citation frequency increases faster after being submitted to arXiv, so some authors would still submit their journal papers to arXiv.

All of the findings of this research indicate that the arXiv preprint archive has changed the scholarly communication patterns of the LIS and Robotics fields in a positive way. Though in these disciplines there is still a significant number of papers that are not on arXiv and the picture of ongoing changes in scholarly communication in a networked information environment is complex, the convenient, fast and high efficiency in scholarly communication through Preprint and citation advantage of preprints would prompt more authors to post preprints on the internet and these freely available papers would profit more researchers to have access to the newest research trend, which undoubtedly accelerates the process of scholarly communication and the knowledge innovation.

Our further study will extend to a wider perspective to explore the position of Preprint in scholarly communication in more disciplines, and other preprint archives such as E-LIS (the largest international open repository in the field of Library and Information Science) and ChinaXiv will also be the research objects.

Abstract
On the basis of the integration of citation indexes, the traditional h-index, and the quantitative index of times cited, this paper proposes a comprehensive and comparative approach to analyze the influence of academic exchange, the diffusion of knowledge, and the contribution influence among authors. It integrates citation analysis, social network analysis, principal component analysis, entropy weight method, and Skyline operator from an integrated and comparative perspective of three-dimensional citation (author co-citation, author bibliographic coupling, and author cross-citation). Further, using the above idea, we conduct an exploratory research to find the scholars with comprehensive influence in the field of gene editing. The results were found to correspond well with the actual situation. Under the introduction of a weighted direct citation index, more important contributors to knowledge exchange and communication in this field were identified.

Conference Topic
Citation and co-citation analysis

Introduction
Research on scholars’ academic influence evaluation has been conducted for a long time. Scientific and effective evaluation of academic influence is essential both in terms of its basic function (e.g., motivating, guiding, and regulating) and specific application (e.g., performance appraisal, resource allocation, and talent introduction). The application of the information metrology theory and method in the academic influence evaluation, especially the use of citation analysis in traditional bibliometrics, has been a popular topic in the academic field. Especially since E. Garfield created the citation index and proposed the journal impact factor index, research workers and scientific research management personnel from various disciplines have begun directly or indirectly evaluating scholars’ academic influence by examining factors such as the number of papers published, cited frequency, h-index or its derivative index (Alonso, 2010), and journal impact factor. However, after the “San Francisco
Declaration on Research Assessment” and “Leiden manifesto” proposals, “make scientific research evaluation more scientific” has become a widely-discussed topic in recent years. The following are two core points:

1. Since impact factor is unsuitable for the evaluation of individual contributions, which or which group of quantitative indicators can replace it?

2. Since single indicator evaluation of academic influence is biased, how can various indicators be compared and integrated to make them more scientific and reasonable?

This paper aims to explore the optimization and comprehensive use of core quantitative indicators other than the impact factor and also focuses on the comparison and fusion of citation network indexes.

There are three main types of author associated relations based on the citation level: author co-citation, author bibliographic coupling, and author direct/cross citation. Each of the three kinds of citation analyses has unique applicability and emphasizes on revealing scholars’ academic association and reflecting their academic influence. The author co-citation network is mainly used to reveal core authors’ academic contribution; the author bibliographic coupling network mainly reveals the influence of the current research activity; and the author direct/cross-citation analysis indicates the inner link between authors while dynamically revealing the influence of knowledge exchange and diffusion. Therefore, it is necessary to compare the results of the three analyses and then make a comprehensive measurement with the integration of the three-dimensional citation network, which is the first major topic of this study.

Despite the controversy over applying simple bibliometric indicators in scientific evaluation, it is undeniable that the citation frequency, the $h$-index, and other factors are still indispensable quantitative indicators when evaluating academic influence. Considering the differences between the evaluation indexes and to avoid the disadvantages of using a single index evaluation, numerous researchers (Moed, 2014; Sidiropoulos, 2016) proposed the idea of comprehensive evaluation. However, research on the comprehensive evaluation of three types of citation network indicators and traditional quantitative indicators is still sporadic, which is the second major topic of this study.

Data and methodology

Basic Data

The field of gene editing emerged in the early 1980s. In the past 10 years, especially since the advent of CRISPR/Cas9 (clustered regulatory interspaced short palindromic repeats/CRISPR-associated protein 9) technology, it has become a popular topic globally. Therefore, the data for this study comprise a set of downloaded records retrieved from Web of Science with “gene edit*” or “CRISPR” as the keywords, covering four types of documents (articles, proceeding papers, reviews, and book reviews). The period covered is from 1980 to 2015. Due to name disambiguation, we manually used authors’ full name and the information of their organization to identify complete author names. Finally, we selected 111 authors whose $h$-index was more than five and papers published amounted to more than 10 as core authors in this field, that is, the research subject of this paper.
Methodologies

Compared with co-citation and bibliographic coupling, direct citation is a direct citing relation without a third-party paper. In this paper, we refer to the weighted direct citations (WDC) proposed by Persson (2010). WDC integrates direct citations strength with weighted co-citations strength and weighted bibliographic coupling strength into a new citation strength. Normalized weighted direct citation (NWDC) is further obtained by normalizing co-citation and bibliographic coupling citation strengths. However, the difference is that the WDC proposed by Persson is demonstrated and applied at the literature level while in this paper it will be applied at the author level. As the author relation is generally based on a specific set of documents, the process is relatively more complex. The principle of the algorithm is depicted in Figure 1, in which the coupling and co-citation frequencies are calculated using the minimum value (Wang, 2014).

![Figure 1. Principle diagram of author weighted direct citation](image)

In Figure 1, $l$ represents the number of times author B is cited by author A; $c$ represents the minimum number of times author A and author B are citing document C (i.e., the coupling frequency of A and B to the citation of C); $m$ represents the total cited frequency of document C; $d$ represents the minimum number of times author A and author B are cited in document D; and $n$ represents the total number of references in document D. In the citation relation depicted in Figure 1, the WDC value of author A and author B is $l + c + d$ and the NWDC value is $l + c/m + d/n$. The Visual Basic for Applications (VBA) program in Excel can process all types of citation analysis data. VBA is a macro language for Visual Basic that Microsoft has developed to perform generic automation (OLE) tasks in its desktop applications.

The $h$-degree of nodes (Zhao, 2011) means that a node has at the most $h$ links in the weighted network, the weight of which is not less than $h$. Hence, it not only considers the number of adjacent nodes but also the strength of the link. Considering this, this paper selects $h$-degree to measure scholars’ comprehensive influence for a single citation network. Due to the difference in characteristics of the core author index, this paper adopts the principal component analysis (PCA) method, the entropy weight method, and Skyline operator (Sidiropoulos, 2016) to measure core scholars’ influence.

The $h$-degree of nodes (Zhao, 2011) means that a node has at the most $h$ links in the weighted network, the weight of which is not less than $h$. Hence, it not only considers the number of adjacent nodes but also the strength of the link. Considering this, this paper selects $h$-degree to measure scholars’ comprehensive influence for a single citation network. However, considering the change of calculation process and network attributes in the integrated network, the paper adopts the centrality indicators to measure the influence of scholars. Based on the idea that the importance of the node not only depends on the number of its neighbor nodes but also the importance of the neighbor nodes, this paper selects in-degree, out-degree, and eigenvector
centrality to measure scholars’ influence in the integrated network. Degree centrality reveals the citing and cited concentration degree intuitively. The eigenvector centrality reflects the author’s own importance by the importance of the associated author. In addition to the above-mentioned citation network indicators, four traditional quantitative indicators (the number of publications, $h$-index, total number of citations, and average cited frequency) are also included in the study, to evaluate scholars’ influence from academic contribution and academic influence two aspects. Due to the difference in characteristics of the core author index, this paper adopts the principal component analysis (PCA) method, the entropy weight method, and Skyline operator (Sidiropoulos, 2016) to measure core scholars’ influence.

Results and discussion

To begin with, the author co-citation matrix, author bibliographic coupling matrix, and author direct citation matrix of core authors in the gene editing field are all established. Next, we adopt the NWDC network (see Figure 2) to measure core authors’ comprehensive influence in three-dimensional citations. The visual analytics examines using Ucinet. To visualize more clearly, we set the threshold to 0.1. As depicted in Figure 2, the overall structure of the NWDC network is divided into two major categories. The lower left network contains lesser nodes but is dense, whereas the upper right has more nodes but is sparse.

![Figure 2. NWDC network](image)

Since the core author direct citation network belongs to the weighted directed network, the NWDC network is also the weighted directed network. Therefore, we choose NWDC network in-degree and out-degree as two indicators to measure core author influence. As shown in Table 1, authors such as Makarova KS, Marraffini LA, and Wiedenheft B are the most cited while those such as Barrangou R, Westra ER, and Makarova KS are the most citing.

</table>
Finally, 10 indicators are considered in the comprehensive evaluation system of core authors’ influence. They include the single network measure index (direct citation $h$-degree, co-citation $h$-degree, and coupling $h$-degree), the integrated network measure index (NWDC in-degree, NWDC out-degree, and NWDC eigenvector centrality), and the traditional quantitative index (number of publications, $h$-index, total number of citations, and average cited frequency). However, to some extent, all indicators may reflect overlapping information. It is difficult to objectively evaluate the core authors’ influence directly by using the above indicators. Therefore, the PCA method is used to reduce the dimension of these evaluation indexes, and a few independent indexes (principal components) are obtained. The results of the total variance reveal that the initial eigenvalue of the three components is greater than 1, and the cumulative variance is up to 87.543%. Furthermore, in combination with the gravel plot, the number of principal components is set to 3. In addition, the component load matrix results after orthogonal rotation (as shown in Table 2) show that direct citation $h$-degree, co-citation $h$-degree, coupling $h$-degree, NWDC in-degree, NWDC out-degree, and NWDC eigenvector centrality are closely related to principal component 1; the number of publications and $h$-index are highly correlated with principal component 2; and the total number of citations and average cited frequency are closely related to principal component 3. Simultaneously, the indexes contained in principal component 1 are found to be mainly citation network indexes, which are used to measure scholars’ knowledge exchange and communication in this field; those contained in principal component 2 are mainly paper number indexes, reflecting scholars’ academic contribution; those in principal component 3, are citation quality indexes, reflecting scholars’ academic influence.

According to the score coefficient matrix, we can obtain scores of the three principal components for each core author. After the orthogonal rotation transformation, the three comprehensive indicators are independent of each other and
reveal scholars’ knowledge diffusion and control, academic contribution, and academic influence, respectively. To reveal scholars’ academic influence comprehensively, first use the three principal components as independent indicators of the Skyline operator to identify the Skyline set, that is, 12 outstanding comprehensive influential scholars (see Table 3).

However, ranking is inevitable in scientific evaluation. Although the Skyline operator can select outstanding scholars, it cannot provide their objective ranking. Therefore, to further test the effectiveness of the Skyline operator and obtain the ranking, this paper calculates the weight of each principal component by using the entropy weight method; thus, it obtains each author’s influence score through the standardized data. The top 12 authors are shown in Table 3. In contrast, the outstanding scholars obtained using the Skyline operator and the objective weighting method are found to be broadly consistent, especially for the extremely excellent scholars. It also proves the comprehensiveness and effectiveness of the Skyline operator.

**Conclusions**

In this paper, 17 scholars with outstanding influence in the gene editing field are identified using the objective weighting method and the Skyline operator, which corresponds with promoters’ actual situation in gene editing, especially that of CRISPR technology. Meanwhile, some differences are observed between the scholars selected by the two methods. For example, Zhang F et al., without high citation network index scores but having certain influence, cannot be effectively identified using the entropy weight method. Therefore, it is necessary to combine the two methods when selecting outstanding scholars. It is worth noting that more outstanding scholars are identified, such as Makarova KS, Marraffini LA, Horvath P, van der Oost J, and Wiedenheft B, in the introduction of the citation network indexes. Although they are not prominent in the traditional evaluation indexes, they have played an important role in the promotion of knowledge exchange and communication, and their academic contribution and influence should not be ignored. The results also suggest
that citation network indexes are effective supplements to comprehensive influence measurement that use only traditional indicators.

Abstract
This study examines the social web presence of NIH groundbreaking research to discover to what extent the articles have been discussed on the social web, in general, and what type of users and networks are shaped around them on Twitter, in particular. Both altmetric (including tweet counts, Facebook posts, blog and news posts and Wiki citations) and citation counts of articles were examined and a moderate correlation was found between citation counts and altmetric counts. Altmetric indicators correlate more strongly with each other and the highest correlation was found between tweet counts and Facebook post counts. 58% of tweets about the NIH articles are posted by scientists and individual citizens (the general public) and the scientists are the major group tend to tweet these articles for the first time. The general public is mainly interested in tweeting the NIH research on promising medical advances. The retweet network shaped around NIH research was also investigated in order to determine the networking and connections between different type of users and indicate who originate the tweets and who retweet them more; the results show that scientists and citizens are the major groups retweeting the posts originated by other users. Citizens and practitioners were found to have strong networks and they widely retweet each other’s posts.

Conference Topic
Altmetrics

Introduction
Research diffusion mainly has three aspects: research flow from one scientific area to other areas; scientific knowledge dissemination from the academic community to the industry; and research spreading from the academic to the public. Knowledge diffusion could be considered as a signal of innovation where research outcomes applied to industrial production. The diffusion of research from the academic to the public has a more complicated process for different reasons; the general public may not be interested in academic research outputs as they find them too technical to understand; and the research community may not pay much attention to produce or report their outputs in a layman language. However, the public engagement in research outputs has gained increasing attention recently and new methods and tools are proposed to investigate to what extent and how research produced by academia influence the general public. Altmetrics are alternative indicators derived from
the social web platforms that have been proposed to give immediate impact evidence and to help assess the contributions of science to society beyond the scientific community (Priem, Taraborelli, Groth, & Neylon, 2011). Tweet count linking to articles on Twitter is a prominent altmetric indicator showing an immediate impact (Thelwall, Haustein, Larivière, & Sugimoto, 2013). Despite the increasing number of research on altmetrics especially tweet mentions, some questions have yet remained unanswered about the quality and reliability of such platforms in measuring the influence of research outputs on different parts of a society; for example, what type of research is grabbing a higher attention on Twitter? how is research disseminated or discussed on this platform? or who are acting around research articles on Twitter? Although the general public is assumed to be the main active group (Haustein, Tsou, Minik, Brinson, Hayes, Costas, & Sugimoto, 2016), tweets about research may primarily originate from scholars and serve to publicize, rather than discuss, recent research (Thelwall, Tsou, Weingart, Holmberg, & Haustein, 2013).

Scientists are devoting an enormous amount of time and energy to find solutions for problems raised and scientific breakthroughs are increasingly developing to solve the world’s problems. Medical breakthroughs are the most prominent discoveries as they aim at an important aspect of each society i.e. health. The National Institute of Health (NIH) is a primary agency for medical and biomedical research in the United States and the largest public funding body in the world supporting research projects. The agency is investing more than $32 billions a year in the biomedical and health research projects aiming at enhancing life and reducing illness and disability. Research funded by NIH is categorised into three groups: clinical advances in prevention, diagnosis, and treatment of human disease; promising medical advances i.e. potential findings for enhancing human health; and insights from the lab i.e. noteworthy advances in basic research1. NIH research in these categories has led to advancements and breakthroughs in helping people live longer and healthier and they have received top scientific awards like Nobel Prizes; but the question is that are there any societal interactions occurring around these research outputs? To what extent scientific breakthroughs succeed to reach the public attention and solve their problems?

How research is influencing different aspects of society has recently grabbed the attention of research policy makers and funders. Researchers at universities have traditionally been assessed through their research productivity and citation impact but they are or will be also assessed whether their research outputs have any influence on the society and different aspects of it. These are urging scholars to engage in public engagement and social outreach. Altmetric platforms such as Twitter may help to partly answer the questions above through investigating the research disseminated and distributed on Twitter and whether the breakthroughs in science are also important to the general public. Altmetric.com provides information on Twitter user types and categorises users into four groups of ‘member of the public’, ‘practitioner’, ‘science communicator’ and ‘scientist’ but their data has some limitations as through a manual checking, majority of users identified as a member of the public in Altmetric.com are found to be a member of the academia (Tsou, Bowman, Ghazinejad, & Sugimoto, 2015). Few altmetric research addressed this issue and investigated tweeter types through manual checking but their findings vary due to various methods and user classifications used to identify tweeters. A research on 15 top tweeted Finnish articles classified tweeters into 17 categories and reported a high percentage of health care professionals in Medical and Health Sciences, and a high percentage of businessmen? in Social Sciences and Humanities (Vainio & Holmberg, 2017). Another investigation of a random sample of 200 users tweeting research articles classified the users into four groups of ‘brokers’, ‘orators’, ‘broadcasters’ and ‘numblers’ based on two criteria: engagement (tweet content whether it only contains article title or any extra text) and exposure (number of followers). The users were also identified to be an individual or an organisation in each of above

---

categories and the results showed that 68% of the users were individuals (Haustein et al., 2016). But there is no previous study examined the visibility of and interactions around medical research breakthroughs on the social web which is the main focus of current study. This study collects a number of research articles published from the groundbreaking NIH-funded projects and trace them on Twitter to discover to what extent and by whom the articles have been discussed on the platform. The citations to the mentioned articles were collected from the Web of Science (WoS) to compare with tweet counts, Facebook posts, news posts, blog posts, and Wikipedia posts. The main research objective is to investigate to what extent medical research advancements and breakthroughs are discussed on the social web and among the general public acting on Twitter. To reach this goal, two main questions are answered:

1. To what extent is NIH funded research mentioned on different social web platforms versus citation platforms?
2. Which type of users are interacting and engaging around NIH funded research on Twitter? Are they mainly from the public? And who is bringing this research up to Twitter for the first time?
3. Who are the retweeters? Who retweets the tweets posted by scientists or citizens or any other type of users?

Methods
All articles from the three NIH categories including (1) clinical advances in prevention, diagnosis, and treatment of human disease, (2) promising medical advances i.e. findings with potential for enhancing human health, and (3) insights from the lab i.e. noteworthy advances in basic research were retrieved from 2012-2015 accounting for 133 papers, out of which 107 had a DOI. Some articles were classified into two or more categories; so, 37 articles were classified into the first category, 73 articles into the second and 62 articles into the third category. Then, the DOIs were matched with Altmetric.com dataset (last updated version, June 2016) and a number of 16,345 tweets were obtained for all the 107 articles. Author description field of each tweet was extracted from the dataset for further analysis. Altmetric.com provides user types in four groups of ‘member of the public’, ‘practitioner’, ‘science communicator’ and ‘scientist’ but their method to identify user types has some limitations that have been pointed out in previous research; majority of users identified as a member of public by Altmetric.com are actually found to be individual researchers (Tsou, Bowman, Ghazinejad, & Sugimoto, 2015). Moreover, a Twitter account with a blank bio is categorized under ‘public’ rather than ‘unknown’ (Altmetric.com). Hence, six different types of users were designated for this research and each tweet in the dataset was manually checked for its Twitter account to be an/a: individual scientist, individual citizen (a member of the public), organisation, journals/publishers, practitioner, or Blank or other. The results of manual checking for user types was compared with that of Altmetric.com. As seen in Table 1, more than 82% of tweets in each NIH category were found to be a member of the public while individual scientists are the major group tweeting NIH research in all three categories based on the results from manual checking (Table 4). Other altmetric counts including Facebook mentions, blog posts, news posts and Wiki citations were also retrieved from Altmetric.com. The citation counts to articles were obtained from the in-house version of the Web of Science (WoS) provided by Leiden University. The July-2016 version of WoS was used to give both citation and altmetric counts the same time window.

Results

To what extent is NIH funded research visible on different social web platforms versus citation platforms?

Different social web platforms including Twitter, Facebook, news outlets, blogs, and Wikipedia were examined for mentions of NIH research articles. WoS was also gauged for the signs of scientific impact. As seen in Table 2, NIH research was highly cited (226.2 citations per article on average) and they were also highly tweeted with an average of 178.3 tweets per article. The research had an average of 21.7 news posts, 15.4 Facebook posts and 9 blog posts but they were scarcely cited in Wikipedia. The correlation between citation counts and each of altmetric counts is tested. The results show that number of citations moderately correlate with all altmetric indicators. Number of tweets strongly correlate with the number of Facebook, news and blog posts. Facebook posts are in a strong correlation with news and blog posts and moderately correlate with the number of wiki citations. Number of news posts also strongly correlate with the number of blog posts (Table 3). Across the NIH categories, research that received the highest number of tweets, Facebook posts, news posts and blog posts, were less cited. The results show that research in clinical advances (prevention, diagnosis, and treatment of human disease) had the highest mentions on Twitter, Facebook, news and blogs but they were least cited compared to that of the other two categories. Wikipedia citations positively correlate with WoS citation counts (Table 4).

Which type of users are interacting and engaging around NIH funded research on Twitter? Are they mainly from the public? And who is bringing this research up to Twitter for the first time?
The 16,345 tweets made to the NIH articles were considered to be manually checked in terms of their users and their results are presented in Tables 5-7. The results showed that in the entire dataset, around 33% of tweets were made by individual scientists. Individual citizens are the second major group posting 25.17% of the tweets and practitioners that are mainly health care professionals and biologists made 13.67% of the tweets to NIH research articles. Journals/publishers tweeted the lowest tweets and had the least contribution (5.87%) (Table 5). Across the three NIH categories, quite the same pattern is observed as around 30% of tweets in category 1, 35% in category 2, and 38% in category 3 are posted by individual scientists. The second major group is also citizens across all three categories (Table 6).
The type of users tweeted research articles for the first time was also examined. The findings showed that more than 40% of articles were tweeted by scientists for the first time. 22% of the articles were also tweeted by journals/publishers for the first time and more than 10% were tweeted first by citizens (Table 7).

Who are the retweeters? Who retweets the tweets posted by scientists or citizens or any other type of users?

The aim is to investigate the network of retweeters for each type of users on Twitter. The results show that 58% of tweets posted by individual citizens are retweeted by citizens. Interestingly, 17% of tweets from citizens are retweeted by scientists and also another 17% by practitioners. Tweets originated by scientists are mainly retweeted by other scientists (45%). 31% of scientists’ tweets are retweeted by citizens. Citizens are the main group retweeting the tweets originated by practitioners (36% of practitioners’ tweets are retweeted by citizens). The tweets originated by journals/publishers are mainly retweeted by scientists (40%) and then citizens (26%). Tweets by organizations are equally retweeted by scientists and citizens (each group retweeted 35% organization’s tweets) (See Figures 1-5). The contribution of citizens in retweeting other tweets is very high which shows that they mainly play their role as a re-distributer and not the main disseminator.

Figure 1. Users who retweet citizens’ tweets

Figure 2. Users who retweet scientists’ tweets
The tweet and retweet networks of the most tweeted article in the dataset

In this section, the most tweeted publication in the dataset functions as an example for conducting an in-depth analysis, which could contribute to understand and examine the role of individual citizens in the discussion of an important medical publication.

The publication tweeted the most is entitled ‘Nurse staffing and education and hospital mortality in nine European countries’, which was published in Lancet, 2014. The paper belongs to the first NIH category, showing that it holds significant promising medical advances. The paper analyzed the relations of nurses’ workloads and the likelihood of patient death and suggesting ‘patient deaths in hospital might be reduced by easing nurses’ workloads and emphasizing education in hiring’. This paper received around 2,200 tweets, which is 12 times more than the number of citations it received. The reason that this paper attracted a high attention on Twitter might be that the paper’s topic is not extremely difficult for non-professionals to understand, and is so relevant to public health. Analyzing users who tweet this paper showed that individual citizens posted most tweets around this paper, accounting for 28% of users, followed by practitioners (26% of total tweets were originated by them). The results show that general public actively participated in the scientific communication around this paper.

For more information about this paper, see: https://www.nih.gov/news-events/nih-research-matters/nurse-staffing-education-affect-patient-safety.
To examine the role of individual citizens in acting around this paper on Twitter, the original tweets and their retweets were investigated. The results show that around 32%, 28% and 19% of tweets originated by scientists, practitioners, and organizations. This result is plausible because both scientists and practitioners are more likely to follow and monitor the development of scientific research. Hence, they may be informed of new and promising publications faster than the public. Individual citizens are the fourth group originating tweets about this paper (Table 8) but they are the major group retweeting the original tweets posted about this article (Table 9), showing that they follow what scientists and practitioners tweet and that they are mainly inclined to retweet their tweets. While scientists, journals/publishers and organizations are the main disseminators of research on Twitter, citizens mainly follow and re-distribute what posted by other users. The top five tweeters who originated tweets about this paper were an organization account, a journal/publisher account and three scientists. The tweets by these five original tweeters were retweeted between 32-84 times. The high retweets could be because of the number of followers that organizations and journals/publishers have that their posts are retweeted more frequently than the other users. Tweets originated by citizens were not retweeted much, showing that other users are not interested in the research shared by this group.

Discussions and conclusion
Twitter seems a primary social web to spread academic research and the NIH groundbreaking articles are highly mentioned on this platform compared to the other social web platforms. The articles even received more citations than tweet counts and while they were cited 226.2 times on average, they were tweeted 178.3 times on average. Twitter intensity of NIH articles is 5 times higher than that of reported in Didegah, Mejlggaard, and Sorensen (in press) for a sample of random articles in biomedical and health research (34.3 tweets per article). The NIH research received 15.4 mentions on Facebook, 21.7 mentions in blogs, and 9 mentions in news on average but they have been very rarely cited in Wikipedia. Previous research also shows higher counts of tweets to research articles than the other social web mentions (Thelwall, Haustein, Larivière, & Sugimoto, 2013). A moderate correlation was found between number of citations and altmetric counts. However, altmetric indicators highly correlate with each other and the highest correlation was found between number of tweets and number of Facebook posts. The citation and altmetric counts to articles vary across NIH categories. The articles representing clinical advances in prevention, diagnosis, and treatment of human disease are more mentioned on the social web and the articles representing insights from the lab are mentioned the least. This is vice versa for citations, as the articles disseminating the insights from the lab are more cited than the articles representing clinical advances and also promising medical advances. This may show that the social web users are more interested in the clinical advances in prevention, diagnosis, and treatment of human disease, while scientific community tends to cite the lab insights. The type of users tweeting the articles showed that well above 58% of tweets of the articles were posted by scientists and the lay people, respectively. Practitioners contributed to 13.7% of tweets posted about the articles. Two recent research showed that medical research is majorly tweeted by practitioners (Vainio & Holmberg, 2017; Didegah, Mejlggaard, & Sorensen, in press). The difference may be due to different samples used; while groundbreaking articles among the medical research community are the focus of this study, both previous studies examined samples of highly tweeted medical articles. Journals and publishers are the minor group tweeting articles (they only did 6% of tweets). Scientists are the major group tweeting articles from all three NIH categories also. The high average of citations per article may be a consequence of high activities around the articles on Twitter by the scientists. Interestingly, the second major group tweeting articles on promising medical advances is individual citizens while the second major group tweeting articles on clinical advances and lab insights are practitioners, showing a public interest in the articles on the promising medical advances. The individual scientists are also the first group tweeting the NIH groundbreaking articles. Some of these scientists may probably be the authors of the articles publicizing their research on Twitter right after publication. About 22% of tweets were posted by journals/publishers for the first time. Around 56% of the NIH groundbreaking articles are published in Nature and Science, respectively. These two journals have active Twitter accounts and tweet their recent articles frequently. This may show the role of journals activities on the social web in informing their recently published articles online.

The retweet network shows that scientists and citizens are the major groups retweeting the tweets originated by the other users. Citizens are the major group retweeting the posts originated by practitioners and practitioners are also the main group retweeting the tweets by citizens which shows the strong connection between these two groups on Twitter in sharing research publications. Furthermore, the citizens who are interested in practitioners’ tweets and take an action and retweet their posts could be mainly among patients. This shows that practitioners and patients are widely following each other and have strong networking on Twitter.

The high engagement of citizens in acting around NIH research breakthroughs may be because first, these papers are written in a language that is understandable for lay people and second, the topics and problems discussed are of a public interest.
In short, medical breakthroughs identified through NIH groundbreaking funded research are widely mentioned on Twitter. The articles are also highly cited; an external factor that positively contributed to high citations of these articles could be that the articles are highly tweeted by scientists and also that these articles are mentioned on Twitter for the first time by the scientists. The lay people also showed a wide interest in acting around the NIH research on Twitter and they are mainly interested in the research on the promising medical advances. In the next phase of this study, the tweets about the NIH research will be further investigated through a content analysis in order to identify what the users are saying about these articles and how deeply they are engaging in the articles content and results.

Neologisms and affiliation name: a bibliometric perspective on the institutionalization of interventional radiology.

Philippe Gorry

philippe.gorry@u-bordeaux.fr

Abstract
Delimitation of scientific subfields constitutes one of the key problems in scientometrics. De Bruin and Moed (1993) suggested that “corporate address words” or word co-occurrence in affiliation field could be used. In science, researchers construct knowledge through neologisms. Studies of new scientific concepts indicated us new trends on naming institutions with neologisms. Therefore, one can postulate that neologisms are markers of emerging scientific field, and naming institution after neologisms could be part of a legitimation process. The aim of this paper is to explore this hypothesis through the bibliometric analysis of one case study related to the diffusion process of the concept of "interventional radiology" (IR). The study of the history of IR concept and its trends using affiliation addresses allows us to better understand how IR field has attempted to institutionalize and to gain its autonomy. Several institutions publishing in the field of IR have undertaken a legitimization process by entitling department "interventional radiology", but the specialty has partially or internationally failed to gain its scientific autonomy. In conclusion, measuring the trend of newly named institutions after a neologism can be used to assess the degree of institutionalization for a new medical or scientific field.

Science of science

Introduction
Affiliation name, neologism and institutionalization
Delimitation of scientific subfields constitutes one of the key problems in bibliometrics. Several methods have been proposed based on indexing systems, co-citation and co-word analysis. De Bruin and Moed suggested in 1993 that “corporate address words” are words referring to scientific (sub)fields and then, can be used to delimitate research field. However, since his pioneering work on corporate addresses in publications with the study of words co-occurrence in the affiliation field, his idea didn’t receive much attention in the bibliometric literature with the exception of the literature on the affiliation disambiguation problem and institutions ranking. The limitation of this approach is that the affiliation addresses don’t contain cognitive words with high frequency, beside words such as university, faculty, mathematics or biology for examples. However, science and technology are producing a plethora of new words or neologisms (Fernandez-Silva, 2016). A neologism is a word term, or phrase which has been recently coined to apply to new concept or to make older terminology more contemporary. In science, researchers construct knowledge through term formation, and used them as rhetorical device in scientific papers, especially at a time when scientific understanding is exploding, producing entirely new scientific field (Pecman, 2014).
Preliminary results of ongoing scientometric analysis on the study of the career of concepts such has “health technology assessment” (Benoit & Gorry, 2017) or “regenerative medicine” (Kawecki & Gorry, 2015) indicated us new trends on naming institution with neologism related to these emerging medical or scientific fields. Therefore, one can postulate that neologisms are markers of emerging scientific field, and naming institution after neologisms could be part of a legitimation process of new research field. Legitimation or legitimacy refer in social sciences to the process of making something normative in the society. It's a public search for a social identity becomes widespread in a group whenever the status of new scientific field has yet to win acceptance or is under attack (Merton, 1973).
The aim of this paper is to explore this hypothesis through the bibliometric study of the capture of one neologism in affiliation address. This new bibliometric indicator could be seen as a measure of the degree of institutionalization (Raina & Gupta, 1988).

Case study
Interventional radiology (IR) was born in the 1960s, but its institutional recognition was late and incomplete. IR is still the subject of turf wars between different medical disciplines and it is not clear if this field will one day become an independent medical specialty (Rosch, 2003). The aim of this study is to analyze the diffusion process of the concept of IR using a scientometric approach. The study of the history of this concept and its trends allows us to better understand how this medical field has attempted to institutionalize and to gain its autonomy. The term “interventional radiology” is widely used by many individuals, academic institutions, professional bodies, and funding organizations. It has become an accepted neologism despite the lack of an agreed upon clear or precise definition (Mignot & Gorry, unpublished results).

Method
A literature search on “interventional radiology” concept was conducted in PubMed database. First, a search query was conducted with the medical subject heading (MeSH) “radiology, interventional” as well complementary terms such as “interventional magnetic resonance imaging”, “interventional radiography”, and “interventional ultrasonography”. But the MeSH was not sensitive enough: while the term of “interventional radiology” was first connoted by Wallace in 1976, it was only referenced in the thesaurus in 1990. Therefore, all the keyword strings were associated with a disjunction boolean operator, and searched within the title or abstracts fields. In order to control the validity of the obtained corpus, we tested the occurrence of the concepts in the documents. Unsurprisingly, “coronary angiography”, “angioplasty”, “catheter”, that define IR field very well, were the most recurrent terms. Therefore, the publications corpus was closely related to the “Interventional radiology” field. A corpus of 26655 documents in all types of records were harvested through 31 December 2014. Second, a search query was conducted within the affiliation field with the term “interventional radiology”. A second corpus of 6616 publications were harvested through 31 December 2014. Both corpus was extracted from Pubmed® database and imported, parsed and disambiguated for author and affiliation names with the help of Intellixir®, a statistical content analysis and text mining software-as service (SaaS) in order to build an in-house database (Gorry & Ragouet, 2016). The disambiguation, is based on a lexical similarity approach with a three-gram based splitting technique. During a first step, the SaaS automatically disambiguate institution names in affiliation field with a similarity score higher than 90%; at the end, a post-processing step allow the investigator to manually aggregate or not the remaining affiliation data. Then, we analysed the resulting corpus by conducting descriptive statistics analysis and drawing choropleth map using Intellixir® (Benoit & Gorry, 2017). Thus, we were able to examine the history of the concept, identify the actors involved in IR (authors, journals, institutions and countries) and understand the institutionalization of this medical field.

Result
Analysis of “interventional radiology” concept through keywords, abstract and MeSH
The data obtained were first organized to build a timescale, corresponding to the growth of publications referring to “interventional radiology” for the period retained (Fig. 1). While interventional radiology is born with the invention of angioplasty by Dotter in 1964 (Gorry & Ragouet, 2016), Pubmed® recognize a first publication titled “Interventional radiology”
published by Wallace in 1976. The temporal distribution of publications suggests a peripheral status of interventional radiology in the literature until a turning point in the late 1980’s. From that time, the growth of the publications has become exponential, and reached more than 2000 articles in 2010. Four general steps can be dissociated on the curve: 1976-1987, 1987-1992, 1992-2001, & 2001-2014. It can be seen that the occurrences of the concept in the literature did not significantly progressed until 1992. Then, after a period of growth, the use of the concept step down. Since 2001, the term use at a faster growth rate reflecting a new step.

**Figure 1. Trend of publications referring to “interventional radiology”**.

![Graph showing the trend of publications referring to “interventional radiology”](image)

**Analysis of “interventional radiology” concept through affiliation field**

Among the corpus of documents harvested through the use of “interventional radiology” in the affiliation field, we identified 100 different institutions after disambiguation. During the same period, the number of new institutions publishing in the IR field, regardless of their denomination, was 754. The first publishing institution with affiliation entitled with “interventional radiology” term appeared in 1987: it was the Department of Radiology, Angiography and Interventional Radiology at Brigham and Women's Hospital (US).

**Figure 2. Trends of new institution entitled “interventional radiology”**.

![Graph showing the trends of new institution entitled “interventional radiology”](image)
Then, the number of new institution entitled “interventional radiology” year after year was measured (Fig. 2). The number of new IR named institution reached a maximum (n=10) in 2001 and followed a rapid decline with only one new IR named institution in 2013 (Fig. 2: black box). In parallel, one can visualize through the measure of the cumulated IR name institution number that this phenomenon is reaching a plateau (Fig. 2: dashed line). These trends parallel, with a time lag, that of new institutions publishing in the IR field with a maximum (n=71) in 1994, and a rapid decline thereafter (data not show).

Figure 3. World distribution of institutions entitled “interventional radiology” by country.

The contribution of different countries to this trend to name institution after “interventional radiology” was estimated by the location of the IR affiliated institutions with at least one publication in the field of IR, and the top countries were ranked by percentage of IR publications over the total IR publications number (n=6616). As shown in the pie chart (Fig. 3), USA rank first with 34% of IR publications, Germany published the second-highest number of total publications with 15%, followed by China, Italy, and Japan. Out of the 20 top countries, two were emerging economies, China and Turkey. This distribution should be compare to the one for IR publication field as a whole whether the institutions are titled or not with IR (Mignot, L. & Gorry, P. unpublished results).

Figure 4. World map of institution entitled “interventional radiology”.
A cartographic analysis of spatial distribution of “interventional radiology” named institutions allowed us to get a better visualization of the geographic distribution based on the zip code information, independent of the ratio of IR publication by institution (Fig. 4). The comparison of geographical trends concerning the use of “interventional radiology” term in affiliation confirms the important number of IR named institutions in the top countries, but also reveals the implantation of such IR named institutions in many countries around the world except for Africa, including developing countries such as Brazil, India, Russia, …

Finally, we looked at the scientific productivity of the institution named after “interventional radiology” by measuring the number of publications referring to IR term as keyword (Table 1). The ranking of the top IR named institution shows that the most productive institutions were Duisburg-Essen University, followed by the Frankfurt University, and then by the University of Chicago. Then, the first IR named institution by country is reported. We identified among the top 20 IR named institution, department of radiology belonging to university and/or hospital in the main countries (Germany, USA, China) but also in Honk Kong, Austria or Croatia. However, the ranking of these IR named institutions should be relativized by looking at their ranking in the whole corpus of IR publications (Table 1: column Rank IR publication). Some discrepancy could be observed especially in the case of the Sha Tin University or the Zagreb University. Indeed, top institutions publishing IR related articles are not titled after IR term.

Discussion

The promotion of the concept of "interventional radiology" and the attempt of institutionalization of a disciplinary identity has taken place several years after the first medical developments of the specialty. This is confirmed by the dynamic of scientific publications. However, its institutional recognition was late and incomplete. To this day, interventional radiology remains a heterogeneous field with unstable borders. All of these might explain why several institutions have undertaken a legitimization process by entitling department "interventional radiology". The observed trend varies from country to country across advanced and developing economies, the (re-)named institution after IR are struggling to reach the top publishing institutions, and this phenomenon is declining on the overall. This could be interpreted through the theory of innovation diffusion, when a new technology or a market share
is reaching a saturation level (Rogers, 1965). This is due to its hybrid origins (radiology, cardiology, surgery) (Gorry & Ragouet, 2016), but also to the fact that interventional radiologists are still divided regarding choices to make for their future (to remain part of radiology or to emancipate as an independent specialty) (Rosch, 2003). Institution (re-)naming through neologisms might be considered as a branding strategy used by scientific community and academic institution competing for identity and resources (Drori et al, 2013). It refers to theories of organizational identity and institutionalism. Our results highlight the role of social strategies in constructing scientific knowledge and nourish the debate between philosophers and sociologists of science (Fueller, 2000; Longino, 2001).

In conclusion, measuring the trend of newly named institutions after a neologism can be used to assess the institutionalization of new medical or scientific field and to test hypothesis based on qualitative approaches (historical, sociological or political) or quantitative models integrating economic indicators (Benoit & Gorry, 2013). It would open new avenues to explore kuhnian scientific revolution in modern science and nourish history and sociology of science.

Acknowledgments

This work is supported by France’s Institut National du Cancer as part of Project #6165 titled ‘‘Interventional radiology in oncology: a multidisciplinary approach to medical innovation and its social recognition’’, and project #2015-179 titled “Comparative analysis of three translational processes: radiofrequency, HIFU and magnetic hyperthermia cases”. The author would like to thank Emilie Bisbau for her assistance.

Abstract
In this study, we analyse the publication portfolio on mental and behavioural disorders to explore how this information can inform priority setting in grant allocation for this disease area by the Department of Health of the Catalan government. We compare the disease burden, publications and funding for each mental health condition, using data from the Global Burden of Disease (WHO), Web of Science (WoS) articles selected with MeSH terms (linking WoS with PubMed) and WoS funding acknowledgement. The data obtained suggest that Catalonia underinvests in unipolar depression in comparison to bipolar disorder and schizophrenia. It also highlights that these areas of mental health research are mainly focused on psychiatry and substantially funded by pharmaceutical companies (about 20%-40% of publications).

Conference Topic
Science policy and research assessment

Introduction
Public policies in science are partly shifting their focus towards supporting research that helps address societal problems or grand challenges. According to various analyses, such as Sarewitz (1996), Chalmers et al. (2014) or Stirling (2015), there is a significant misalignment between the focus of much mission-oriented research and the societal needs or demands that such research purports to address. Yet, while many analysts may agree with the idea of better aligning science supply with societal needs (Sarewitz and Pielke, 2007), the operationalisation of such comparison remains challenging.

On the science supply side, one can produce estimates of research portfolio contents on the basis of resources (people, funding) invested in research areas or in terms of research outputs such as publications (Wallace and Rafols, 2015), but it is not obvious how to classify science inputs or outputs into categories that relate to social demands. On the side of societal demands, making estimating social needs is even more difficult and controversial, as it is highly dependent on problem framings (e.g. see Lawrence (2004) on obesity).

Health research is unique in having some data available to estimate both supply and demand. Health related articles have been tagged with medical descriptors such as MeSH (PubMed’s Medical Subject Headings) that relate publications to health conditions. And Global Burden of Disease is an estimate of a societal need for a given health (Murray and López, 2013), which has been institutionalised by the World Health Organisation (WHO) and thus offers a
platform for comparison. Using these data, Agarwal and Searls (2009) and Evans et al. (2014) compared the disease burden for disease groups against the number of publications (matched by MeSH), at the global level. The clearly showed that global publication patterns mainly respond to the health needs of the developed countries. Similar studies by Lewison and colleagues had compared publications with disease burden for specific diseases such as malaria (Lewison and Srivastava, 2008) or cancer in India (Lewison and Roe, 2012) using title keywords to capture relevant papers.

In order to support priority setting in health research, besides providing information on existing publications focus and on disease burden, current degree of funding for certain is also relevant. To analyse degree of funding on certain diseases, Grassano et al. (2017) looked at funding acknowledgement in cancer research in the UK (see also Paul-Hus et al., 2016).

In this study, we analyse the publication portfolio on mental and behavioural disorders to explore how this information can inform priority setting in grant allocation for this disease area by the Dept. of Health of the Catalan government. By examining the distribution of disease burden, publications and funding across ten different mental disorders, we provide decision makers with information that helps them allocate grant with public health considerations.

**Methods**

We obtained the global burden of disease estimates from a dedicated WHO website, using 2012 data.¹ This data source provides estimates of burden in terms of *Disability-Adjusted Life Years* (DALYs), which sums the years not lived until life expectancy age due to deaths produced by a condition (*Years of Life Lost*) and the time not fully enjoyed because of a health condition (*Years Lost due to a Disability*). These estimates are given in categories defined in terms of the Internal Classification of Disease 10 (ICD10)².

We matched the ICD10 categories with MeSH terms using various sources. As main source to establish the correspondence between ICD10 and the Medical Subject Headings (MeSH) we used the Unified Medical Language System (UMLS), produced by the U.S. National Library of Medicine. UMLS does not always provide the equivalence between the two classification systems and therefore in some cases we had to find the closest MeSH for a given ICD10 code. The ICD10 category of ‘Endocrine, blood and immune disorders’ was not considered in this study due to unclear correspondence between ICD10 and MeSH descriptors. In many cases, there is a one-to-one correspondence, but in a few cases one ICD10 category needs to be covered by various MeSH terms. Following Agarwal and Searls (2009), we removed publications from categories to avoid counting twice a publication in two diseases. In this case, publications were left in the MeSH term closer to root of the MeSH tree (e.g. cancer related publications were removed from other disease categories and kept in ‘Malignant neoplasms’).

Publications were obtained from CWTS inhouse version of the Web of Science (WoS) for the period 2009-2013 (5 years) on the basis of their MeSH terms. To do so, we relied in an existing matching in WoS between WoS and MEDLINE/PubMed records, which allows us the use of all the fields in both databases for the same publication.

² [http://www.icd10data.com](http://www.icd10data.com)
Results
The management of a research portfolio should consider a variety of issues, including the diversity of topics (here health conditions) covered, its alignment with perceived societal needs, the possibilities for synergist interactions among topics and the perceived scientific opportunities of a topic at a given moment (Wallace and Rafols, 2015). The analysis below focuses on the alignment as when comparing disease burden and publications, or the diversity of disciplines, but let us stress those broader issues should be considered (which we hope to discuss in the final form of this preliminary paper).

We first compare the disease burden and publications across broad fields, in order to estimate the relative weight of mental health research in Catalonia, benchmarking it against the world, the EU-15 (mainly the western and southern countries of the European Union) and Spain, as shown in Figure 1. Since there are no estimates of disease burden for Catalonia, its publications can be compared to EU-15 and Spain’s disease burden. Regarding mental health, one can observe that Catalonia has a proportion of publications which is substantially lower than its disease burden, but a bit higher than the EU-15 or Spain. Hence, Catalonia is a bit specialised in mental health compared to its European neighbours.

Figure 2 shows the relative disease burden and relative publication focus for the area of mental and behavioural disorders. Childhood behavioural disorders and mental disability are estimated to have a low disease burden in relation to the publications devoted to these conditions. Drug use disorder and schizophrenia are areas in which Catalonia has relatively more publications than burden, with a pattern similar to the world, whereas in unipolar disorder in an area of potential underinvestment. Bipolar disorder is a condition that has relatively many publications in Catalonia in relation to disease burden – a situation that is not observed across the world or for EU-15. Other conditions do not show a strong difference between relative publication and relative disease burden.

In terms of disciplines, ‘Psychiatry’ is found in Figure 3 the dominant Web of Science Category in research on mental disorders in Catalonia. Further research is needed to see if this is also the case in other European countries. Other relevant disciplines are clearly related to specific health conditions, for example, ‘Substance Abuse’ for drug and alcohol use disorders, or ‘Genetics and Heredity’ for idiopathic intellectual disability. Most research is carried out by universities, in particular for schizophrenia, bipolar disorder and unipolar depression (Figure 4). However, hospitals also carry out or collaborate in 40% or more of the publications all other conditions.

Finally, the Spanish Health Funding Agency (Instituto de Salud Carlos III) is found to be main funder, as shown in Figure 5. Funding from the Catalan government is slightly higher (in number of publications including acknowledgement) to that from other Ministries of the Spanish government. About 20% of publications acknowledge funding by pharmaceuticals – 45% in the case of bipolar disorders.

Discussion
This study has aimed at providing information that supports priority-setting regarding research on mental disorders in Catalonia. We have provided various perspectives about current research focus: the relative burden of mental health as compared to publications, the

3 We included under the Health Funding Agency also other funding acknowledged to the Ministry of Health, who manages the agency, given ambiguities in acknowledgements.
relative disease burden of each mental or behavioural disorder as compared to publications, the disciplinary focus of mental health research, the main research performers and the main funders. To our knowledge this is the first study combining disease burden, number of publication and funding acknowledgements.

The main insights gained are the research that Catalonia underinvests in unipolar depression in comparison to bipolar disorder and schizophrenia. We also found that mental health research is mainly focused on psychiatry and substantially funded by pharmaceutical companies (about 20% of publications). In the ISSI conference, we plan to present views by different stakeholders on what this information suggests in terms of desired future research priorities by the Catalan government in mental health.

Abstract
In the recent decades, the growing importance of interdisciplinary fields, such as biotechnology and new materials, has been witnessed constantly. Such researches often involve the collaboration of not only transcending national boundaries or disciplinary boundaries, but also transcending sectors, such as universities and industry. Highly-cited scientists represent some of world’s most influential scientific minds, so analyzing the characteristics of their research activities might provide insights about preferential conditions that foster high-impact work. Regarding the shortage of the researches on the characteristics of scientific collaborations of highly-cited scientists, this study is hoped to contribute some information in this understudied subject by examining the collaboration characteristics of high-cited agricultural scientists.

Key words
Highly-cited Scientists· Cross-boundary collaboration· Agricultural Science· International collaboration· Interdisciplinary collaboration· University-industry-government collaboration

Conference Topic
Studies on the level of individual scientists

Introduction
Scientific collaborations play a vital role in research and development (R&D) processes by communication and knowledge-sharing practices (Clarke 1967; Qin 1997; Beaver 2001; Leimu and Koricheva 2005; Wagner & Leydesdorff 2005; Wuchty et al., 2007; Leydesdorff and Wagner 2008; McKelvey et al. 2015). The previous findings show that collaboration procedures vary according to different needs, such as specialized knowledge or skills, access to high-end equipment, and data or materials (Bozeman and Corley 2004; Melin 2000; Thorsteinsdottir 2000).

In recent decades, the growing importance of interdisciplinary fields, such as biotechnology and new materials, has been witnessed constantly. Such researches often involve the collaboration of not only transcending national boundaries (Yong et al. 2016) or disciplinary boundaries (Peng and Haoxiang 2015), but also transcending sectors, for example, universities and industry (Hema and Raiah 2016). In addition, there are various political factors encouraging greater level of collaboration among
researchers (Katz and Martin 1997). National Science Foundation (NSF) initiated the industry/University Cooperative Research Centers (U/UCRC) program to develop long-term partnerships among industry, academe, and government. And almost all research universities in the USA and Europe have established technology transfer offices that connect the university and private sector (Siegel et al. 2007). Chinese government also issued a series of plans on national scientific and technological innovation, explicitly putting forward to boost university to participate in the collaborations with public research institutes and enterprises (Yin et al. 2016). All of these policies draw on the assumption that strong connections between universities and the private sector are necessary for innovation and economic development (Etzkowitz and Leydesdorff 1999).

Highly-cited scientists represent some of world’s most influential scientific minds, then understanding the characteristics of their research activities might provide insights about preferential conditions that foster high-impact work. Meanwhile, the achievements of eminent scientists offer exemplars and benchmarks by which the rest of us can gauge our own career trajectories and successes (Hermanowicz 1998, 2005). Prior studies have focused primarily on their academic age, career change, lifestyle choices and work habits (John et al. 2010; Deng 2014; Miao et al. 2013). However, very little is known about the characteristics of scientific collaborations of highly-cited scientists. This study is hoped to add some information to this understudied subject by examining the collaboration characteristics of high-cited agricultural scientists.

Concepts and Framework
The rhetoric of boundaries is signified by spatial metaphors of turf, territory, and domain (Klein, 1996). Metaphors of place call attention to the ways categories and classifications stake out differences. In studies of science, where the concept of boundary work arose, the primary focus has been disciplinary formations (Gieryn 1983). In studying the Social Science Research Council, Donald Fisher applied the concept to interdisciplinary activities (Donald 1990). Boundary-crossing behavior occurs in all knowledge fields though, because the problem of boundaries is universal. Boundaries are generally based on knowledge, technology, geography, or some combination of these attributes (Ramlogan et al, 2007; Carlsson, 2006; Malerba, 2005; Wolfe and Gertler, 1998; Cooke, 1997). Some scholars discuss research collaboration as transcending geographic boundaries, motivated instead by a particular problem (Ramlogan et al, 2007; Carlsson, 2006; Malerba, 2005). But multidimensional concept of proximity goes beyond mere geographic closeness to include individuals who are institutionally proximate by sharing organizational structures, regulations, or cultures (Lander, 2013; Holden, 2008). Indeed, Cross-boundary collaboration attempts to break down those boundaries existing in geographic space, scientific disciplines and industrial organization for knowledge sharing.

Cross-boundary collaboration is depicted in Figure 1 as three dimensions (ranging from narrow to broad scope) on which scientific collaboration, regional coalitions, and inter-sector partnerships can be compared. The scope of disciplinary dimension,
incorporated in Figure 1, encompasses three key concepts related to the boundaries of disciplines, multidisciplinarity, interdisciplinarity and transdisciplinarity (Stokols et al, 2003; Wagner et al, 2011). For both the organizational and geographic dimensions, the narrower levels are nested within each of successively broader levels of collaboration (Stokols, 2006). In this article, we combine the framework with bibliometric methods to discover the characteristics of cross-boundary collaboration of highly-cited agricultural scientists.

**Methods and Data**

**Methods**

**International Collaborations**

International collaboration in science can be considered as a communications network that is different from national systems and has its own internal dynamics (Gibbons et al. 1994; Ziman 1994). Based on the thought of fractional count, Wang et al. introduced the International Collaboration Activity Index (ICAI), including five sub-indicators, Average Number of Collaboration Countries per Paper, Paper Collaboration Ratio, Collaborative Leadership Index, International Collaboration Range, and Publishing Paper Ratio, to comprehensively measure the degree of international collaboration at the country or region level (Wang et al. 2014). In this article, we try to apply ICAI indicator to measure the international collaboration of highly-cited scientists at individual level.

\[
\text{ICAI} = \text{ANCCP} \times \text{PCR} \times \text{CLI} \times \text{ICR} \times \text{PPR}
\]

\[
\text{ANCCP} = \frac{\sum_{h=1}^{n} P_n}{\sum_{h=1}^{N} P_n}
\]

\[
\text{PCR} = \frac{\sum_{n=2}^{N} P_n}{\sum_{n=1}^{N} P_n}
\]

\[
\text{CLI} = \frac{\sum_{n=2}^{N} P_n}{\sum_{n=2}^{N} P_n}
\]

\[
\text{ICR} = \frac{TN}{PP}
\]

In the formula:

Average Number of Collaboration Countries per Paper (ANCP) is defined as the number of times the highly-cited researchers have cooperated with authors from the other countries or regions, and reflects the breadth of one highly-cited researcher in
international collaboration from the microscopic view. Among them n represents the number of countries or regions in a paper. (n-1) is regarded as the number of times of international collaboration. And Assuming that a highly-cited researcher P owns Pn papers completed by authors from n countries or regions and N is the maximum value of n (N≥n). \( P_n^{RP} \) represents the number of papers of highly-cited researchers as corresponding authors.

Paper Collaboration Ratio (PCR) is defined as how much a highly-cited researcher’s multinational papers accounted for his or her total number of papers.

Collaborative Leadership Index (CLI) reflects how a highly-cited researcher is motivated with regards to international collaborations. \( \sum_{n=2}^{N} P_n^{RP} \) is the total number of multinational papers that highly-cited researcher P has taken part in as the corresponding author. \( \sum_{n=2}^{N} P_n \) represents the number of multinational papers a highly-cited researcher P has taken parts in.

International Collaboration Range (ICR) is defined as how many partner countries or regions have been involved in collaborations, which can be described as an absolute value. \( TN \) is the total number of countries or regions with which a highly-cited researcher P has cooperated. This indicator reflects the breadth of one highly-cited researcher in international collaboration from the macro view.

Publishing Paper Ratio (PPR) is defined as how much the total number of papers a highly-cited researcher has published accounted for the total number of papers in the field. \( TP \) is the total number of papers in the field.

**Interdisciplinary Collaboration**

Boundary-crossing publication outside one’s own discipline represents a much more direct form of interdisciplinary information transfer than does citation, since information is presented by members of the discipline in which it originates (Pierce, 1999). So, in this study, 22 ESI fields of Thomson Reuters were used as a standard to classify publication, and we explored interdisciplinary collaboration behaviors of highly-cited scientists by analyzing their publication outside agricultural science.

**Cross-sector Collaboration**

Co-authorship of journal publications is often seen to represent the transfer of knowledge (Murray 2002). Two organizations are described as co-authors if they are both listed in the address filed of a paper. Authors listing more than one organizational affiliation on a paper thus represent collaboration between these organizations. These authors are seen as “boundary spanners” who facilitate the translation of knowledge between their organizational affiliations (Swan et al. 2007).

In order to determine the synergistic effect of university-industry-government collaboration, and find out a networked infrastructure for knowledge-based innovation systems, Leydesdorff has deduced an algorithm to measure the dynamic relations of “university-industry-government”, called TH algorithm (Leydesdorff, 2003). It is based on the mutual information in the three dimensions of the Triple Helix. In
information theory, Shannon defined entropy as probability of occurrence of discrete random events, which means the greater the uncertainty of events are, the greater the entropy is (Shannon, 1948). On the contrary, if a system operates safely, stably and orderly, then the value of entropy will be small. In the case of only one variable, the formula is:

\[ H = - \sum_j P_j \log_2 P_j \]

\( H \) represents entropy, that is, the average of information content, and \( P_j \) is the probability of the emergence of the number \( j \) information. Correspondingly, the entropy of two-dimensional distributed data is:

\[ H = - \sum_j \sum_l P_{ij} \log_2 P_{ij} \]

\( P_{ij} \) represents the joint probability distributions of event \( i \) and event \( j \). The mutual information between two dimensions of the probability distribution can be expressed as

\[ T_{ij} = H_i + H_j - H_{ij} \]. Suppose that \( u, j, g \) represent the number of publications of university, industry, and government, then the mutual information in three dimensions can be derived as

\[ T_{uig} = H_u + H_i + H_g - H_{ui} - H_{ug} - H_{ig} - H_{uig} \].

This study defines mutual information \( T \) as uncertainty of measurable variables, taking mutual information as a dynamic indicator to measure the close degree of each body. McGill pointed out that the three dimensional mutual information is the self-organizing measurement of the system, and is negatively correlated. It is used to explain the self-organizing problems of the network due to the lack of central coordination (McGill, 1954). When the value of \( T_{uig} \) is negative, it indicates that the three dimensional relationship plays the self-organization function in the system. As the value of \( T_{uig} \) is getting smaller, the whole system’s self-organization level will get higher, which suggests that the relation among UIG collaboration is getting closer.

According to Burt’s theory of structural holes (Ronald, 1992), nodes with high betweenness centrality play the role of a broker or gatekeeper to connect the nodes and sub-groups. So, they can most frequently control information flows in the network. Hence, in order to find which institutions occupied the dominant position in resource acquisition, we used the social network analysis method. We drew a UIG collaboration network map of highly-cited agricultural scientists’ affiliations, and ordered the networks nodes according to the value of betweenness centrality.

Data

Data Retrieval

In this study we selected the academic papers authored by 128 highly-cited agricultural scientists (2003-2013) according to 2015 World Most Influential Scientific Elites Report published by Thomson Reuters. Based on the report, publications authored by the 128 scientists and published from 2003 to 2013 are downloaded from SCI/SSCI of Thomson Reuters. Only document types of Articles
and Review are included. To guarantee the recall ratio, we retrieved data by authors’ family names and their first initials. After eliminating duplicates, 33760 publications were covered.

Data Cleaning

Author name disambiguation has become an active area of bibliometric research. It is a well-known problem in both cases: a single name may represent multiple individual authors and an individual author may publish or be indexed under multiple names, especially for none-English-speaking authors. In order to solve this problem, Thomson Reuters, Elsevier and other large database service providers introduce Research ID or Author ID as unique identifier of the author's academic identity. Some scholars have also developed a lot of methods for indentifying author’s name (Han et al., 2004; Han et al., 2005; Treeratpituk and Giles, 2009).

Thomson Reuters provided a lot of useful information about highly-cited scientists including their full names, affiliation names and Research IDs (but only 64 scientists’ Research ID can be found). For those scientists who lack Research ID information, this paper adopts K-way clustering algorithm proposed by Han (Han et al., 2004; Han et al., 2005) to identify highly-cited scientists’ papers. Finally, 12050 academic papers formed our target data set.

Data Normalization

Regionalization

In WoS dataset, C1 represents the author’s address, so we segment the address field so as to obtain the nation information. If this paper includes more than 2 national information, then it is considered as an international collaboration paper which reached 5324 pieces finally.

Subject Classification

This study is based on the Thomson Reuters ESI (Essential Science Indicators) classification system as standard. ESI subject classification mainly includes 22 major categories, which is classified according to the mapping relationship between the subject classification and the journal name. 11547 out of 12050 academic papers correspond to the correct ESI categories, and the other 503 need artificial judgment to match the ESI discipline classification system.

Author’s Affiliation Classification

Leydesdorff’s research result indicates that the mechanism type can be divided according to address cognitive word. This research’s data collecting process is as follows:

(a) We extracted institution addresses from 12050 papers data. Removing duplicate data, we got 27951 address information;

(b) Then, we began to identify and classify these addresses. If the address includes “UNIV OR COLL”, then it belongs to group “U” (university). Addresses that
Results and Analysis

General situation

Through the analysis of highly-cited scientists’ basic information provided by Thomson Reuters, we can find that 128 highly-cited agricultural scientists are from 26 countries/regions, and 85 institutions. (see Table 1). In the term of institution type, 95 highly-cited agricultural scientists come from colleges and universities, occupying 74.2% of the total; only one of highly-cited agricultural scientists works in enterprise (Dover Science Corporation in USA); the other 32 highly-cited agricultural scientists belong to government-led public institutions, such as United States Department of Agriculture (12), Spanish National Research Council (4), French Academy of Agriculture science (2), and so on.

Highly-cited agricultural scientists are productive author who publish an average of 94.1 papers in SCI/SSCI annually during the year of 2003-2013. Highly-cited agricultural scientists from developed countries, like the USA and European countries, lead a prominent performance in the output of their academic publications (Table 2).

International collaboration

From 2003 to 2013, highly-cited agricultural scientists have published 5324 international collaboration papers in the field of agriculture science, accounting for 44.2% of the total number of papers. As Fig. 2 shows, the output and the proportion of international collaboration papers present a year-by-year growth trend. Apparently, in 2012 and 2013, the proportion of international collaboration papers from highly-cited agricultural scientists is more than 50% of the total. It has become an obvious trend that highly-cited agricultural scientist are paying more attention to international collaboration.

Fig. 2 International Collaboration Papers of Highly-cited Agricultural Scientists from 2003 to 2013

ICAI indicator can reflect the collaboration degree of highly-cited scientists in multi-dimension. Table 3 shows some relative information about active agricultural...
scientists. The results show that highly-cited agricultural scientists in developed countries, such as the United States and European countries, are leading a more active participation in international collaboration. They continue to improve their own research strength by expanding international collaboration chances and using global scientific resources effectively. Meanwhile, two agricultural scientists from China and Thailand have a higher participation degree in the international collaboration, indicating that developing countries are also seeking international collaboration opportunities and strengthening their ability, in order to make up insufficiencies of science and technology resources in their countries.

In addition, based on the five international collaboration indicators (ANCP, PCR, CLI, ICR, PPR), we classified 128 highly-cited agricultural scientists by using hierarchical cluster analysis. According to Table 4, 31 scientists in cluster 1, occupying 24.2%, perform more actively in the international collaboration. 61 scientists in cluster 2, accounting for 47.7%, have a higher ICR, but lower CLI and PPR than scientists in cluster 1. 36 scientists in cluster 3, occupying 28.1%, get lower grades in the 5 indicators than scientists in the other two clusters, so it can be regarded as relatively inactive in the international collaboration.

The method of hierarchical clustering: using Ward algorithm to cluster, and choosing Squared Euclidean distance as the metric standards, as well as, Z score to eliminate the influence of the dimension of each index.
Interdisciplinary Collaboration

From 2003 to 2013, highly-cited agricultural scientists have published 9006 co-authored papers, accounting for 74.7%. Among them, the number of interdisciplinary collaboration papers is 3691, which take up 30.6% of the total. Besides, there are up to 5315 interdisciplinary collaboration papers, occupying 44.1%, as shown in Fig. 1. We can see that only 3 out of 128 scientists published papers in the single subject, indicating interdisciplinary collaboration is a common phenomenon in highly-cited agricultural scientists group.

As Table 5 shows, interdisciplinary collaboration papers in the field of agriculture science are mainly concentrated on neighbor areas, such as biology and biochemistry, animal and plant sciences, and chemistry. On the contrary, few highly-cited agricultural scientists publish papers in long-distance discipline areas, such as material science, economics and business, space science.

The UIG collaboration degree of highly-cited agricultural scientists presented a volatile growth trend from 2003 to 2013 (Fig. 4). According to affiliation types, universities (-54.17) owned higher UIG (inverse indictor) than governments (-84.17) and industries (-198.24) on average, which illustrates that the UIG collaboration degree of highly-cited agricultural scientists from universities is lower than the scientists from the other two types of institutions. The reason may be that colleges and universities are usually more inclined to basic research work, but the government and enterprises spend a lot on the commercialization of research findings. However, with universities paying more attention to the commercialization of research achievements, we can foresee that the gap of the UIG collaboration degree between universities and the other two types of institutions will be narrowed.

![Fig. 4 T_UIG of Highly-cited Agricultural Scientists from 2003 to 2013](image)

According to the top 10 highly-cited agricultural scientists in UIG collaboration, the majority of collaboration institutions came from their own countries. Some of the world famous transnational enterprises, such as Mars Company and Pfizer, have become some highly-cited researchers’ important UIG collaboration partners.

</table>
As the scientific collaboration network of highly-cited researchers displays (Fig. 5), most of the universities are located in the network’s core position with 0.671 betweenness centrality on average. So we can figure out that collaboration between universities is still an important form for scientific collaboration. Nevertheless, some government-dominated public institutions appear at the edge of scientific collaboration networks, and can function as bridge (the betweeness centrality of these 6 governmental public institutions is 0.655 on average). And they build up UIG collaboration relationships with some universities. Besides, the Swiss Nestle (betweeness centrality value: 0.539) also accounts for a place in the network map. It co-authored with 34 scientists, and published a total of 135 academic papers, illustrating this corporation’s imperative status in the relation of UIG collaboration of this field.

**Fig. 5 Scientific Collaboration Network of Highly-cited Agricultural Scientists**

Network setting parameters and algorithms: the size of the nodes denotes the number of the publications of the institution (≥20); the color depth of the nodes denotes the value of betweenness centrality; the thickness of edges denotes the number of collaboration papers. Force Altlas algorithm is used for layout. Label color represents UIG: Black=U, Red=I, Blue=G).
Conclusion and Discussion

This study tried to contribute some information to the understudied field by making a bibliometric analysis on academic papers authored by 128 highly-cited agricultural scientists, based on the analysis framework of cross-boundary collaboration from three dimensions: international collaboration, interdisciplinary collaboration and university-industry-government (UIG) collaboration. The results showed that, firstly, Colleges and universities were the main affiliations of the highly-cited agricultural scientists, and highly-cited scientists from developed countries performed outstanding in academic paper output. Secondly, international collaboration papers of highly-cited agricultural scientists showed an increasing trend. 71.9% of the highly-cited agricultural scientists are active in the international collaboration. Thirdly, interdisciplinary collaboration among highly-cited agricultural scientists was very common. In particularly, adjacent subjects became the main field of interdisciplinary collaboration of highly-cited agricultural scientists. On the contrary, few highly-cited agricultural scientists published papers in long-distance discipline areas. Fourthly, UIG collaboration of highly-cited agricultural scientists from universities was less active than those from government institutions and enterprises. Nestle has become an important partner of highly-cited agricultural scientists in UIG collaboration.

For training a new generation of cross-boundary scientists, it is very important to design new educational strategies. Within university settings, courses and research mentorship opportunities emphasizing transdisciplinary approaches to science and community action should be developed (Stokols, 2006). And within community contexts, new workshops and training modules focusing on the challenges associated with cross-boundary collaborations and practical strategies that can be used by participants to improve their communications and coordination efforts would provide a valuable resource for the members of scientific teams, community coalitions, and inter-sector partnerships. Meanwhile, the knowledge innovation of universities should break through itself, paying attention to collaboration with the government and enterprises to promote heterogeneous resources flow in universities, government and enterprises (Becher and Trowler, 2001).

Bibliometric studies will help research organizations acquire a more comprehensive understanding of cross-boundary collaboration characteristics of high-cited scientists. The analysis of the characteristics of research collaboration is also very relevant to policymaking. For example, funding agencies and decision makers can allocate budgetary support for collaboration between university and industry and the facilitation of multidisciplinary communication.

A scientometric method for assessing an institution’s scientific collaboration policy

Hamid Bouabid,
Faculty of Science, Mohammed V University in Rabat, 4, Avenue Ibn Battuta, BP 1014 RP, Rabat, Morocco, h.bouabid@hotmail.com

Abstract
The paper suggests a comprehensive method for an institution's scientific collaboration policy assessment. This method is based mainly on indicators: signed agreements, co-publications, their citations and scientific fields as front science. The method also uses a mapping of collaborative institutions and fields to assess the proximity of the institution in its collaborative cluster as well as multidisciplinarity in this cluster. Three major classes of collaborative institutions are derived from the method: (1) a class where there is coherence between co-publications and agreements; the university has to faithfully intensify its collaboration with this class; (2) a class where there is a substantial amount of co-publications but no collaboration agreement; the university should consider setting up a formal frame for collaborative research; and (3) a class grouping institutions which cited the university knowledge and considered as potential partners for the university.

Conference topic
Methods and techniques - Science policy and research assessment.

Introduction and background
Science and technology (S&T) are increasingly open, multidisciplinary and highly integrative. Therefore, collaboration offers several opportunities and contributes to increased productivity and excellence in S&T. Several authors have demonstrated that there is a strong correlation between scientific collaboration and research productivity and impact (Katz and Martin, 1997, Lee and Bozeman, 2005, He et al., 2009, Abramo et al., 2011a and Finlay et al., 2012). Defazio et al. (2009) modeled the effect of collaboration and funding on productivity for three periods: pre-funding, during funding and post-funding. They found that receiving funding increases researcher productivity by approximately 14%, while collaborating with a partner in the network in the post-funding period increases productivity by approximately 70%. The positive
effect of collaborations on the impact of papers has also been proven using citations or impact (Katz and Hicks, 1997, Guerrero-Bote et al., 2013, He et al., 2009, Levitt and Thelwell, 2010). While there exists a rich literature offering findings and conclusions on collaboration assessments at the scientist -micro- level (Traore and Landry, 1997; Melin, 2000; Hara et al., 2003; Jha and Welch, 2010; Lee and Bozeman, 2005), or at the regional, national or international -macro- level (Tijis et al., 2010; Hoekman et al, 2010; Choi, 2012, Bordons et al., 2013), there are far fewer assessments of scientific collaboration at the institutional level, as done by Adams (2005), Ponds et al. (2007), Ortega and Aguillo (2013), Barth et al. (2014), Han et al. (2014) and Yan and Guns (2015). Furthermore, the methods applied in these papers are different and less methodologically organized to link collaborative inputs (agreements) to outputs (co-publications) for policy issues. Indeed, for example, Ponds et al. (2007) make use of the gravity model to examine the proximity effect of collaboration between different kinds or similar institutions. The work by Barth et al. (2014) was based on network and cluster analysis (carried out using VOSviewer software) to identify similar institutions for collaboration and potential partner’ ones. Finally, Yan and Guns (2015) applied eight algorithms to collaboration at the author, institution and country levels for predicting and shaping the dynamics of collaboration starting from existing topology.

**Data and Method**

In this assessment, all frameworks, agreements, conventions and Memorandum of Understanding (MoU), were considered acts of collaboration. Other types of contracts, tenders, and sponsoring agreements or similar were excluded. During the whole period, UM5S signed 248 agreements.

The University Mohammed V - Souissi (UM5S) comprises the following 10 institutions:

- Medicine and pharmacy faculty;
- Dental medicine faculty;
- National high school of technology teaching;
- National high school of computer science and systems analysis;
- Law and Economics faculty in Souissi;
- Law and Economics faculty in Sale;
- Education sciences faculty;
- Institute for African studies;
- Institute for Arabic studies and research;
- University Institute for scientific research.

The Web of Science database was used to retrieve publications and co-publications (co-authored ones), where all kinds of publications were considered (article, review, proceeding, letter, editorial, etc). In order to compare agreements and co-publications, the analysis covers
the second period from 2010 to 2013 (end of June 2013). UM5S published almost 600 publications during this period, of which 63% were co-publications. In this analysis, a co-publication is defined as a paper authored by the UM5S and at least one other institution (national or international).

To map and analyze co-publications, Salton's Cosine (Salton, 1983) is used as the index for calculating the proximity between the entities (institution, field, key-words, etc) of the network. Figure 1 reports the proposed method to assess the policy of university scientific collaboration.

![Fig. 1: Scheme and stream of the proposed method for collaboration policy assessment](image)

Figure 1 plots the method process. The first stage consists of compiling data and information as a policy inputs. The second stage refers to the process of the analysis itself comprising three levels: (i) the stock of active collaboration agreements, which represents, for a given year, the difference between the number of cumulative valid agreements and the number of expired agreements up to that year, (ii) the coherence between agreements and co-publications and (iii) the impact of co-publications as measured by their citations. To achieve this analysis five indicators are produced in order to build up the three classes of collaborative institutions. In another institution's assessment, this number will depend on its collaboration policy.

**Results and discussion**

For the whole period, the stock of active collaboration agreements has been calculated, as described in the Data and Method section. Its analysis is not part of this paper.
**Coherence between agreements and co-publications**

Through the indicator of co-publication, the method quantifies the share of each institution in the collaboration activities of the university. For UM5S, the method has shown a national co-publication dominance amongst overall university co-publications (Table 1). Major national collaborative institutions are the Specialized Hospitals in Rabat, Hassan II University in Casablanca, and Ibn Tofail University in Kenitra. The different institutions belonging to the CHU Ibn Sina are from now on not considered separately but included in it. Furthermore, Academy Hassan II of Science and Technology is excluded since it is more of a funding body and not a research institution. Similarly, and for coherence purposes, the Ministry of Health will not be considered at all as a collaborative institution.

On the international level it is also noted that there is a diversity of collaborative institutions (Table 1). It is worth mentioning that two-thirds of the 39 UM5S collaborative institutions (above the threshold of 10 co-publications) according to co-publications with UM5S are not under any collaboration agreement with UM5S, demonstrating a clear distortion between agreement as input proxy and co-publication as its output proxy. Cross-checking the results in Table 1 from either signed agreements and co-publications according to the method in Figure 1 allows us to build up two classes:

- **Class 1**: institutions with which the university has collaboration agreements as well as co-publications with their researchers, such as National Institute of Health, University Mohammed V Agdal, Ibn Sina University Hospital (CHU), University Ibn Tofail, CNRS-France, University Zaragoza, University Bordeaux, Université de Montréal, Université Laval, Cheikh Zaid Hospital, University Cadi Ayyad;

- **Class 2**: institutions with which there is no collaboration agreement, but there is substantial co-publication activity, such as: Military University Hospital Mohammed V, University Hassan II (Casablanca and Mohammedia), University Autonoma of Madrid, King Saud University, University Mohammed I, University of Technology Czestochowa, University Lodz, University of Kyoto, European Hospital Georges Pompidou, University Nancy 1, Hospital Virgen Camino, Medical Center Erasmus, University Valencia, University Rouen, CHU Limoges, University Liege, CHU of Tours, University Sidi Mohammed Ben Abdellah, University Paris 7.

While Autonoma University in Spain appeared to be a collaborative institution to the UM5 without any agreement, we found that the university had signed several agreements with other Spanish institutions but with no scientific output, such as: University Laguna, Universia
Holding, university Murcia, university Las Islas Baléares and University Cadiz. It is one of the illustrative cases of discrepancy between agreements and co-publications.

</tbody>
</table>

* Ibn Sina Hosp institutions

** including ENSEIRB, Univ Michel de Montaigne and univ Montesquieu
The same case holds for some French institutions. Indeed, while no agreement was signed with University Paris 7 despite many co-publications, we found that several agreements were set with institutions in Paris such as: University Paris 13, University Paris Dauphine, University Paris René Descartes, Institute for Languages and Civilizations.

**Impact of co-publications**

This part of the method is mainly based on science mapping which has been proven to be a useful tool in assessment.

1. **Impact of co-publications**

Collaboration with high-productivity partners tends to increase impact as proved by Katz and Hicks (1997) who found that while collaborating with an author from the home or domestic institution increases the average impact by approximately 0.75 citations, collaborating with an author from a foreign institution increases the impact by about 1.6 citations. Likewise, Abramo et al. (2011b) confirmed that more productive scientists and those with high impact collaborate more abroad than their colleagues (They warned, however, that the reverse was not always true). In this regard, we provide in Table 2 the impact indicator for institutions of the two classes in order to ascertain those with higher impact than that of UM5S. Table 2 shows that almost all of the collaborative institutions were more knowledge productive (not normalized to university size). Despite its slightly lower impact rate, but closer to that of UM5S, Ibn Tofail University is one of the small-size but performed universities in Morocco (Bouabid, 2014).

Three institutions were excluded for having a number of publications below the threshold of 100 publications during the same period: National Institute of Health (Class 1), Hospital Cheikh Zaid (Class 1) and Hospital Virgen Camino (Class 2). Two other institutions were excluded for having lower impact than that of UM5S (shown in grey in Table 2).

At the end of this stage of the method's stream, the two classes comprise the following:

- **Class 1**: University University Mohammed V-Agdal, University Ibn Tofail, CNRS-France, University Zaragoza, University Bordeaux, Université de Montréal, Université Laval, University Cadi Ayyad. The scientific collaboration with this class should be strengthened since there is correlation between co-publication practices and collaboration agreements;

- **Class 2**: University Hassan II (Casablanca and Mohammedia), University Autonoma of Madrid, King Saud University, University Mohammed I, University of Technology Czestochowa, University Lodz, University of Kyoto, European Hospital Georges Pompidou, University Nancy 1, Medical Center Erasmus, University Valencia, University
Rouen, University Liege, CHU of Tours, University Sidi Mohammed Ben Abdellah, University Paris 7. The scientific collaboration for this class is distorted and unbalanced and the university should consider setting up a formal framework for collaboration for its researchers to enhance their research activities.

* p: is the number of publications during the period from January 1st 2010 to June 30th 2013.
** c: is the number of citations gained by the publications p in the time window: January 1st 2010 to December 31th 2014.
-- : means that the number of publications is below the threshold
As a policy implication, for the Class 2 institutions a 'bottom-up' approach is required to identify university researchers involved who would contribute to setting up formal scientific collaboration with these institutions. In fact, the scientific collaborations were found to be mostly based on individual initiative as was reported by Bordons et al. (2013) rather than a result of policy action. Melin (2000) suggested that scientists themselves should choose with whom they would like to cooperate, and under which forms.

2. Multidisciplinarity in co-publications

To assess proximity to collaborative institutions and the multidisciplinarity in collaboration of UM5S, as a key component of the method clusters are drawn in a heterogeneous map crossing both collaborating institutions and scientific fields for the university in terms of co-publications (Figure 2). Despite its relative complexity, this kind of map provides a complete visualization and is of greater value by combining both institutions and fields. For the first point, higher proximity - e.g. closeness - is shown to be more prevalent with specialized institutions in Rabat such as Children’s Hospital (Hôpital des enfants), Ibn Sina University Hospital, Mohammed V Military Hospital and National Institute of Health, as well as with Ibn Tofail University (35 kilometers north of Rabat). For the second point, Figure 2 pictures a multidisciplinary collaboration with very limited institutions: Ibn Tofail University (Class 1) and Georges Pompidou European Hospital (Class 2) as identified by the overlap of more than two different circles - sub-clusters (marked with arrows in Fig. 2). Policy collaboration focus should be on these institutions as multidisciplinary collaborative ones.

3. Research Fronts/advanced knowledge in co-publications

In addition to the classification presented above, a qualitative indicator is employed to check the relevance of considering these classes in the university collaboration policy. The objective is to ensure that the topics addressed in the research collaboration with these institutions are in 'Research Fronts' as defined by Thomson Reuters in its Science Watch©. This part of analysis is not presented in this paper. However, it was found that the topics addressed in the scientific collaboration were generally in the Research Fronts such as: genetics, genomes and gene expression, tissue engineering, immunology, aging, thin films, remote sensing, neurosciences, polymer, etc.
Finally, considering the overall knowledge production stream, the results showed that some institutions from emerging countries such as China, India, Brazil, and Turkey are likely to be potential collaborative partners for the university since they have been citing its papers (Table 3) and with respect to their fast-growing knowledge production. These institutions are grouped into a third class as potential partners. Surprisingly, no co-publication or agreement were found with any of these institutions. Only institutions having more than five citations each (as a threshold) to UM5S’ publications are considered as citing institution from these countries.

Setting this threshold, all Turkish and Indian institutions were excluded. After this filter, the UM5S's potential partners are listed in Table 4. Neither publications nor citations of the Chinese Academy of Science is reported, because it is more a funding and policy-making body than a research institution, even if its output is almost 120,940 publications during the period of study. Similar to the institutions of classes 1 and 2, all the institutions of class 3 were found to have a higher impact on the scientific community worldwide (between almost 4 and 6 citations per publication) compared to that of the UM5S (1.82).

4. Conclusion

A method is suggested for assessing a university scientific collaboration policy. Starting from data on agreements, co-publications, Research Fronts and citations, scientometric indicators were built along with science mapping in a comprehensive and organized method to inform about the coherence between co-publications as research collaboration outputs and collaboration agreements as a ‘legal’ frame input. The method stands to provide valuable inputs for policy assessment and design by identifying three distinctive institution classes for collaboration. The first class comprises institutions for which there were both co-publications and collaboration agreements; the university has to intensify its collaboration with this class.

The second class comprises institutions with significant co-publications and higher impact but no collaboration agreement; the university should consider setting up a formal ‘bottom-up’ frame of collaboration to better enhance existing individual collaborating activities. The third class comprises institutions highly citing university knowledge and having higher impact, thus providing potential collaborative partners.

Abstract
This study provides a preliminary analysis of the international profiles in collaboration and mobility using the seven countries indicated in the US executive order of January 27, 2017. The objective of this research is to analyze the flow of knowledge between countries and the relative importance of specific countries in order to inform evidence-based science policy. The work serves as a proof-of-concept of the utility of asymmetry and affinity indexes for collaboration and mobility. Comparative analyses of these indicators can be useful for informing immigration policies and motivating collaboration and mobility initiatives. Our analysis reinforces many of the established understandings of collaboration and mobility relationships—emphasizing the importance of geographic and cultural similarities. The analysis also explores the varied lenses on the importance of particular countries, when viewed from egocentric and relational perspectives. Our analysis suggests that comparisons of collaboration and mobility from an affinity perspective can identify gaps for mobility initiatives, given established scientific relationships. This approach can inform international immigration policies, but can also serve to identify potential partnerships at other levels of analysis (e.g., institutional, sectoral, or by state/province).

Conference Topic
Science communication; Science policy

Introduction and Background
Immigration is heralded as the key contemporary policy issue (Duncan, 2016; Bildt, 2017). Across the globe, political leaders are proposing and implementing nationalistic policies that restrict global mobility. One notable example is the executive order signed by United States President Trump on January 27, 2017 temporarily suspending entry of individuals from seven countries (i.e., Iran, Iraq, Libya, Somalia, Sudan, Syria, and Yemen) and placing restrictions on visa renewals for an additional 38 countries. Scientists home and abroad decried the executive order as impeding science, providing anecdotes of students, postdocs, and researchers who were trapped either home or abroad and unable to continue in their scientific activities (Morello & Reardon, 2017). However, there was little research on the scientific relationships among these countries and the implications of the policies for the scientific community.

Previous analysis showed the exponential growth of scientific connections at the global level over the last two decades (Adams, 2013; Wagner et al., 2015), primarily measured through collaboration (or co-authorship) (Newman, 2001; Barabási et al., 2002; Glanzel & Schubert,
2004; Leydesdorff & Wagner, 2008; Perianes-Rodriguez et al., 2009; Chinchilla-Rodriguez, et al, 2010; Gazni, et al., 2012; Wagner, Park, & Leydesdorff, 2015). Less understood is how scientists create relationship among countries through mobility. The use of bibliometric methods, in particular, has received scant attention, with a few notable exceptions (Moed & Halevi, 2014; Sugimoto, Robinson-Garcia, & Costas, 2016). However, there are traces of international relationships embedded in publication data: scholars co-author publications with scholars from other countries, they co-affiliate in multiple countries, and they change countries across their publication career. This data, however, has not been effectively harnessed to inform policy.

We provide here a proof-of-concept analysis, demonstrating the utility of bibliometric data to inform our understanding of the scientific relationship between countries, by using the countries indicated in the so-called “immigration ban” of January 2017. We present an approach that measures proportional production and probabilistic affinities for both collaboration and mobility, to describe the relationship in the context of the global scientific system. Furthermore, we compare these two indicators of international connectivity—collaboration and mobility—to provide a more refined understanding of the role of certain countries in the global knowledge network.

The vast differences in the volume and research capacities of different countries is a topic of concern for constructing valid indicators of international collaboration. In general, the more countries differ in scientific size, the larger the difference in relative terms (Luukkonen, Tijssen, Persson, & Silvertsen, 1993). Furthermore, the existence of collaboration and mobility between two countries implies reciprocity, but may not be symmetric. This is well-understood in network science: the degree of reciprocity is determined not by the definition of the link but by the extent to which two nodes report the same relationships with one another and two nodes exhibit proportional relationships based on overall performance of each one of all nodes in the network (Tichy, Tushman, & Fombrun, 1979). Several indices exist to measure network asymmetries (Luukkonen et al., 1993; van Eck & Waltman, 2009). Among them, two particular indices—Affinity Index (AFI) and Probabilistic Affinity Index (PAI)—have been used to measure the relative strength of networking science. The first one is size-dependent and the latter is size-independent. AFI allows for the calibration of relative importance and asymmetries between countries, measuring the amount of collaborative papers published jointly and the total number of international collaborations of each country and also, the number of active authors and the number of mobile authors. In a similar way, taking into account all the potential partners in the network and by removing the size dependency, PAI reveals the affinities that are largely dependent upon different drivers of scientific collaboration and mobility. In particular, the PAI is highly sensitive and reveals the limit of the scientific sizes as a predictor of relationships. Previous studies have employed AFI and PAI (e.g., Zitt et al., 2000; Finardi & Buratti, 2016) to analyze collaboration, but no previous study has, to our knowledge, applied these measures to analyze the connections constructed through mobility.

We examine, for each of the seven countries for which visas were temporarily suspended as well as the United States, four dimensions: (a) asymmetry of collaboration, (b) asymmetry of mobility, (c) affinity for collaboration, and (d) affinity for mobility. We provide collaboration and mobility in parallel to highlight the different insights that can be gained by examining these indicators in concert, rather than independently. Our objective is to provide bibliometric tools to bring scientific evidence to arguments of anecdote in this time of heightened concern over globalization.

Data and Methods

By using affiliation data from scientific publications, it is possible to track the trajectory of individual scientists and analyze collaboration and mobility at the level of research groups,
subject areas, and countries (Moed & Halevi, 2014; Sugimoto, Robinson-Garcia, & Costas, 2016). In this study, we use co-authorship as a measure to examine international collaboration and the number of affiliations of scholars with different countries as a proxy of international mobility in a sample composed of the seven countries involved in the immigration ban--Iran, Iraq, Libya, Somalia, Sudan, Syria and Yemen--and the United States.

The data is drawn from a curated version of the Web of Science housed at CWTS (Leiden University). Author data from 2008 to the present has been disambiguated using an author disambiguation algorithm developed by Caron and van Eck (2014), wherein individuals are matched with distinct publication records based on similarities in co-authorship networks and affiliation information. The use of a disambiguation algorithm is necessary to identify mobility at the individual level. We therefore restrict our data to the period 2008-2015, to utilize this disambiguated data (14,097,939 publications). We further refine our data only to those links which contain at least one of the countries of interest in our sample and include only those individuals who have at least 2 publications (n=3,521,797). These nation-to-nation links were associated with 8,168,640 publications (2008-2015) across 216 countries. For collaboration, we considered all authors listed on the papers and their connections to countries. Reprint affiliations have been included for both collaboration and mobility analysis and all document types were included.

Country names were cleaned and standardized (e.g., merging Timor-Leste and East Timor, Congo and Republic of Congo as well as Zaire and the Democratic Republic of Congo). The cleaning resulted in 213 countries. We then enriched this data by adding additional classifications. Every country was assigned to one of eight geographical regions: North America, Latin America and the Caribbean, Africa, Asia, the Middle East, the Pacific Region, Eastern Europe, and Western Europe. Income level category, as defined by the World Bank (2016) was used as a proxy for economic capacity. The Scientific Technological and Capacity Index (Wagner et al., 2001) was used as an indicator of scientific capacity. This index categorizes countries into four groups of unequal sizes: advanced (n=22), proficient (n=24), developing (n=22), and lagging (n=80). In the present study, an additional group (“other”) is added to account for the 66 countries that were not placed in the Wagner et al. (2001) classification.

Full-counting is used to attribute the credit to authors for collaboration and mobility. Thus, the sum of publications and authors exceeds the total number of publications. From these data, we calculate the following indicators:

- total number of publications per country (# papers);
- position in the ranking of the number of publications at the international level (Rank # papers);
- number of publications with international collaboration (#papers in international collaboration);
- proportion of papers with foreign partners (% international collaboration);
- number of countries involved in international collaboration (# collaborators countries);
- percentage of countries reached in international collaboration with respect the total number of potential collaborators (% collaborators countries);
- number of authors per country (# authors),
- number of international mobile authors per country (# authors in international mobility);
- percentage mobile authors with respect the total authors (% mobile authors);
- number of countries with mobility connections (#mobility countries),
- percentage of countries reached in international mobility with respect the total number of potential countries (% mobility countries);
- ratio of the proportion of collaborators countries among all potential collaborators;
and the proportion of the countries with mobility connections among all potential countries (Ratio collab-mobil). For example, Yemen is collaborating with 109 out of 212 countries reaching around 50% of potential collaborators, at the same time is reaching around the 12% of potential mobile connections. That means that Yemen multiplies by four the number of countries in collaboration respect those with mobility (Table 1).

To measure the asymmetry in collaboration and mobility patterns, we use a pair of inclusion indexes, $AFI(i,j)$, and counterpart, $AFI(j,i)$, with one-way normalization. AFI is a measure of the links between a given country (i) with another country (j), compared to the total links country (j) with the entire world during the same period. $AFI(i,j)$ is calculated as:

$$AFI(i,j) = \frac{n(i,j)}{\sum_j n(i,j)}$$

where $n(i,j)$ is the volume of links between countries i and j. This index is size-dependent given that the preference for partner j in $AFI(i,j)$ is influenced by the global size of j (conversely, preference is dependent upon the size of i for $AFI(j,i)$). This index highlights the important partners in terms of quantity and demonstrates the asymmetry in partnership.

To normalize by the size of both countries, we employ the Probabilistic Affinity Index (PAI), widely used in science policy to demonstrate the degree to which proximity (both material and immaterial) contributes to scientific relationships among the countries (Zitt et al., 2000). The index is capable of demonstrating strong relationships with small countries and presents the strength of relationships in their global context. For PAI, we refer to Zitt et al. (2000)’s algorithm and apply it to calculate the relationships between countries for both collaboration and mobility:

$$PAI(i,j) = \frac{[n(\ldots)n(i,j)/n(i)n(j)]^2 - 1}{[n(\ldots)n(i,j)/n(i)n(j)]^2 + 1}$$

where $n(i) = \sum_j n(i,j)$ and $n(\ldots) = \sum_{i\neq j} n(i,j)$. PAI is normalized into [0,1] in order to make it comparable with AFI.

Each indicator yields a different lens on the international portfolio of a given country. The affinity index reveals asymmetries, demonstrating that collaborations with country i might constitute a large portion of the total collaborations of country i, but a small proportion of the collaborations of country j. It simultaneously provides an indicator of the main collaborators in the global network. PAI, on the other hand, highlights the strengths of countries that might not have high output, but have disproportionately strong connections in the global environment. We present, for both collaboration and mobility, the 50 main and preferred partners for the countries in our sample, according to the AFI and PAI.

**Results**

**Overview of collaboration and mobility**

The seven countries differ in both economic and scientific dimensions. Iran, Iraq, and Libya are economically considered as upper-level income countries, whereas Sudan, Syria, and Yemen are in the lower-middle income bracket for countries. Somalia is in the lowest income level. Somalia is also distinct in terms of the profile of scientific output and the size of the scientific workforce—having the lowest of both for the seven (Table 1). Iran is the most prolific country in the set—contributing 1.8% of the share of world publications, placing it in 17th place worldwide in terms of scientific output. The next most productive country in the set is Iraq, which is ranked 82nd globally in terms of production and produces 0.05% of the world output.
The general international profile of the countries also differs—nearly all publications from Somalia are authored with an international partner, whereas only a fifth of publications from Iran are the result of international collaboration. Iran and Sudan have the widest collaboration portfolios in terms of number of international partners—reaching 76 and 75% (respectively) of potential collaborative partners in this dataset. Somalia has the fewest, reaching less than 20% of potential partnerships, likely as a result of the low output.

Mobility provides a different lens on international partnerships. For example, Iraq has one of the lowest rates of collaboration, yet nearly half of the researchers in Iraq have some degree of mobility and reaches nearly a quarter of all potential partners. Iran is the only country that remains stable across the two lists—appearing as both the least collaborative and the country with the lowest percentage of mobile researchers. However, even with the lower degree of mobility, it still reaches nearly 40% of potential mobility countries, second in this set only to the United States (at 88%). These results suggest that collaboration and mobility indicators present different images of the international profiles of countries. A comparison of the indicators suggests that mobility is a more selective indicator: in all countries, the ties between collaborative countries is higher than the ties established through mobility. In a way, mobility is a costlier (particularly from a human, social and economic point of view) event than collaboration, thus explaining the prominence of collaboration over mobility.

The dominant partners for both collaboration and mobility are scientifically “advanced” countries (Table 2). Yemen is an exception, collaborating predominately with “lagging” countries. All countries have a demonstrable share of connections with lagging countries, when compared to “developing” and “proficient” countries showing homophily in their international relationships.

Western Europe is also a dominant partner, but with some exceptions (Table 3). For example, the plurality of Iraq’s mobility and collaboration partners come from the Middle East. Somalia’s mobility is limited to Africa and Asia; and Sudan and Yemen have mobility largely with Asian countries.

Country-specific analysis

**Iran.** High producing and advanced countries, such as the United States and Canada, lead in terms of the top connections for both collaboration and mobility, when considering the AFI for Iran (Figure 1A). For example, Iran publishes more than 22% of internationally-collaborative publications with the US and 20% of Iranian researchers (those for whom their first publication was in Iran) have been affiliated with the US. However, Iran also has a strong connection with Malaysia—a scientifically lagging country with upper middle income. Among the countries with the strongest ties, collaboration is stronger with the US, Germany, and the United Kingdom than mobility, whereas the inverse is true with Canada and Malaysia. Overall, using AFI as the measurement, Iran tends to have stronger relationships in terms of collaboration than mobility.

PAI presents a very different portfolio in terms of international connections. The strongest partners using this index include Azerbaijan, Malaysia, Armenia, and Iraq—reinforcing the importance of geographical, linguistic, and cultural ties. Canada also remains highly ranked according to this index. The United States, however, drops considerably in the ranking and the United Kingdom show a negative index in terms of mobility. As with AFI, the connection with the US on the PAI is stronger with collaboration than mobility. This preference is invariable across the 50 preferred partners for Iraq. Several countries have a very high probability index for collaboration, but negative ranks for mobility. These include several Latin American (i.e., Brazil, Mexico, Chile) and Middle Eastern (i.e., Pakistan, Saudi Arabia, Egyptian) countries. This may suggest potential avenues for mobility programs.

**Iraq.** Iraq collaborates with 115 countries and has researchers with mobility connections with 50, including Palau and Luxembourg, with whom there are no collaborations in common (Figure 1B). As measured with AFI, Malaysia captures the largest share of collaboration and mobility relations with Iraq, followed by the UK, the US, and China. Countries such as the US, Italy, Jordan, and Saudi Arabia have demonstrably higher AFI indexes in collaboration than mobility; however, for the most part there is an evenness in the collaboration and mobility patterns for Iraq according to AFI.

Taking into consideration all potential partners with PAI, the strongest relationships are with Malaysia, Kuwait, Brunei, Libya, Yemen, Afghanistan, Syria, Oman and Jordan (PAI 0.99 and 0.95 in collaboration and mobility). Among the most developed countries only the United Kingdom, Australia, and Sweden are preferred partners (with PAI values of 0.75 and 0.7 in mobility and 0.93 and 0.87 in collaboration). In contrast, Iraq shows low affinities with China, Germany, and the USA. This suggests that some scientifically developed countries located in...
Europe, the Pacific region, and Asia are acting as bridges of enhancing the connectivity of Iraqi science. As with Iran, the comparison between collaboration and mobility using PAI reveals gaps in partnerships. For example, Iraq has strong affinities for collaboration with Saudi Arabia and Israel (0.99 and 0.93, respectively), but no mobility. There are, of course, political explanations for these discrepancies, but the measurement provides a neutral way to identify communities that have demonstrated scientific affinities (i.e., through collaboration) which could be explored in further policy initiatives.

**Sudan.** As seen in Figure 2, Sudan has mobility with 46 countries (39%) and collaborates with 161 (74.5%), a similar figure to the one observed in Iran despite the difference in number of publications. In terms of size, Sudan’s main partners in mobility are Saudi Arabia, China, Malaysia, Germany, South Africa, the United Kingdom and the USA (5.5%); while the collaborative partners are different—the US is the top collaborative partner followed by Saudi Arabia, the United Kingdom, Germany, and China. Similar to Iran, collaboration tends to be much higher in all cases than mobility, as measured by AFI.

When correcting for size, the strongest partners are Eritrea, Bahrain, Brunei (in mobility, but not collaboration), Saudi Arabia, Malaysia, South Africa, Uganda, Yemen, Cote Ivoire, Ethiopia, Zambia, Oman, and Kenya. In the case of Sudan, neighbors and language matters in the strength of the relationships with the exception of Malaysia. The United States has a fairly high collaboration PAI, but is low in terms of mobility, similar to other advanced countries, such as France, Switzerland, and Canada. This may indicate avenues for potential collaboration between these advanced countries and Sudan, a lagging country.

![Figure 2. Main partners of Sudan (left A) and Syria (right B) in mobility and in collaboration according to AFI (top) and preferred partners in PAI (bottom).](image)

**Syria.** Nearly three-quarters of Syria’s output (71.2%) is the result of international collaboration, written in collaboration with 134 countries. More than a third of Syrian authors have mobility, linking Syria with 40 countries. As with Sudan, Syria does not have a parallel relationship between collaboration and mobility—the US, for instance, is highest in collaboration by AFI, but is ranked fourth by mobility. France, Germany, and the UK are strong partners on both dimensions. Across the top 50 countries, Syria has a pronounced emphasis on collaboration over mobility.

PAI again demonstrates the importance of socio-cultural factors in establishing collaborative ties. Syria’s preferred partners in this index include Yemen, Uzbekistan, Jordan, Afghanistan, Morocco, Lebanon, Ethiopia, Iraq, Sri Lanka, United Arab Emirates, Saudi Arabia, and Qatar. A second preferential zone is formed by European countries—including France, Turkey, Germany, Austria, the United Kingdom, Hungary, and Portugal. The US is not a preferred partner, demonstrating low degrees of mobility, despite fairly high levels of
collaborative affinity. Syria has several countries in its profile with extreme differences in affinity between collaboration and mobility, including Oman, Tunisia, Algeria, Pakistan, Serbia, Argentina, and Israel.

**Yemen.** Yemen collaborates with 109 countries and has mobility connections with 27 countries. (these are not entirely overlapping units, as there is mobility, but no collaborative publications with Madagascar). The strongest partners in terms of size include Malaysia, Saudi Arabia, and Egypt. By the AFI, the US is ranked fourth in terms of collaboration and sixth by mobility. Yemen demonstrates higher degree of collaboration than mobility by AFI.

There are stronger similarities between preferred partners by AFI and PAI. Using PAI, the strongest ties are with Syria, Malaysia, Saudi Arabia, Egypt, Qatar, and Sudan. When considering the entire global context, Yemen has several countries for whom there are less than expected values for both mobility and collaboration, including South Korea, Sweden, Canada, Japan, Australia, and Spain.

**Libya.** Libya has collaborative partnerships with 119 countries and mobility with 33 countries (including Lesotho, Kyrgyzstan, and the West Indies with which Libya has no collaborative papers). In gross volume, the main partners in collaboration are the United Kingdom, Egypt, France, India, Malaysia, and the USA (9.8% in collaboration and 2.3% in mobility). Collaboration is the dominant form of connection.

The preferred partners are Lebanon, Angola, Malaysia, Iraq, Serbia, Oman, Qatar, Finland, and Greece. The second zone of influence comprised the United Kingdom, United Arab Emirates, France, and India. The Unites States is not a preferred partner. Libya’s collaboration and mobility ties with many African countries are much lower than would be expected, given the global scientific network.

**Somalia.** Somalia has the lowest rate of publication across the seven countries, with collaborative ties with 40 countries and mobility ties with only two—Kenya and Malaysia. The US is the fourth most important partner in AFI, after Kenya, Malaysia, and the United Kingdom. Somalia is outperforming expected collaboration rates in all countries, but is underperforming expected values of mobility in all countries save Kenya and Malaysia.

**United States.** Given that our proof-of-concept study focuses on the relationship of the US with the seven countries in the executive order, it is necessary to also take an egocentric analysis of the US for context. The US has one of the lowest levels of international collaboration due to size and scientific capacity, but serves as the dominant collaboration for nearly all countries across the world. We provide both the top 50 connections, but also the countries in examination...
(the fact that these do not overlap suggests the comparatively weaker relationship between these countries from the perspective of the US). According to AFI, the strongest partners include (in order of importance) China, the UK, Germany, Canada, France, Italy, Japan, South Korea, and Switzerland. Collaboration rates are higher than mobility rates for all countries except for China and Iran, countries with the exception of China and Iran where the percentages are slightly higher (China: 18% for collaboration and 19% mobility; Iran 1% for both collaboration and mobility).

**Figure 4.** Main partners of USA in mobility and in collaboration according to AFI (top) and preferred partners in PAI (bottom).

When size dependence is removed, Israel is the main collaborative partner with the US, followed by China, South Korea, Tukey, Taiwan, Peru, Lebanon, Uganda, and Canada. Unlike the other countries studied, Malaysia is not a preferred partner. In the global market, the US is outperforming in terms of collaboration across all the countries. However, it has lower than expected values in terms of mobility with Pakistan, Belgium, Saudi Arabia, and Malaysia (within the top 50 counties) and with six of the seven countries (Iran is the exception).

**Discussion and Further Research**

This work presents a case study of the application of asymmetry and affinity measures to better understand the implications of migration policies. Using the countries suspended in the 2017 US executive order, we present an egocentric view of each country involved in order to analyze the strength and reciprocity of the relationships of each of the various countries with the US and with other preferred partners. Although affinity indexes have long been used to analyze international collaboration, this is the first analysis to explore the insights gained when mobility and collaboration are analyzed in parallel. For the case under study, we demonstrated an asymmetrical relationship between each of these countries and the US—the US was a dominant country in terms of collaboration and mobility for the seven countries, though they represented a small fraction of the share of US scientific relationships. Of the seven, Iran was the most important scientific country for the US, with higher than expected amounts of collaboration and mobility. Across the countries, Malaysia was a consistently preferred partner—a particularly striking relationship given the low affinity between the US and Malaysia.

Internationalization of science affects the research performance of countries and in certain degree depends on the attractiveness of a partner in the global network. The country with which the scientific relationship is established is important for indicator construction,
given unequal magnitude of contributions between partners. The results of this study demonstrate that, despite the low volume of international publications and mobile researchers for many countries, the number of countries reached is relatively high. This internationalization presents policy challenges and opportunities, particularly for developing and lagging countries that are simultaneously confronted with critical internal conditions that often isolate them from countries with high scientific capacity. Despite these barriers, international collaboration seems to respond to the dynamics created by the self-interests of individual scientists rather than to other structural, institutional, or policy-related factors (Leydesdorff & Wagner, 2008). This is evident in the degree of internationalization of the countries in our sample.

Previous studies have revealed different drivers underlying the formation of collaborations networks such as geographical and cultural proximity, thematic similarity, regional partnership, as well as the reputation and attractiveness of the receiving partner (Zitt, Bassecoulard, & Okubo, 2000; Archambault, Beauchesne, Côté, & Roberge, 2011; Adams et al. 2014; Finardi & Buratti, 2016). Our results confirmed these pre-existing notions: AFI demonstrated the asymmetries and preferential attachments to countries with high reputation and scientific capacity. PAI reinforced the importance of geographic and linguistic proximity. Large countries, like the US, have extremely high breadth across the scientific network—serving as a collaborative partner with all and a mobile partner for many. Smaller countries, in turn, rely upon international collaboration for a large share of their output. However, there is a distinct lack of reciprocity in terms of mobility. Whereas there are established scientific similarities, on the basis of patterns of collaboration, this does not necessarily lead to increased mobility. Mobility, therefore, is a more selective indicator; while collaborations can be established without colocation, mobility—even in the case of co-affiliation—(i.e., researchers with a double appointment with two or more international institutions but keeping ties with their country of origin) often requires some degree of travel and human interaction, having a higher social, human, and economic cost. Mobility is thus likely to be heavily influenced by political environments. Given that the countries in our sample have experienced embargos, invasions, civil wars, and revolutions in the course of the time period under investigation, these are likely to have influenced mobility rates (Moed, 2016).

Scientific relationships are highly resource-dependent (Pouris & Ho, 2014). However, our analysis has demonstrated the potential utility of combining collaboration and mobility indicators to identify preferred partners, inform policies, and identify potential areas for establishing mobility programs. This method could be extended to multiple levels of analysis, for example, to the institutional level, to examine intra- and inter-national collaboration networks. Further research should investigate the degree to which mobility and collaboration initiatives are successful in facilitating relationships between partners, particularly those that are not already established as preferred or dominant partners, and how to enhance the attractiveness of countries in the global scientific system.

**Limitations and further analysis**

This study requires further analysis in order to overcome some of the limitations and respond to other important questions related to the capacities and influences of countries in science. The data examines only those authors whose first publication occurred in or after 2008. This provides only limited diachronic analysis. More data and analysis are necessary to further inform a longitudinal analysis of collaboration and migration patterns, especially due to the inflationary effect on the traditional measurements of collaboration based on affiliations, that creates some overlaps when we are comparing collaboration and mobility. There is a major general limitation of collaboration analysis based on author affiliations and further analysis should be done to minimize this effect. In further research, we intend to complement our analysis with a time component, allowing us to analyze some key points such as authors’
choices regarding institution address selection from publication data. This will facilitate the analysis of causal relationships, examining the relationship between collaboration and migration as well as the effects of policies and political action (Hottenrott and Lawson, 2017). We also plan to analyze positions occupied in the bylines of co-authorship, the impact of publications as a result of these relationships, the institutional reputation of destinations, and the degree to which topic changes occur as a result of these interactions. At the methodological level, approaches with different counting methods (Perianes-Rodríguez et al., 2016) and scale-adjusted metrics will be explored in order to assure an accurate comparison of relational capacities of countries with different sizes and capacities (Archambault et al., 2011; Finardi & Buratti 2016). There are also several other elements, such as the thematic specialization of science, which should be taken into account when analyzing collaborative preferences between countries (Glanzel 2000; Radosveic & Yoruk 2014).

Abstract
With the continuous deepening and development of scientific collaboration, relationships within the scientific collaboration network are becoming more and more complex, exhibiting symbiotic characteristics. From the viewpoint of symbiosis, we examine the typical teacher–student relationship using social network analysis. We study the network characteristics of this typical form of collaboration based on the resultant published research papers, considering the contribution of symbiosis in the scientific collaboration index to analyze the evolution of the symbiotic relationship between collaborative objects. The results indicate that the symbiotic relationship between teacher and student shows obvious variations from the “old leads young” model; young researchers draw support from the teacher’s resources to improve their own level of scientific research with continuous progress and development. Moreover, the collaborative symbiosis degree between teacher and student changes with time.

Conference Topic
Social network analysis; Studies on the level of individual scientists

Introduction
Scientific research collaboration has become a significant feature and an important driving force in today’s scientific development; scientific collaboration is conducive to the realization of knowledge complementarity, resource integration, and interdisciplinary research. Scientific collaboration exhibits new features as the relationship between the collaborative subjects continuously deepens and evolves. However, scientific collaboration has transformed from the early point-to-point collaboration and chained collaboration pattern to the complex collaboration network mode, which resembles biological symbiosis between the collaborative subjects. This has prompted us to develop a theoretical framework and model to describe and explore this new scientific collaboration. Currently, interest is mostly focused on the network characteristics of scientific collaboration, and network theory has been used to study the structure and evolution of scientific collaboration. However, network theory can only reveal the external characteristics of scientific collaboration and does not consider the intrinsic motivation for the collaboration itself. On the contrary, symbiosis theory provides us with the appropriate perspective. Modern symbiosis theory is no longer confined to biology and has been extended to the fields of economics and social sciences, where it has been used to explain enterprise symbiosis relationships, industry–university–research symbiosis networks, etc.
In the era of big science, scientific collaboration has become the main pattern of scientific research; thus, research on scientific collaboration has also emerged steadily. After the twenty-first century, new research has been emerged in the field of scientific collaboration. Social network techniques and bibliometric indicators have been applied in the field of scientific collaboration (Hou et al., 2013). In fact, Newman’s publication on this subject has aroused widespread concern, reaching 1790 citations as of April 27, 2017. Newman used the Medline database to investigate the structure of scientific collaboration networks in biological medicine, physics, and computer science. The results show that scientific collaboration exhibits high clustering properties; the co-author network presents a typical small-world phenomenon (Newman, 2001) (reference [16]). Newman regarded that when constructing a collaboration network, authors of joint publications have an associative relation; in fact, this association definition is widely used in the research of scientific collaboration network. Research on structure of scientific collaboration using bibliometric indicators published by Glanzel (2002) received continued attention. Afterwards, bibliometric indicators, such as the number of papers, average number of authors, number of collaborators, maximum size of the scientific collaboration team, and aggregation degree, have been widely applied in the research of scientific collaboration networks (Cavusoglu & Turker, 2014; Wang et al., 2015). Social network analysis has been proven to be very effective for analyzing and visualizing co-authorship networks (Huerta-Barrientos et al., 2014; Otte & Rousseau, 2002; White, 2003; Kretschmer & Aguillo, 2004). Subsequently, complex network analysis methods were used for investigating the structure of scientific collaboration networks. Ding (2011) combined topic modeling and path-finding algorithms to study the collaboration and citation tendencies of productive authors in the field of information retrieval.

Research on the structure of scientific collaboration networks is a frontier subject in the field of scientometrics. Egghe (2003) and Newman (2001) studied scientific weighted collaboration networks and indicated that the distribution of weights reflects the activity of academic exchanges in this field; specifically, they noted that active scientists tend to collaborate with or aid other active scientists. Qiu et al. (2014) utilized the frequency statistical method for the first time to construct a network of the collaborative age of scholars in the field of informatics. Homophily and preferential attachment are two common mechanisms in a network’s evolutionary process. For these mechanisms, Wang and Zhu (2014) observed a simultaneous change in the regulations in the evolutionary processes of a scientific collaboration network and revealed that there are random selection, restrictive selection, and active selection features of collaborative links in the early, middle, and final stages of the evolution of collaboration networks respectively. Chen et al. (2013) analyzed the evolution of co-authorship networks in the journal Scientometrics from the micro and the macro angle.

The concept of “symbiosis” was first proposed by a German biologist named Anton de Bary in 1879; this concept was associated with survival needs, where two or more organisms gradually form a symbiotic relationship of coexistence and coevolution.
based on a particular pattern of interdependence and interaction. Yuan (1998) referenced the concept of symbiosis and developed related theories. He constructed the framework of “symbiosis theory” in economic analysis, using symbiosis theory research to solve practical economic problems in China and get some new ideas, perspectives, and methods. In recent decades, symbiosis theory has been gradually extended to the field of Social Sciences and Management Science and has achieved initial success, resulting in some research hotspot such as “the industrial symbiosis network” (Wang et al., 2005; Albino et al., 2015; Domenech et al., 2011), “enterprise cluster symbiosis” (Wang et al., 2006), and “the industry–university–research symbiosis network” (Feng et al., 2013). In the background of highly integrated knowledge, using symbiosis theory to investigate the characteristics of academic collaboration is also an innovative and challenging work. Shi et al. (2013), from the perspective of symbiosis theory, using the methods of literature research, social network analysis, mathematical statistics, and quantitative analysis, analyzed the inter-provincial cooperation mechanism and the regional characteristics of sports scientific research in China. Smith (2011) performed a quantitative analysis of citations from Wikipedia articles to documents in institutional repositories and revealed a potential symbiotic relationship between Wikipedia and academic research in the institutional repository. However, other research have not been found for the measurement of the scientific cooperation based on the symbiotic theory. These previous findings on the structural characteristics and evolution trend of scientific collaboration networks obtained via social networking techniques are quite relevant to the scope of the present research. However, the symbiotic relationships within the framework of scientific collaboration have not been investigated. In scientific collaboration relationships, there is a complementarity between the partners regarding knowledge, expertise, and resources. Therefore, there is the possibility of “symbiosis”. It is of great theoretical and practical significance to reveal the structure and evolution of scientific collaboration networks from the perspective of symbiosis. In this study, we reveal the scientific symbiosis network structure and its evolutionary trends using the symbiosis degree index by analyzing the scientific collaboration symbiotic relationship between academicians of the Chinese Academy of Sciences and their collaborators.

Data and Methods

Data
The academicians of the Chinese Academy of Sciences represent the highest academic level of Chinese scientists, play an important role in the development of the country and its society, and enjoy high social prestige. In a preliminary work, we studied the characteristics of a scientific collaboration network between academicians and found that there was a long-term and stable partnership between academicians and between academicians and non-academicians (Liu et al., 2015). Especially, in terms of the teacher–student relationship, the collaboration between Li Shushen and Xia Jianbai is the most typical example. The scientific collaboration between the two academicians lasted more than 15 years, and they co-authored at least one paper every
year. Thus, we firmly believe that their scientific collaboration showed symbiotic characteristics.

The official website of the Chinese Academy of Sciences provides the basic information of the academicians, such as gender, date of birth, place of origin, time of election, work units, as well as their main fields of research experience and award-winning situations. We selected the Web of Science database as the paper search source database. Using the full names and the abbreviations of the English names of the academicians, We can get their SCI publications. After that, the search results were screened manually according to their institutions, research areas, and other information regarding their published works to acquire the exact number of all their publications.

In this study, we choose Li Shushen and Xia Jianbai to investigate the teacher-student collaboration pattern (shown in Table 1). They are academicians of the Information Technology and Science Department, have been working at the Institute of Semiconductors of the Chinese Academy of Sciences, and have maintained long-term and frequent collaborative relations. Xia Jianbai obtained his master’s degree from the Department of Physics of Peking University in 1965, and he was elected as an academician of the Chinese Academy of Sciences in 2001. Li Shushen received his doctor’s degree from the Institute of Semiconductors of the Chinese Academy of Sciences in 1996, and he was elected as an academician of the Chinese Academy of Sciences in 2011. They published their first co-authored paper in 1994, when Li Shushen was a Ph.D. student at the Institute of Semiconductors; thus, this paper affirms that their relationship was a collaboration between teacher and student. For the next 20 years, they maintained a collaborative relationship without interruption. Here, we define this cooperative relationship as the symbiosis relationship. So is there any significant change in the symbiosis degree of scientific collaboration between a teacher and student in long-term collaboration? In this paper, we perform an empirical analysis on the symbiotic relationship between teacher and student in the form of collaboration.

Measurement of symbiosis degree

Symbiosis is a self-organizing process, wherein mutual understanding and collaboration are established between the symbiotic units; moreover, there is complementarity and interdependence in terms of material resources, information, and energy. In biology, symbiosis is considered one of the fundamental mechanisms leading to species innovations that trigger species evolution. In sociology, this symbiotic relationship promotes economic innovation, technological innovation, and institutional innovation. From the viewpoint of scientific collaboration, a
complementary relationship exists between knowledge, expertise, and resources among the collaborative subjects. The scientific collaboration relationship is a symbiotic relationship because there is continuous exchange of information and transmission of knowledge, which evolves with the collaboration. This produces not only new knowledge units but also new symbiotic forms, thereby transforming the collaboration structure. Therefore, scientific collaboration is the practical response to the symbiotic relationship between the subjects.

Chunqing Yuan explicitly put forward the theory of symbiosis in 1998, which distinguishes four types of symbiotic relationships based on the subjects’ behavior patterns: parasitism, commensalism, symmetrical mutualism, and asymmetric mutualism. In this paper, we borrow the symbiosis degree index from symbiosis-degree analysis, which is generally applied in biology research to determine the behavior pattern between the selected symbiotic subjects (A and B) in different periods. To ensure a continuous and uninterrupted collaboration relationship between the two symbiotic subjects, the following two criteria were followed when choosing the subjects: (1) the two scientists collaborated for more than 15 years, and (2) they maintained close collaboration, that is, they published at least one co-author paper once a year. Based on this, we defined the scientific collaboration symbiosis degree \( R_i \) of symbiotic individuals in the period \( i \), which is represented as

\[
R_i = \frac{(y_{i+1} - y_i)/y_i}{(x_{i+1} - x_i)/x_i},
\]

where \( x_i \) is the number of joint achievements of the symbiotic subjects A during the collaboration period \( i \) (i.e., the number of collaborative papers published, the number of co-citations, etc.), and \( y_i \) is the total number of achievements of the symbiotic subjects B in the scientific research during the period \( i \) (total number of papers published, the number of citations, etc.). The formula reflects that the rate of change in all the achievements of a scientist (total number of papers published or total citations) depends on the rate of change of the joint contributions (the number of co-authored papers or joint citations) that are obtained through scientific collaboration. Therefore, it reveals the roles of scientific collaboration in terms of the academic output (number of papers) or influence (cited frequency) of an academician. The symbiosis degree contributing to the scientific collaboration indicator reflects the extent of the benefit of the collaboration to the scientific research symbiotic subjects as well as the extent of the dependence of the symbiotic subjects on the collaborative relationship. Here, the number of individual publications and the citation frequency represent an individual’s research productivity and influence respectively. When \( x_i \) represents the number of papers, \( R_i \) represents the degree to which the symbiotic relationship contributes to scientific productivity. When \( x_i \) represents the citation
frequency, $R_i$ represents the degree to which the symbiotic relationship contributes to scientific influence.

The extent of dependence of the two symbiotic subjects (A and B) on the scientific collaboration in different periods is calculated using the symbiosis degree index ($R_a$ and $R_b$, respectively). Table 2 presents the four types of symbiotic relationship established between A and B under different conditions.

<table>

</tr>
<tr>
<td>$R_a = R_b = 0$</td>
<td>No symbiotic relationship</td>
<td>The two symbiotic subjects develop independently</td>
</tr>
</tbody>
</table>

In addition, owing to the limitations of the actual situation, it is unlikely that $R_a = R_b$. Under normal circumstances, there is probably a difference between the experimental value and the theoretical value; this error falls within a limited range, that is, we consider the experimental value and the theoretical value to be almost equal. In this paper, we borrow the relevant concepts of probability and statistics; moreover, when $0.95 < \frac{R_a}{R_b} < 1.05$, we consider that the values of $R_a$ and $R_b$ are relatively close and there is a symmetrical mutualistic symbiotic relationship between A and B.

**Empirical analysis**

*Evolution characteristics of the collaborative symbiotic network between a teacher and student*
Based on the collected data, we use the Thomson Data Analyzer (TDA) to clean the data, extract the author’s information regarding all the papers, and then create the collaboration matrix between the academicians after further processing. Ucinet is used for the network index analysis and for drawing the co-authorship network map at each time point. Figure 1 shows the collaboration network between academicians Xia Jianbai and Li Shushen. In this figure, we observe that the two academicians had their own collaboration networks in different periods and maintained a strong collaborative relationship. In Figure 1, the reason why such a division of the time period between teacher and student, based on before and after teacher and student elected as academicians, taking every five years for a stage. The teacher Xia Jianbai was elected as an academician in 2001, the student Li Shushen was elected as an academician in 2011, so we take 2001 and 2011 as the dividing point to explore the teacher-student symbiotic relationship changes before and after they elected as academicians.

Figure 1. Scientific collaboration network between Xia Jianbai and Li Shushen
After conducting centrality analysis of the collaborative relationship between the two academicians, the centrality of the network is obtained by ranking the top five co-authors, as shown in Table 3. After analyzing the data, we can conclude that in the collaboration network, the centrality degree of Li Shushen is higher than that of Xia Jianbai and that the closeness centrality and betweenness centrality of Xia Jianbai are higher than Li Shushen’s. Thus, it can be seen that young academicians have a certain advantage in the number of papers published; however, old academicians are stronger than the young academicians in the important role of the overall collaborative relationship and the utilization of the overall resources of these two aspects. At the same time, another researcher Li Jingbo maintained a close collaboration with these two academicians. Investigating Li Jingbo’s academic background, we found that he also worked at the China Institute of Semiconductors. In 2001, he was awarded his doctor’s degree from the China Institute of Semiconductors. In 2007, he was selected by the “Hundred Talents Program” of the Chinese Academy of Sciences. In 2009, he won the “National Outstanding Youth Fund” and many other honors.

Collaborative symbiotic relationship between a teacher and student

Did the symbiotic relationship between the two academicians remain immutable in the past 20 years? To explore the evolutionary process of the symbiotic relationship between the two academicians, we compare the scientific collaboration symbiosis degree indices (number of co-authored papers and joint citation frequency). For Li Shushen and Xia Jianbai, we obtain the SCI datasets pertaining to their published papers and select all the SCI papers co-authored by the two academicians. Then, we examine the time-series distribution of the number of collaborative papers and the joint citation frequency of the two academicians for the last 20 years (Table 4). Both indices gradually increased, reaching a peak in 2006–2010; then, they decreased.

</tbody>
</table>

Based on the above statistical results, the number of papers represents the scientific research productivity of the academician, and the citation frequency represents the scientific research influence. We calculate the symbiosis degree of scientific collaboration productivity and influence of the collaborative papers of the two academicians in five periods between 1994 and 2014 (Tables 5 and 6, respectively). In these two tables, $R_1$ represents the symbiosis degree of the scientific collaboration of Li Shushen, and $R_2$ represents the symbiosis degree of the scientific collaboration of Xia Jianbai.

Figure 2 shows the histogram of the symbiosis degree of collaborative productivity between teacher and student; the abscissa represents the time in years, and the ordinate represents the size of the symbiosis degree of productivity indicator based on the analysis of the symbiosis degree of collaborative productivity. In 1994–1995, $R_1 > R_2 > 0$, which reveals that there is an asymmetric mutualistic symbiosis relationship between the two academicians and that there is a large difference in terms of dependence on the collaboration between the two academicians. The student relied on the collaboration in the initial academic stage; collaborative papers contributed more to Li Shushen’s scientific productivity. In 1996–2000, $R_2 > R_1 > 0$, which indicates that the two subjects were both more dependent on the collaborative relationship; their relationship transformed to an asymmetric mutualistic symbiotic relationship. Although there are some differences between the two academicians in terms of the extent of their dependence on the collaboration, the differences is not too large, and their academic collaboration proceeded harmoniously. In 2001–2005, $R_1 > 0 > R_2$, which indicates that the collaborative relationship between the two academicians in this period was beneficial to the scientific research output of Li Shushen; however, there was no advantage for the scientific research output of Xia Jianbai. After the teacher was elected as an academician, the student became more dependent on collaboration with the teacher. Therefore, the symbiotic relationship between the two academicians at this time is of the form of commensalism. In 2006–2010, $R_2 > R_1 > 0$, which indicates that there was a certain dependence on the collaborative relationship between the two academicians at this time. There is a difference in the dependence on the collaboration between the two, but this is not large, and the degree of dependence is small; the relationship between the two is an asymmetric mutualistic symbiotic relationship. In 2011–2014, $R_2 > R_1 > 0$, which indicates that Xia Jianbai had a stronger dependence on the collaboration. There is a big difference between the two subjects in terms of the degree of dependence on the collaboration; the teacher had a strong dependence on the collaboration with the student in the later period of his academic career, and the relationship between the two is an asymmetric mutualistic symbiotic relationship.

</tr>
</tbody>
</table>

Figure 2. Symbiosis degree of collaborative productivity between teacher and student

Figure 3 shows the histogram of the symbiosis degree of collaborative influence between the teacher and student, where the abscissa indicates the time in years, and the ordinate indicates the value of the symbiosis degree of the influence indicator. In 1994–1995, \(R_1 > R_2 > 0\), which indicates that there is an asymmetric mutualistic symbiotic relationship between the two subjects. As in the case of the symbiosis degree of productivity of their collaborative papers, there is a big difference between the two subjects in terms of their dependence on the collaboration, and the citation frequency produced by collaborative papers contributes the most to the influence of the published papers of young Li Shushen. In 1996–2000, \(R_1 > R_2 > 0\), which indicates that the two subjects have greater dependence on the collaborative
relationship, i.e., $\left| \frac{R_2}{R_1} \right| > 0.95$. There is a difference between the two in terms of their dependence on the collaboration; however, this is only 0.003, close to the symmetric mutualistic symbiosis state. In 2001–2005, $R_1 > 0 > R_2$, which indicates that during this period, the collaborative relationship between the two was beneficial to the academic influence of Li Shushen, but there was no advantage to the academic influence of Xia Jianbai. After the latter was elected as an academician, his student became more dependent on their collaboration; their symbiotic relationship was of the form of commensalism. In 2006–2010, $R_1 > R_2 > 0$, which indicates that the two have a certain dependence on the collaborative relationship during this period, i.e., $\left| \frac{R_2}{R_1} \right| > 0.95$. The difference in the dependence between the two is 0.02, which is very small. Thus, we consider that their relationship is a symmetrical mutualistic symbiotic relationship. In 2011–2014, $R_1 > R_2 > 0$, which indicates that the subjects have a certain dependence on the collaborative relationship, i.e., $\left| \frac{R_2}{R_1} \right| > 0.95$. In terms of influence, there is a small difference of 0.04 between their dependence on the collaboration. Thus, their relationship may be characterized as a symmetrical mutualistic symbiotic relationship.

Xia Jianbai was elected as an academician in 2001. In 1996–2000, the two scholars maintained a high degree of symbiosis in their scientific collaboration, indicating that the two scholars who were elected as academicians were dependent on each other through scientific collaboration to improve their academic productivity and influence. In 2001–2005, Xia Jianbai was elected as an academician. Li Shushen had not been elected yet. At that time, Li Shushen relied more on Xia Jianbai, who was an academician, and their collaboration was more beneficial to Li Shushen, who was not elected as an academician.

</tbody>
</table>
From the above-mentioned example of a collaborative symbiosis between a teacher and student, we can see that the change in the number of collaborative papers affected the scientific research productivity of the two academicians. The young academian was more likely to benefit in 2001–2005, whereas in the other periods, the relationship between them was an asymmetric mutualistic symbiotic relationship. When they were in the initial stage of their collaboration, the young academian was more likely to benefit. However, with time, in the later stage of their collaboration, the old academian relied on the young academian to some extent. The number and the citation frequency of their collaborative papers have different impacts on the total number and the total citation frequency of the research papers of the two academicians; the symbiotic relationship between the two academicians appears to have varied in degree over time.

**Conclusion**

In this paper, we examined scientific collaboration structure between a teacher and student from the viewpoint of symbiosis by constructing the scientific research collaborative symbiosis network between them and analyzing the evolution of their symbiotic relationship and its effect on their productivity and influence. The following conclusions are drawn from this empirical analysis: (1) In a collaborative
symbiosis network between a teacher and student, the old leads the young, i.e., the young researchers draw support from the teachers’ integrated resources to improve their levels of doing scientific research, stepping forward unceasingly and growing. (2) In a collaborative symbiosis network, apart from the two symbiotic subjects, the other collaborators play an important role through their scientific achievements and academic status. (3) The degree of collaborative symbiosis between the teacher and student has obvious characteristics of alienation with time; at the beginning of their collaboration, the student relies more on the collaboration, whereas later on, the teacher’s reliance on the collaboration becomes greater than the student’s.

This study can serve as a reference for exploring the structure and characteristics of the symbiosis network of scientific collaboration and optimizing the selection of scientific partners in the process of scientific research. Firstly, in the process of scientific research, we should pay attention to the collaboration between teachers and students; the teachers’ driving effect on the students should not be underestimated. Secondly, scientific celebrities can produce significant knowledge spillover effects, striving for more resources for the field they belong to and contributing to the overall output growth in this field, which facilitates the other scientists to engage in research more effectively. In future research, we believe that the symbiotic relationship between two collaborative symbiotic subjects can be extended to the study of the symbiotic relationship of the ternary structure, further expanding the research objects and scope of the study and providing more data on symbiotic relationships in scientific collaboration.

The limitations of this paper are as follows. Firstly, this paper only chose Xia Jianbai and Li Shushen as an example of the symbiotic relationship between teachers and students. In later studies, we will continue to expand the number of research sample and the research field to make the research results more general. Secondly, we will study the interdisciplinary or multidisciplinary collaboration between scholars contrasting with symbiotic collaboration research. Thirdly, this paper only explores the changes of the symbiotic relationship between teacher and student before and after they elected as academicians respectively. In future research, we will consider matching the symbiotic relationship types with career stages, for instance, the PhD period, the Postdoc period, the first years at Assistant Prof. level etc.

Acknowledgments
This research received the financial support from National Science Foundation of China: Study on the Structure and Evolution of the Scientific Collaboration Network of Academicians from the Perspective of Symbiosis: A Case Study of Academicians of CAS and NAS under grant number 71603015. Our gratitude also goes to the anonymous reviewers for their valuable comments.

Abstract
Based on the Essential Science Indicators (ESI) database, this study analysed 2140 highly cited papers (HCP) and 4499 authors of these articles in the field of Economics and Business. By ESI definition, the HCP are those in the top 1% of the rankings. This study defines a 'top scientist' as one with at least 5 HCP and determined that there were 76 top scientists in the period 2005-2014, among which 46 researchers (60.5%) were from the USA. The results show a significant positive correlation between HCP and h-index of these top scientists. The study also found that the collaboration network among these top scholars is not very close, but a relatively tight subnetwork with 13 top scientists has formed.

Conference Topic
Studies on the level of individual scientists; The application of informetrics on evaluation

Introduction
Analysing the most influential scientists is one of the hot issues in research on the level of individual scientists. Many scholars have carried out extensive research into such topics including top scientists (Costas, van Leeuwen, & Bordons, 2012; Abramo, D’Angelo, & Soldatenkova, 2017; Charlton, & Andras, 2008; Baccini et al., 2012), core scientists (Furukawa & Goto, 2006), star scientists (Zucker & Darby, 1996), top researchers (Goodall, 2006; Miller, Coble, & Lusk, 2013; Lima et al., 2015; Kegen, 2015; Cortés, Mora-Valencia, & Perote, 2016), highly cited researchers (Clarivate Analytics, 2016), top authors (Walters & Arndt, 1999), and top scholars (Thieme, 2007). They have come to some valuable conclusions, but for the question of how to identify the top scientists, there are a variety of practices.

The current paper proposes that highly cited papers (HCP) can be used as a viable approach to distinguish the most influential scholars. In the Essential Science Indicators (ESI) database, HCP are those papers that rank in the top 1% by citation counts for field and year, using a time span limited to 10 years with bimonthly updates during the current year. The ESI database is based on over 10 million articles published in the more than 12000 journals included in the Web of Science database, and this database has become one of the most important tools to evaluate the academic influence of researchers, universities, institutions, and countries.
In this study, the ESI database was used to identify the top scientists in the field of Economics and Business. This paper proposes the criterion that top scientists should have at least five HCP. The paper is driven by the following questions:

Q1. According to the number of highly cited papers, who are the top scientists in Economics and Business? Which countries do they come from?

Q2. Is there a correlation between HCP and h-index of these top scientists?

Q3. Are there any collaboration networks among these top researchers?

**Methods and data**

We identified 2140 highly cited papers in the field of Economics and Business from 2005 to 2014 in the ESI database and then downloaded these papers from the Web of Science one by one. The ESI database is updated every two months. The data collection time was July 22 to 26, 2015, soon after the closest EIS update time on July 7, 2015. These 2140 HCP (two retracted publications were ignored) include 1899 articles (88.7%) and 241 reviews (11.3%). Figure 1 shows an increasing trend of HCP in Economics and Business during the period of 2005-2014. The number of highly cited papers increased from 140 papers in 2005 to 252 papers in 2014, an increase of 80%. The year that had the highest number of highly cited papers was 2013 with 259 papers, followed by 2012 with 257 papers, and 2014 with 252 papers. Regression analysis showed that HCP increased with the year of publication, with $R^2$ being 0.8863 and the regression model indicating significance ($p < .01$).

![Figure 1. Trends by year of highly cited papers in Economics and Business (2005-2014).](image)

When analysing the collaboration network among top scientists, this study used the software Sci². Based on Cyber Infrastructure Shell (CIShell), Sci² was developed by Katy Börner and his team in Indiana University (Sci² Team, 2009). As an open source software framework, CIShell is powerful for integrating datasets, algorithms, tools, and computing resources easily. Not only can Sci² determine statistics and carry out other analysis of data, but it can also detect many kinds of networks, for example, co-author networks and co-cited networks.

In calculating h-indices (Hirsch, 2005) of top scientists in Economics and Business, this paper used the Web of Science database. The scientists’ h-indices were collected in late October and early November of 2016. The data was from the Web of Science with the search tags of ‘AU = (a top scientist’s name) AND SU = (Business & Economics)’, and the time span was set as
2005 to 2014. After getting the scientists’ number of publications and citations and distinguishing the authors who have the same name, we could acquire their h-indices.

**Results**

**Ranking analysis**

Overall, there were 4499 authors who together published the 2140 highly cited papers. Considering that HCP means top 1% in citation rankings, this study looked for the top 1% of these HCP authors. It was determined that listed 76 scientists had at least 5 HCP (Table 1). Although the number of such scientists reached 1.6%, the lowest ranked author with 5 HCP is ranked 34th, which is in the top 1%. Thus, in this paper, a ‘top scientist’ is defined as one who had at least 5 HCP during the study period. J. J. Heckman, who won the Nobel Prize in 2000 for his pioneering work in econometrics and microeconomics, was the most productive scientist with 12 HCP, followed by A. Falk, L. Kilian, M. Lenzen, and M. W. Peng with 9 HCP each. There are 46 top researchers (60.5%) who come from the USA (i.e. doing their research in the USA). The Netherlands and England rank second with 5 top scientists each. Canada, Japan, and Hong Kong, China rank fourth with 3 top scientists each, followed by Australia, Austria, Germany, and Lithuania with two top scientists. Seven other countries, Belgium, Brazil, Finland, France, Italy, Norway, and Switzerland, have one top scientist each.

</table>
As to the h-index (Table 1), the best performance was by M.A. Hitt (h-index = 33), followed by S.A. Zahra (31), D. Acemoglu (29), A.M. Grant (28), S.A. Zahra (27), M.W. Peng (27), A. Shleifer (26), E.K. Zavadskas (26), T. Sueyoshi (26), J.J. Heckman (25), H. Aguinis (25), and F. Luthans (25). In Figure 2, scatter plots between highly cited papers and h-index are shown, and a positive correlation between these two factors can be roughly judged. The Spearman correlation coefficient between them is 0.242 (p < .05), which indicates that when evaluating the influence of scholars, the HCP and h-index are mutually supportive indicators. They are considerably useful evaluation methods.

Collaboration network analysis

Figure 3 demonstrates that the collaboration network among the 76 scientists is quite disconnected. There are 43 subnetworks: one subnetwork with 13 nodes (i.e. top scientists),
one subnetwork with 7 nodes, two subnetworks each with 3 nodes, 11 subnetworks each with 2 nodes, and 28 isolated nodes.

Figure 3. The collaboration network of top 76 scientists in Economics and Business (2005-2014).

Clearly, the largest subnetwork is in the middle of the graph with 13 nodes, which includes P. Havlik (7 HCP), H. Valin, (7 HCP), A. Tabeau (6 HCP), M. Von Lampe (6 HCP), H. Van Meijl (6 HCP), D. Willenbockel (5 HCP), D. Van Der Mensbrugghe (5 HCP), P. Kyle (5 HCP), G.C. Nelson (5 HCP), T. Hasegawa (5 HCP), S. Fujimori (5 HCP), C. Schmitz (5 HCP), and E. Heyhoe (5 HCP). They are strongly interconnected and, among them, the most cooperation was between P. Havlik and H. Valin, who have published 7 HCP together. These 13 scholars come from many countries: Austria (P. Havlik, H. Valin), Netherlands (A. Tabeau, H. Van Meijl), France (M. Von Lampe), Japan (S. Fujimori, T. Hasegawa), USA (P. Kyle, G.C. Nelson), Germany (C. Schmitz), Italy (D. Van der Mensbrugghe), England (D. Willenbockel), and Australia (E. Heyhoe). Their main research topics are socioeconomic, agricultural economics, climate change, land-use change, ecosystems, and sustainability.

Conclusions

In this paper, based on ESI database, 2140 highly cited papers and 4499 authors in Economics and Business were analysed. In accordance with the HCP rankings in which ‘high’ means top 1%, this study identified the 76 ‘top’ scientists as those with at least 5 HCP. Of these top scholars, 46 (60.5%) were from the USA. The Netherlands and England rank second with five authors, respectively. The number of top scholars in the other 14 countries was below three. Moreover, the study shows that there is a fairly strong correlation between HCP and h-index. The Spearman correlation coefficient between them is 0.242 (p < .05), which indicates that when assessing the individual’s impact, the HCP and h-index are mutually supportive approaches.
This study also finds that the collaboration network among these top scholars is not very close, and there are 43 subnetworks. However, the analysis revealed a relatively tight subnetwork with 13 top scientists: P. Havlik (7 HCP), H. Valin, (7 HCP), A. Tabeau (6 HCP), M. Von Lampe (6 HCP), H. Van Meijl (6 HCP), D. Willenbockel (5 HCP), D. Van Der Mensbrugghe (5 HCP), P. Kyle (5 HCP), G.C. Nelson (5 HCP), T. Hasegawa (5 HCP), S. Fujimori (5 HCP), C. Schmitz (5 HCP), and E. Heyhoe (5 HCP). Most of their research focuses on socioeconomic, agricultural economics, climate change, land-use change, ecosystems, and sustainability.

Abstract

The Web of Science subject categories constitute a ubiquitous standard partition of disciplines in the Web of Science database and many bibliometric analyses. Due to the classification of complete journal issues, they have been criticized as being too broad, while entailing substantial implications on normalization exercises. Several alternatives have been proposed, but due to the unknown ground truth no proposal has found widespread application. Furthermore an empirical analysis of the Subject Categories’ shortcomings on a comprehensive scale has not been conducted.

In this research-in-progress paper we thus measure the topical coherence of all Web of Science Subject Categories via an extensive clustering exercise including all articles indexed in the Web of Science between 2003 and 2012. This descriptive analysis will be supplemented by a regression analysis explaining the influence of several explanatory factors on the varying Subject Categories’ coherence levels.

Given the current state of the ongoing analysis, we can verify the coarseness of the Web of Science Subject Categories and additionally observe an increase in topical heterogeneity over time, which we will analyse in the upcoming regression.

Conference Topic

indicators, metrology, databases, methods and techniques

Introduction

Publication and citation indicators are usually normalized in order to compensate for different publication and citation behaviour. For bibliometric studies that are based on the Web of Science (WoS) the overlapping classification system of subject categories (SCs) as provided by the database producer is mostly used. Citation indicators such as the mean normalized citation score (Waltman, van Eck, van Leeuwen, Visser & van Raan, 2011) normalize the citation rate of a given publication body with expected values calculated on the basis of the subject categories. The observed values are therefore related to their subject contexts in order to ensure comparability.

The WoS SCs are often criticized within the bibliometric community, especially because the classification is not carried out at the level of the individual articles, but rather at the level of journals issues. This is generally considered to be relatively inaccurate, particularly regarding increasing interdisciplinarity (Gómez, Bordons, Fernández & Méndez, 1996). New journals are assigned to existing subject categories by partially manual, partially algorithmic methods on the basis of citation data (Leydesdorff & Rafols, 2009, Pudovkin & Garfield, 2002). These methods are not publicly documented.

In general, a wide range of alternative clustering and community detection algorithms is available (Kou, Peng & Wang, 2014, Subelj, van Eck & Waltman, 2016); theses algorithms can be based on a similarity measure between publications or entire journals. Different principles to infer the similarity have been proposed in the literature: they can be determined
either on the basis of citation data (usually bibliographic coupling or cross-citation) or the actual text (e.g. shared use of terms or phrases). In recent years, hybrid approaches combining citation and textual approaches were propagated (Thijs, Schiebel & Glänzel, 2013, Thijs, Zhang & Glänzel, 2015), as they compensate for both the lack of recall of the citation perspective and the lack of precision of the textual approaches.

While some comparative analyses of the WoS SC classification with alternative science maps based on inter-journal citation relationships have been proposed (Boyack, Klavans & Börner, 2005, Leydesdorff, 2006), these studies ultimately lack a gold standard to evaluate the diverse mappings. To partly address this issue and control for the randomness arising from the application of varying data sets, a comparative analysis of different methods on the basis of an identical data set is proposed in a current special edition of Scientometrics (Gläser, Glänzel & Scharnhorst, 2017). But without assured knowledge on the ground truth the benefit of entire alternatives to the proprietary SC classification (Glänzel & Schubert, 2003, Ruiz-Castillo & Waltman, 2014) cannot be assessed. Consequently none of these proposals have been adopted widely by the community until now, and the subject categories, probably due to their ubiquitous availability, are still the standard in the bibliometric community.

Nevertheless the subject categories of the WoS obviously vary in size and specificity. Van Eck, Waltman, Van Raan, Klautz, & Peul (2013) show evidence of heterogeneity within several medical subject categories along the dimensions of clinical and experimental research. Publications that are identifiable as experimental within the graphical representation exhibit higher citation counts. This finding poses, especially on the micro level, severe problems for the normalization with subject categories. However, due to its focus on medicine and a certain period of time, a comprehensive analysis on the subject is still missing, while being essential for an informed normalization in the computation of the MNCS and any percentile methods due to potential heterogeneous citation levels.

In this research-in-progress paper we analyse the topical coherence of the WoS SC classification via an internal clustering of articles within the SCs. By predominantly focusing on the subject-matter of an article we follow the general principle of scientific writing, namely progressing knowledge on a particular subject, and attach less value to diverging perspectives, which would result in a different partition of the articles (Wang & Rohe, 2016). The main research question is to what extent potential heterogeneities affect the normalization with SCs, whether more or less problematic areas of the classification with respect to coherence can be identified and how the phenomenon develops over time. Furthermore, we test approaches (such as citation autarky) to explain heterogeneous content structures with differing citation patterns within SCs in order to obtain informative background knowledge for any attempt to construct a more diverse alternative to the WoS SC classification.

**Method**

As stated, we assess the internal coherence of the WoS SCs by employing a hierarchical clustering approach and then by interpreting the number of resulting cluster as well as varying cluster specific citation levels as measures of coherence. Subsequently we analyse the observed level of coherence via explanatory factors. Consequently the clustering technique is not understood as resulting in a natural partition of the publications representing the unknown ground truth. It is rather applied as an operational measuring device (Dingle, 1950) to facilitate a valid comparison of the SCs’ internal coherence, because validating a representational measure with an unknown ground truth seems rather challenging (Hand, 1996). Indeed, the main interest of our work is a comparison of the operationally measured
coherence values across the SCs and a supplemental regression analysis explaining the influence of several explanatory factors on the varying SCs’ coherence levels.

To this end, we firstly define the relations among all articles in a particular SC and year according to their topical accordance and supply the resulting distance to the clustering algorithm. The subject-matter of an article is induced, albeit imperfectly, via the corresponding author keywords and reference list and we match any two articles based upon jointly applied author keywords and commonly referred literature (bibliometric coupling). Citations are predominantly understood as carrying cognitive information (Merton, 1957), marking concepts (Small, 1978) and consequently establishing a priority claim on the particular content (Kaplan, 1965). Given this perspective, citing a document might be understood as an act of acknowledgment and reward towards the cited document (Ravetz, 1971). Persuasive and perfunctory citations (Kaplan, 1965) diverge from this Mertonian ideal and illustrate the social facet of citations. In contrast, author keywords predominantly refer to concepts without any link to one or several persons. They thus reduce to some extent the social nuisance in this reference system.

A local cosine similarity $\text{sim}_{\text{loc}}^{(A,B)}_X$ between the articles $A$ and $B$ on the elements of the set $X \in \{\text{author keywords, referred literature}\}$ is computed separately for keywords and references via

$$\text{sim}_{\text{loc}}^{(A,B)}_X = \frac{|X(A) \cup X(B)|}{\sqrt{|X(A)||X(B)|}},$$

where $|\cdot|$ denotes the cardinality of a set. In a pre-processing step, the set of keywords is generalized by a stemming procedure to neutralize flexional variants used by the respective authors. At the same time the bibliometric coupling relation between any two articles is sharpened by excluding review articles, publications with a time lag of more than 10 years and non-source items, that is publications not published in the set of journals indexed in the WoS, but solely referred to by an indexed article.

Furthermore we extend this local perspective to a global level by transferring the local cosine similarity into a global one, $\text{sim}_{\text{glo}}^{(A,B)}_X$ (Ahlgren, Jarneving, & Rousseau, 2003). Thereby we consistently and throughout our study apply a global perspective including all publications in a particular SC and year at every step. We construct a similarity on such a global level by comparing the local similarities of article $A$ to all other articles $\hat{A}$ and itself with the vector of local similarities of article $B$ with $\hat{B}$ and itself. Apart from this theoretical argument of a consistent approach taking into account the whole SC, the global approach also incorporates important empirical advantages, like a decrease in the sparsity and a higher level of variance in the distance matrix decreasing the likelihood of ties and their severe consequences for clustering.

However, the cosine distance $\text{dist}_{\text{glo}}^{(A,B)} = 1 - \text{sim}_{\text{glo}}^{(A,B)}_X$ does not denote a proper distance metric, as neither the Cauchy–Schwarz inequality nor the coincidence axiom hold up. Hence, we transfer the cosine similarity to the angular distance via the inverse cosine and map the values in a normalization step into the interval $[0,1]$. Lastly we take an average on the distances resulting from author keywords and bibliometric coupling with equal weights in order to combine them to a hybrid distance measure (Braam, Moed & van Raan, 1991a, Braam, Moed & van Raan, 1991b)
These hybrid distances between all articles of a SC in a specific year constitute the basis for the subsequent clustering approach. We opt for an implementation based on agglomerative clustering foregoing the popular modularity based community detection algorithms due to their restriction to local and not global steps to improve the objective function. A local focus in the greedy optimization increases the likelihood to reach varying local optima across the SCs which would consequently diminish the comparability across SCs. In contrast, this comparability is ensured in our hierarchical clustering setting via a uniform application of the same linkage criteria and cut-off across SCs and years. We apply the so-called “ward linkage criterion”, following Bagatelj (1988), who justified the use of any dissimilarities instead of squared Euclidean distances for the Ward method.

Preliminary Results
Due to the extensive scope of the analysis incorporating all WoS SCs for the years 2003 - 2012, we currently can present preliminary results for a non-random sample of 19 SCs.

All SCs possess several clusters at some point of the observation period and can be classified as heterogeneous according to our measure. Taking into account the applied keywords and reference patterns, these SCs contain several subgroups differing by the respective subject-matter. The left panel of Figure 1 depicts the corresponding number of clusters per SC and year. The mean (90% quantile) number of clusters increases from 48 (122) to 95 (238) clusters in the observed time period, thus exhibiting a notable growth. This increase over time might mirror a potential rise in the level of specialisation in the WoS indexed articles, even when the actual amount of differentiation – measured by the number of clusters – depends on the applied configuration of both dissimilarity measures and clustering which might still be improved.

Whereas the observed increase in topical heterogeneity is interesting in itself, this scientific development entails a problem for bibliometrics only if the cluster specific citation levels vary within the observed clusters of a SC. The right panel in Figure 1 reports on the coefficient of variation on the cluster specific means:

\[ \text{CoV} = \frac{SD(\text{citations}_{\text{cluster}|\text{SC}})}{\text{citations}_{\text{SC}}}, \]

where \( \text{citations}_{\text{cluster}|\text{SC}} \) denotes a vector of average numbers of citations received by articles in the cluster \( c \in \{1, \ldots, C\} \) in a certain SC. The magnitude of the variation in mean citations across the clusters amounts on average to 75% to 150% of the mean citations received by the whole SC. This mean appears stationary without any trend, but is accompanied by a high volatility and demonstrates a substantial difference between the average citations of articles in the clusters and the SC as a total.

Give the current state of 19 SCs, the WoS SC classification seems too coarse to reflect the topical heterogeneity observed in the articles indexed in the WoS. Furthermore the heterogeneity seems to increase over time. However, a more detailed and comprehensive verdict will be reported once the processing of the remaining SCs has been completed.
Outlook

This research-in-progress paper will result in a descriptive analysis of the topical coherence of all SCs in the WoS for the years 2003-2012, an endeavour encompassing more than 10 million articles, and secondly will bring up explanatory models which explore the reasons for the observed variation in topical coherence across the SCs. Consequently we will present a descriptive analysis on the whole set of SCs and extract explanatory variables from the WoS database to conduct an inferential analysis which ideally results in informative background knowledge to construct a more diverse alternative to the WoS SCs classification.

Abstract
In this study, scholarly communication system of open access is examined through comprehensiveness and overlap of coverage. For open access systems, search engine includes Google Scholar; aggregate institutional repository include OAIster; the physic open source, i.e., arXiv. Noble laureates in physics from 2001 to 2013 are selected as samples in this study. Bibliographic records of their publications were retrieved and downloaded from each system, and a computer program was developed to perform the analytical tasks of sorting, comparison, elimination, aggregation and statistics. Bibliographic records retrieved from the three systems undertake quantitative analyses and cross references to determine the comprehensiveness and overlap of their system coverage. The results of the study may provide better references for scholars to select an appropriate open access system as an efficient scholarly communication channel; the academic institute may build institutional repositories, or independently create citation index systems in the future. Suggestions on searching enhancement for open access systems and our future work are presented accordingly.

Conference Topic
Open Access System, Comprehensiveness of System Coverage, Overlap of System Coverage, Scholarly Communication, Academic Assessment

Introduction

To assess the research performance, including research productivity and citation-based research impact, has become an important issue of scholars and research institutes. Take the prediction of the Nobel Prize winners as an example, Thomas Reuters, by using Web of Science, has studied and analyzed the citation results since 2002. They used it to identify the researchers who have the greatest influence in different disciplinary domains including chemistry, physics, psychology or medicine, economics, etc. to be the winners of the “Thomas Reuters Citation Laureates.” Since 2002, this prize has accurately predicted 27 Nobel laureates, indicating there is a certain overlap between the winners of the Citation Laureates selected by means of citation analysis and Nobel laureates. Hence, many people take the Citation Laureates as the leading indicator of Nobel Prize winners (Science Watch, 2013).

The rapid development of the Internet has facilitated the diversification of scholarly communication channels, not only altering the scholarly communication environment, but also further promoting the open access movement. At this stage, the traditional bibliometric study has evolved into webometrics. As the research data of webometrics come from the cyber world, websites, search engines and other open access systems, all can be research subjects or research tools of webometrics. How webometrics precisely and rigorously analyze and evaluate scholars, institutes and academic literature has been a major research topic; and as the important research foundation of webometrics, open access systems differ from one another with respect to the
objectives of construction, respective functions, and scope of collections. Therefore, in webometric studies, it is necessary to understand their differences if they are to be used as the research tools, which hence is the motivation of this research.

Under the “open access” environment institutional repositories, constructed by scholars and non-profit organizations such as academic institutes and libraries, may also possess the function of citation index. For example, the Cite Seer and Citebase in the computer science domain have constructed a citation index for its free online academic publications which include the arXiv.org that has archived the research literature in such domains as physics, mathematics, computer science, and biostatistics (Thelwall, 2008). Moreover, compared to commercial databases, search engines are one of the most popular tools for many users in searching useful information on the web. How should users choose between search engines and other open access systems? What are the differences among these sources? What are the pros and cons in terms of comprehensiveness and overlap of the collected data?

Based on the above background and motivations, this study compares the comprehensiveness and overlap of the data collected in open access systems using webometric methods. The open access systems selected in this study include search engines, Google Scholar; full-text institutional repositories, OAIster; and physics repositories, i.e. arXiv. The following objectives are expected to be achieved in this study:

The academic literatures published by the Nobel laureates in Physics are used as the research samples for comparing the comprehensiveness and overlap of the data collected in various open access systems.

Literature review

Bradford (1953, p. 154) first proposed research on literature overlap and uniqueness in 1937. His study focused on the overlap of journals collected by indexing and abstracting tools, i.e. cited literature simultaneously appearing in two or more databases. Based on the overlap theory by Bradford, Martyn (1967) analyzed the coverage of the abstract journals in his study and discovered that over half of the journals were collected in one or more index and abstract databases. He concluded this would result in a waste of manpower, as users would repetitively retrieve the same data as a result of the overlap in the index and abstract databases.

Nicholls (1989) compared four databases in the library and information domain, namely, Library and Information Science Abstracts (LISA), Educational Resources Information Center (ERIC), Library Literature, and Information Science Abstracts and retrieved 500,000 items of books and literary data during his research. He compared and explained the differences in the coverage among the four databases: Information Science Abstracts contained a large amount of seminar papers and special issue articles; LISA collected a large amount of foreign language materials and information science journals (with relatively few specialized journals on library and information;) the contents collected in Library Literature included books, analytical papers and a modicum of journals on library and information science, while the data collected in ERIC was the most complete among the four.

Hood (1998) conducted an overlap study of all the databases under the Dialog system using the theme of fuzzy set theory by downloading from all the databases of the Dialog system that included “fuzzy” data and selecting the literature related to the “fuzzy set theory.” Altogether he chose more than 30,000 data items between 1965 and 1993 from about 100 different databases. Hood removed the errors, unified all the fields and ultimately selected 15,644 items. He then conducted a comparative study of the overlap distribution, records of the most overlaps, sole records, the duplicate records within the databases, and the overlap among the top ten databases. The study found that there was great difference in the overlap records among the databases; of the 15,644 data items, 9,897 were only covered in one database,
accounting for 63.26%; the data collected by two databases numbered 1,922 pieces, accounting for 12.29%; and the data simultaneously collected in 12 databases numbered 5 pieces, taking up 0.03%. In addition, Hood found that there were internal duplicates in 28 databases, with MATHSCI having the greatest number of internal duplicates i.e. a total of 239 items. The reasons for the high overlap rate of internal duplicates were that both original articles and original papers with abstracts were covered in the database, and that the same article might be collected by various journals. The study finally explained the relative overlap among the various databases, pointing out the relative overlap in INSPEC and SCISEARCH exceeded 40%, which was the highest of all the databases in terms of overlap.

Zhu, Deng, Fang and Zheng (2008) conducted an overlap study on four search engines (i.e. Google, AltaVista, Alltheweb and WiseNut, a search engine in Korean) by using the top N (N=10, 20 or 80) retrieval results of 58 queries chosen from WordTracker service. The WordTracker service records the most popular queries submitted to some famous metasearch engines, e.g., MetaCrawler and Dogpile. The study indicated that the search results retrieved by the four search engines have little overlap. Google, on average, has the highest degree of overlap with the other search engines. Over 75% of the total distinct results are returned by only one search engine, and less than 3% are retrieved by all four search engines.

The study of Esmaeil, Kiaie and Ketab (2011) compared the overlap of six commonly used search engines systems and databases suggested by, Searchenginewatch.com. The study found that among the different search engine systems, the overlap rate of Yahoo with the other engines was the highest, which was about 40%. The recall rate of the physics journals of Curry Guide was 77.1%, and its overlap rate with the other five systems was 43.7%. Taking the physics domain as an example; the data in Meta Search Engine were the most complete among the six open access search engines.

Mitra and Awekar (2017) performed experiments on comparison overlap among four academic search engines (ASEs), Google Scholar, Semantic Scholar, Microsoft Academic and Scopus, which are computer science and engineering related. They collected approximately 2300 query terms from 2012 ACM Computing Classification System as well as 200 keywords from papers published in ACM SIGKDD 2016 Conference. Together, 2500 queries were sent to all four selected ASEs. The search results indicates that for each query, very few research articles appear in the top results list of all four ASEs. The disagreement of search results shows the overlap among of ASEs is significantly low.

In summary, overlap in the coverage and search results of traditional databases and web search engines is well studied. Most of these studies focusing on search engines, such as Google and Yahoo. There are some works investigating the indexing coverage of the web for major academic search engines. However, there is no study on the comparison of comprehensiveness and overlap among academic search engines, aggregate institutional repository and the subject related open access systems. Therefore, the present study is unique in its exploration of coverage of various open access systems on the basis of a quantitative bibliometric analysis of the literature in the subject area of physics.

Research methods

The present study compares the comprehensiveness and overlap of the data collected in various open access systems. Poyer (1984) defines the overlap of journal articles as the same journal article being collected and indexed or abstracted in two or more databases. Meanwhile, the rate of the same journal collected in two or more databases at the same time also constitutes overlap. On the basis of the suggestion of Poyer, in this study, overlap refers to the overlap rate of the same article being collected by two or more systems simultaneously.
This study collected the papers published by Nobel laureates in Physics (2001-2013) (see Appendix 1) and then produced a publication list to serve as the research sample for a comparison study of open access systems. The open access systems selected as research subjects were Google Scholar search engines, full-text institutional repositories, OAIster and physics disciplinary open access system arXiv.

Moreover, as the open access movement emerged in the 1990s, all open access systems, riding on this wave, were constructed in succession. The year of creation of the systems used in this study is respectively as follows: Google Scholar (2004), OAIster (2002) and arXiv.org (1991). Different construction years might have bearings on the difference in the quantity of the data collected in each system; the systems constructed earlier might cover data published in earlier years than those in the systems that were constructed later.

To create the research sample of this study – the publication list of the Nobel laureates in Physics, it was necessary to search the personal publications disclosed by these scholars before a publication list could be created. If the scholars did not provide their publication lists or the lists they provided were not complete, a further step of author search had to be taken to ensure the publication list of the research sample was complete and accurate.

This study searched the name of the aforementioned Nobel laureates in Physics in Google Scholar, OAIster, and arXiv.org separately. After authors with unique names were identified and eliminated, the retrieval results from the systems were then exported and collated. The following fields that had to be exported and analyzed in this study for identifying the correctness of the data in reviewing were the bibliographic records, title, author, publication year, publisher, journal title, volume and issue, number of pages etc.

To avoid errors in the bibliographic data occurred during massive download, the bibliographies were downloaded according to the complete descriptive format to create complete bibliographic data. The data processed by bibliometric methods mostly include text and numeric data. As different systems have different descriptive formats, incomplete descriptions and different description formats might occur when downloading bibliographic data. Therefore, the data must first be rectified through manual search to enable the original massive and jumbled bibliographic data to be standardized and the overlapping bibliographies retrieved from different databases to be removed through the Excel spreadsheet.

After the bibliographic data was collected and processed, manual verification and comparison were needed to ensure the accuracy of the research data, as there might be certain errors such as typographical errors in bibliographies, research papers unrelated to physics, alias of the author, and different titles and descriptive formats for the same journal. The bibliographic list created after eliminating the overlaps and undergoing the bibliographic data processing served as the publication list of the Nobel laureates collated with all the databases.

The completed publication list of the Nobel laureates in Physics must be cross-compared with the scholars’ publication information obtained from various Internet resources, the personal websites of the Nobel laureates in Physics, their research teams or the websites of the institutions they belong to. Only then could the research sample of the study be created – the publication list of the Nobel laureates in Physics (2001-2013).

Based on the research sample of the publication list of the Nobel laureates in Physics, the bibliographic titles were searched in the following three systems, Google Scholar, OAIster and arXiv.org. The search result of each title using each system was then individually recorded, including the descriptive errors and bibliography overlaps, which served as the basis for evaluating the comprehensiveness of and overlap in the bibliography of the Nobel laureates in Physics. Finally, the various results and review of the three systems were organized, statistically assessed, and compared which led to the conclusion and comments in this paper.
Research result

Through the research sample, the publication list of the Nobel laureates in Physics, this study hopes to understand the comprehensiveness and overlap of the literature on physics in the three open access systems under study. The following is a discussion and comparison of the comprehensiveness and overlap (including both internal and external overlaps) in the three open access systems.

Comprehensiveness of three open access systems

Based on the publication list of the Nobel laureates in physics, a total of 6094 items were searched in various open access systems, with the amount and comprehensiveness of bibliographic data shown in Table 1. Google Scholar had the most complete result with 5897 bibliographic items, covering 96.8% of the publication list; while OAIster which includes 45.3% of the data at the bottom. The physics open access system, arXiv includes 49% relevant items of the publication list. The extent of the arXiv collection could still not be compared to search engines, with a difference of about 48%. The comprehensiveness of institutional repository OAIster was not as good as arXiv.

As for the reasons for the highest comprehensiveness of data collected in Google Scholar, this might have been due to utilizing the various search engine to index the literature in the network world; its sources of literature include academic publishers, the institutional repositories of all universities and open access systems. With respect to this study, Google Scholar, in particular, has indexed the open access system of arXiv, rendering its bibliography the most complete.

For the foregoing, the comprehensiveness of the databases and systematically collected data evaluated in terms of physics literature was ranked as follows, starting with the highest: Google Scholar, arXiv, and OAIster.

<table>
<thead>
<tr>
<th>Open access system</th>
<th>Number of Bibliographic Items</th>
<th>Comprehensiveness Ratio*</th>
</tr>
</thead>
<tbody>
<tr>
<td>Google Scholar</td>
<td>5,897</td>
<td>96.77%</td>
</tr>
<tr>
<td>arXiv.org</td>
<td>2,988</td>
<td>49.03%</td>
</tr>
<tr>
<td>OAIster</td>
<td>2,761</td>
<td>45.31%</td>
</tr>
</tbody>
</table>

* The total number of bibliographic items is 6,094.

Overlap of three open access systems

There are two types of system collection overlap: internal and external. The internal overlap, or self-overlap, occurred when duplicated bibliographies exist within each system. The external overlap, or relative overlap, is the same bibliographic items covered in two or more open access systems.

Internal overlap

The internal overlap of the bibliographic data from the retrieval of the list of works by the Nobel laureates in Physics from three open access systems is as shown in Table 2. The arXiv, which is physics disciplinary in nature, has lower internal overlap percentages than other open access systems. The arXiv has the least internal overlap i.e. no internal overlap (0%). Google Scholar has the highest internal overlap rate at 92.7%. As for the internal overlap rate of the institutional repository systems, OAIster is at 13.8%.
Table 2. Internal overlap of the publication list of the Nobel laureates in Physics in the open access systems

<table>
<thead>
<tr>
<th>Open access system</th>
<th>Bibliographic Items</th>
<th>Overlap Item</th>
<th>Overlap Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Google Scholar</td>
<td>5,897</td>
<td>5,464</td>
<td>92.66%</td>
</tr>
<tr>
<td>OAIster</td>
<td>2,761</td>
<td>381</td>
<td>13.80%</td>
</tr>
<tr>
<td>arXiv.org</td>
<td>2,988</td>
<td>0</td>
<td>0%</td>
</tr>
</tbody>
</table>

The reason for the high degree of internal overlap of Google Scholar is the Google Scholar’s indexing of the online world literature. For the publication list of the Nobel laureates in physics in Google Scholar, only 433 documents contained only one source while up to 92.7% of the bibliography contained two or more bibliographic sources. Moreover, Google Custom Search for repository content retrieval and searches the contents of all open access repositories. The retrieval results may include several bibliographic sources. Since the above-mentioned internal overlap is due to multiple bibliographic sources, the situation in each system may differ. Evidently, internal overlap records are caused by the title input discrepancies (e.g. the missing article in the title, the special symbols recorded in spelling, etc.) or the lack of bibliographic information (such as publication title, volume, pages, etc.). The difficulty of identifying one entry to another has deterred system to delete the duplicate bibliographic records.

**External overlap**

Table 3 demonstrates, compared with other open access systems in terms of overlap. Compared with other two open access systems, Google Scholar has overlap rates of 50.67%, 46.82%, respectively.

OAIster has an overlap rate of 100% with the Google Scholar search engine, showing that all the bibliographic data in OAIster are included in the Google Scholar. The arXiv shows the same situation.

The bibliographic overlap rate of OAIster in arXiv is 94.2%, while the overlap rate of arXiv in OAIster is 87.1%. This indicates the bibliographic overlap rate of these two open access systems is quite similar.

Table 3. External overlap of the publication list of the Nobel laureates in Physics in the open access systems (cross-column system and cross-reference system)

<table>
<thead>
<tr>
<th></th>
<th>Google Scholar</th>
<th>arXiv.org</th>
<th>OAIster</th>
</tr>
</thead>
<tbody>
<tr>
<td>Google Scholar</td>
<td>X</td>
<td>50.67%</td>
<td>46.82%</td>
</tr>
<tr>
<td>arXiv.org</td>
<td>100%</td>
<td>X</td>
<td>87.08%</td>
</tr>
<tr>
<td>OAIster</td>
<td>100%</td>
<td>94.24%</td>
<td>X</td>
</tr>
</tbody>
</table>

To sum up, the overlap rate of arXiv, OAIster, compared with Google Scholar has reached 100%, suggesting the information found in other systems can be almost always obtained from Google Scholar. The reason for the high bibliographic overlap rate of Google Scholar with other open access systems is that Google Scholar has the most extensive bibliography and abundant information data resources. The overlap rates of arXiv and OAIster (87.1%) was slightly lower than that of OAIster and arXiv (94.2%). OAIster's bibliographic sources are mostly from academic institutions, which may result in bibliographic duplication overlap.

**Conclusion and suggestions**

Based on the results of the aforementioned comparison, this study analyzes the pros and cons of the three open access systems and makes recommendations according to the analysis
results to serve as a guide for scholars and researchers of webometrics for selection information systems.

In terms of the extensiveness and integrity of data regarding physics literature, the ranking is as follows: Google Scholar, arXiv and OAIster. Google Scholar has the most complete data coverage (96.8%), while OAIster’s integrity is the lowest (45.3%). For the physics open access systems, arXiv has the data coverage of 49%. The institutional repository system OAIster coverage is not as good as arXiv’s.

arXiv has the lowest internal overlap rate (0%) among the studied open access systems. The most internal overlap existing in Google Scholar is largely due to its various sources of bibliographic data, which made the bibliography under the system also differ (one journal from different bibliographic sources would show different index information). Since Google Scholar indexes the international literature online, 92.7% of entries contain two or more bibliographic sources.

The external overlap rate of arXiv, OAIster with Google Scholar was 100%. Over the course of the research, it was noted that Google Scholar’s main bibliographic data was from arXiv. This might have caused the 100% collection overlap of the data in arXiv’s, OAIster’s in Google Scholar.

For physics literature, a user is able to retrieve extensive data using a search engine such as the Google Scholar. In addition, Google Scholar provides users with links to the full-text of the journal (PDF files and web pages) if found. In addition to the scanned early physics literature for full-text search, arXiv also allows full access to open access journals and links to preprinted electronic documents. If these three open access systems do not provide the full text of the literature, the user should purchase commercial databases.

For the foregoing, the open access systems and the future work of this study need to be enhanced and improved as follows:

Open access systems need to implement bibliographic quality control and use a variety of screening mechanisms to eliminate unsuitable or incomplete bibliographic information to maintain the system data quality. The open access system also has to overcome the problems of invalid or incorrect links to avoid irrelevant search results, or the search result not being linked to the source site.

The future research on webometrics and collection overlap, if conducted with research methods such as data mining and/or text mining, will be beneficial to quantitative study. In this case, with query terms from controlled vocabulary system, e.g., subject thesaurus, or keywords from published papers are suggested as searching terms to retrieve relevant sets. Moreover, the future work of this study may be extended to include more academic open access systems and/or commercial databases, e.g. Wos or Scopus, for a complete comparison research.

Abstract
As a frequently used method of depicting scientific intellectual structures, author co-citation analysis (ACA) has been applied to many domains. However, only count-based information is involved as the input of ACA, which is not sufficiently informative for knowledge representations. This article catches several metadata in full text of citing papers but not aims at content-level information, which could increase the amount of information input to ACA but not increase computational complexity a lot. By involving information including the number of mentioned times in a citing paper, the number of context words in a citing sentence, and the published year of a reference, we propose a new method called MFTACA (metadata-in-full-text-based ACA). We combine these pieces of information into traditional ACA and compare the results between ACA and MFTACA by using factor analysis, network analysis, and MDS-measurement. The result of our empirical study indicates that compared with traditional ACA, our proposed method shows a better clustering performance in visualizations and reveals more details in displaying intellectual structures.

Conference Topic
Citation and co-citation analysis; Mapping and visualization; Science of science

Introduction
Author co-citation analysis (ACA) is a bibliometric method in knowledge representation and has shown a good performance in depicting scientific intellectual structures and mapping knowledge domains (White and Griffith, 1981; McCain, 1990; Jeong, Song, and Ding, 2014). More than three decades since its born, ACA has been applied to many disciplines, such as library and information science (White & Griffith, 1998; Ding, Chowdhury, & Foo, 2001; Ding, 2011a; Zhao & Strotmann, 2014), cognitive science (Bruer, 2005), management science (Eom, 1999; Chen & Lien, 2011), and medical science (Chu, Liu, & Tsai, 2012).

Traditional ACA regards two authors with higher co-citation frequency as higher topical relatedness. Such assumption hints that every author pair with the same co-citation frequency as identical, which simply considers count-based instead of content-based information. As the availability of full-text data nowadays, Jeong \textit{et al}. (2014) firstly proposed content-based ACA method and compared the similarity between citing sentences. However, the computational cost of their content-based method could be high because of the processing of words as well as similarity calculation between citing sentences. Actually, with the full-text data, we do not have to employ the content-level information. Nevertheless, instead, several pieces of useful information at metadata level that were ignored previously in full text could be considered to improve the performance of ACA in mapping knowledge domains.
The number of mentioned times of references is a typical piece of information. As pointed out by Ding, Liu, Guo, and Cronin (2013) as well as Zhao, Cappello, and Johnston (2017), the number of mentioned times of a reference represents the importance of the reference to the citing paper. However, traditional ACA regards two co-cited authors with a distinct number of mentioned times in a citing paper as identical, which could be problematic. For example, Zhao and Strotmann (2014) cited (a) Zhao and Strotmann (2008a), (b) White and McCain (1998), and (c) Hirsch (2005), but (a) was mentioned 15 times, (b) twice, while (c) only once in the citing paper. The co-citation strength of pair (a)-(b) and (b)-(c) should be different when we consider their topical relatedness. In this paper, we start to consider the number of mentioned times of references as a supplement into ACA in order to provide more accurate information for mapping knowledge domains.

Besides, the citing sentences containing references could have different numbers of words. From our intuitive thinking, a reference contained in a longer citing sentence should have more topical relatedness to the citing paper than that is contained in a shorter one, because longer sentences are more likely to include more details or interpretations to the reference, which is useful to the citing paper—otherwise it is not likely to be cited with many interpretative words. However, traditional ACA ignores such difference in the length of citing sentences; as a result, we start to consider the difference in the length of citing sentence and combine it into ACA in this paper.

Moreover, the published time of references could also reveal the difference between co-cited authors. For instance, as pointed out by Bu, Liu, and Huang (2016), small difference between the published time of two references implies that the authors tend to focus on similar issues in the same period of time; therefore, the two authors’ relationship could be distinct in knowledge domain maps because they tend to use “various concepts, methods, or even diversified demands” (p.144) in dissimilar periods of time. The information of references; published time is considered in this paper and it is combined with traditional ACA to enhance the performance of knowledge domain mappings.

This article is outlined as follows. At first, the work related to our study and the data with the methods for our analysis are detailed. The findings as well as the comparisons between traditional ACA and our proposed MFTACA then are presented. Finally, the conclusions and the future research are pointed out.

**Related Studies**

Author co-citation analysis (ACA) was proposed by White and Griffith (1981). In 1990, McCain gave a completed overview and set up a standard framework for ACA, in which four steps of ACA implementations were mentioned: (1) Data collection and processing; (2) Construction of raw co-citation matrix; (3) Transformation to correlation matrix; and (4) Data analyses (e.g., factor analysis, clustering analysis, multi-dimensional scaling (MDS) analysis, and network analysis) and result interpretations. More than thirty years, this method has been improved a lot by revising rules to construct raw co-citation matrix and transform to correlation matrix. As pointed out by Persson (2001), the elements in co-citation matrix could be defined as first-author co-citation frequency or all-author co-citation frequency; the latter could to some extent provide more detailed knowledge domain maps (Rousseau & Zuccala, 2004; Zhao, 2006). Meanwhile, the rules of defining main diagonal values (Mêgnighbê to, 2013) and transforming correlation matrix (Ahlgren, Jarneving, & Rousseau, 2003; White, 2004) were both discussed and improved in detail to make the data processing more accurate. Additionally, several
metadata of references, such as published time and venue of references and their keywords, were considered in ACA implementations (Bu et al., 2016), and they were found to play positive roles in improving the performance of ACA maps. Note that the metadata they employed had been obtained from reference lists instead of full text.

Due to the availability of full-text scientific data, Jeong et al. (2014) first explored content-based ACA by comparing the similarity between citing sentences. Their empirical studies show that content-based ACA is able to mine more details in scientific intellectual depicting compared with traditional ACA. However, the computational complexity is high in full text processing, which impedes the applications of their proposed method to various domains widely.

However, when full-text data are used, it is not required to make content- or semantic-level analyses. Several non-content-level metadata are easily accessible in full text, such as the number of mentioned times and the number of context words in the citing paper. In addition, these pieces of information reflect the importance of reference to citing paper. For example, if mentioned many times than others, a reference could have more topical relatedness to the citing paper; if the citing sentence containing certain reference is longer than that containing other references, it is more likely to be interpreted more detailedly and thus has higher possibilities to be related to the citing paper. As a result, this paper combines the number of mentioned times and the number of context words of references into ACA and proposes a new method called MFTACA so as to improve the performance of ACA in knowledge domain mappings.

**Methodology**

The whole process of our algorithm is shown in Figure 1. All of the dataset are derived from full-text in Journal of the American Society for Information Science and Technology (JASIST, currently named as Journal of the Association for Information Science and Technology). After data processing (see details in “Data” section), we extract the number of mentioned times, the number of context words, and published years of references, and combine them into ACA (dotted area in Figure 1, see details in “Methods” section). After the new co-citation matrix is constructed, Pearson’s $r$ is utilized to transform it to correlation matrix. Factor analysis, network analysis, and MDS-measurement is used to process the data, in which Gephi (Bastian, Heymann, & Jacomy, 2009) is applied to display the results of the combined author co-citation network for discussion and analysis. Note that the dotted area in Figure 1 is the major difference among the proposed MFTACA and traditional ACA methods.

**Data**

The dataset used in this research is the same as that in Jeong et al. (2014), in which 1,420 full-text articles with citation links published in JASIST between January 2003 and June 2012 are selected. These 1,420 articles containing 60,068 references are completed by 32,095 authors. In order to make the co-citation matrix denser, we extract most popular 500 authors who have received the most number of citations since they are the most “popular” scholars and are often regarded as the representative of the research going back (Zhao & Strotmann, 2008a; Zhao & Strotmann, 2014).
Methods

Calculation of mentioned time parameters
A paper citing other papers refers that these cited papers (references) are related and useful to the citing paper (CP). Traditionally, these co-cited papers are regarded as equal in traditional co-citation analysis (Ding et al., 2013). However, the importance of cited papers could be distinct (Cano, 1989; Case & Higgins, 2000). Specifically, some references are crucial to the CP because they might be the foundation of CP. In the full-text, the important references could be revealed as multi-mentioned cited papers. For one CP, from an intuitive thinking, the more number of mentioned times a reference has, the more importance it is to the CP (Ding et al., 2013; Zhao et al., 2017). For instance, Zhao and Strotmann (2014) cited (a) Zhao and Strotmann (2008a), (b) White and McCain (1998), and (c) Hirsch (2005), but (a) was mentioned 15 times, (b) twice, while (c) only once. In this case, (a) should be the most important reference to the CP, compared with (b) and (c). Indeed, Zhao and Strotmann (2014) tried to map the knowledge domains of information science (IS) between 2006-2010 while (a) did the same thing but between 1996-2005 with similar methods, ACA and author bibliographic coupling analysis (ABCA), which shows that (a) is closely-related and important to the CP. However, (b) only used ACA to map the knowledge domain of IS instead of ABCA and the result of (b) is also very different from (a) and the CP. The reason (c) is cited is nothing but simply because the indicator “h-index” was used. Hence, we can see that the number of mentioned times of a reference is indeed positively related to its relatedness with CP.

Similar in ACA, if two co-cited authors are both mentioned many times in a CP, their topic relatedness could be high because both of them are closely related to the CP. In the above example, the topical relatedness of (a)-(b) should be higher than that of (b)-(c). Indeed, (a) and
(b) both focus on mapping IS with ACA, but (c) simply introduces an indicator to evaluate scholars. Thus, in our proposed algorithm, we assume that two co-cited authors with more number of mentioned times should be assigned more co-citation weights because they have higher possibilities to be related with each other topically.

Mathematically, suppose that author $A_i$ and $A_j$ are co-cited for $x_{ij}$ times. Specifically, the CP is annotated as $P_{ij,1}, P_{ij,2}, \ldots, P_{ij,x_{ij}}$. In $P_{ij,k}$ ($k = 1, 2, \ldots, x_{ij}$), assume that author $A_i$ is mentioned for $\lambda_{ik}$ times and author $A_j$ is mentioned for $\lambda_{jk}$ times. If we annotate the mentioned time of the cited author with the maximum number of mentions in paper $P_{ij,k}$ as $\lambda_{k_{\text{max}}}$, the mentioned time parameter between author $A_i$ and $A_j$ in paper $P_{ij,k}$, $MT_{ij,k}$, is calculated as:

$$MT_{ij,k} = \frac{\lambda_{ik}\lambda_{jk}}{\lambda_{k_{\text{max}}}}$$

(Eq. 1)

If we consider all of the $MT_{ij,k}$ in citing papers $P_{ij,1}, P_{ij,2}, \ldots, P_{ij,x_{ij}}$, the mentioned time parameter between author $A_i$ and $A_j$ among dataset, $MT_{ij}$, could be defined as:

$$MT_{ij} = \sum_{k=1}^{x_{ij}} MT_{ij,k}$$

(Eq. 2)

**Calculation of context word parameters**

When citing references, CPs tend to use one or more sentences to set up an argument, which is called citing sentences (or citance (Jeong et al., 2014)). However, the length of citing sentences could be distinct. For example, Zhao and Strotmann (2014) cited: (d) Finlay, Sugimoto, Li, and Russell (2012), (e) Milojević, Sugimoto, Yan, and Ding (2011), as well as (f) Sugimoto, Li, Russell, Finlay, and Ding (2011) in the same sentence with 27 words. They shared these 27 words and each of them has been assigned nine words averagely. Meanwhile, Zhao and Strotmann (2014) also cited (g) Zhao and Strotmann (2008b) in a sentence with 31 words. Although all of these references are cited once in the CP, their numbers of context words assigned could be diverse, 9, 9, 9, and 31, respectively.

Basically the number of context words assigned in a CP could reflect the importance of the reference. Specifically, more numbers of context words assigned in a CP reveal that more details and interpretations of the reference is likely to be stated, which hints that it has higher topical relatedness to the CP. For example, CP uses ACA and ABCA to map the knowledge domain of IS field, while (g) explores AACA at a methodology level; both of them are closely related to ACA research. Nevertheless, (d) analysed Library Science (LS) using titles and keywords, (e) employed article title words to depict the structure of LIS, and (f) focused on North American LIS dissertation using Latent Dirichlet Allocation (LDA) method, all of which are not as close as (g) in terms of the topical relatedness with the CP from an intuitive perspective. Indeed, the number of context words assigned to (g) is much more than that to (d), (e), and (f). These show that the number of context words assigned in a CP could be positively related to its topical relatedness to the CP. Similarly in ACA, if two co-cited authors are both assigned many words than others, they topical relatedness should be higher because both of them are closely related to CP.

In $P_{ij,k}$, assume that during its $\mu$th mention ($\mu = 1, 2, \ldots, \lambda_{ik}$), the citing sentence containing author $A_i$ ($A_j$) include $w_{ik\mu}$ ($w_{jk\mu}$) words and mentions $a_{ik\mu}$ ($a_{jk\mu}$) distinct authors ($w_{ik\mu}, w_{jk\mu}, a_{ik\mu}, a_{jk\mu} > 0$). The number of context words of author $A_i$ in paper $P_{ij,k}$, $cw_{i,k}$, could be calculated as (similar to $A_j$):

$$cw_{i,k} = \sum_{\mu=1}^{\lambda_{ik}} \frac{w_{ik\mu}}{a_{ik\mu}}$$

(Eq. 3)
If we annotate the largest number of context words of cited author in paper $P_{ij,k}$ as $cw_{k,max}$, the context word parameter between authors $A_i$ and $A_j$ in paper $P_{ij,k}$, $CW_{ij,k}$, is calculated as:

$$CW_{ij,k} = \frac{cw_{i,k}cw_{j,k}}{cw_{k,max}^2}$$  \hspace{1cm} (Eq. 4)

If we consider all of the $CW_{ij,k}$ in citing papers $P_{ij,1}, P_{ij,2}, \ldots, P_{ij,x_{ij}}$, the context word parameter between authors $A_i$ and $A_j$ among dataset, $CW_{ij}$, could be defined as:

$$CW_{ij} = \frac{1}{x_{ij}} \sum_{k=1}^{x_{ij}} CW_{ij,k}$$ \hspace{1cm} (Eq. 5)

### Calculation of published year parameters

Besides the mentioned time and context word parameters, we also employ published year parameter proposed by Bu et al. (2016), in which it is called time-based parameter. According to Bu et al. (2016), a small difference between two references’ published time refers that they tend to focus on similar research topics in the same time period; a large difference between two references’ published time refers that the representation of the co-cited authors’ relationships should be distinct because they are likely to use different methods, concepts, and tools although they might have similar research issues.

Suppose that $P_{ij,k}$ cites $r_{ik}$ papers published by author $A_i$ and $r_{jk}$ papers published by author $A_j$. The published year of these $r_{ik}$ papers published by author $A_i$ and $r_{jk}$ papers published by author $A_j$ is respectively $t_{ik1}, t_{ik2}, \ldots, t_{ikr_{ik}}, t_{jk1}, t_{jk2}, \ldots, t_{jkr_{jk}}$. Then the average of published year of author $A_i$ in the article $P_{ij,k}$ is calculates as:

$$TB_{i,k} = \frac{1}{r_{ik}} \sum_{v=1}^{r_{ik}} t_{ikv}$$  \hspace{1cm} (Eq. 6)

The published year parameter between authors $A_i$ and $A_j$ in paper $P_{ij,k}$ is defined as the sum of the average of published year of authors $A_i$ and $A_j$:

$$TB_{ij,k} = \frac{1}{1+ln(1+|TB_{i,k}-TB_{j,k}|)}$$ \hspace{1cm} (Eq. 7)

As a result, the average of published year of cited papers written by author $A_i$ among dataset is calculated as:

$$TB_{ij} = \sum_{k=1}^{x_{ij}} TB_{ij,k}$$  \hspace{1cm} (Eq. 8)

### Construction of the co-citation matrix based on three above parameters

The co-citation matrix in our proposed algorithm is based on three above parameters. All of the parameters are normalized into $[0,1]$. If we annotate the largest co-citation frequency among the dataset regardless of which author pairs as $x_{max}$, we can construct the new co-citation matrix, $M = (m_{i,j})$, as:

$$m_{i,j} = w_c \cdot \frac{x_{ij}}{x_{max}} + w_{MT} \cdot MT_{ij} + w_{CW} \cdot CW_{ij} + w_{TB} \cdot TB_{ij}$$  \hspace{1cm} (Eq. 9)

where the four positive weights, $w_c, w_{MT}, w_{CW}$, and $w_{TB}$, are relatively the weight of co-citation, mentioned time, context word, and published year parameters. Note that $w_c + w_{MT} + w_{CW} + w_{TB} = 1.0$.

### Results and Discussion

#### Factor Analysis

In factor analysis, we extract the factors whose Eigen factor is 1.0 or more as the result of factor analysis, regardless in ACA or MFTACA. As shown in Table 1, the number of factors extracted from MFTACA is 18, which is seven more than that in ACA. In terms of the total variance
explained, the factor analysis of ACA could explain 82.8% of total variance while that of MFTACA explains 86.1%.

Although using the same dataset as Jeong et al. (2014), we input approximately 500 authors into factor analysis while Jeong et al. (2014) did 100. We try to compare our results with theirs, which shows in bold in Table 2, where we can find that the results are similar and confirm each other’s. On the other hand, with respect to the factor analysis result of MFTACA, we can find...
many detailed sub-fields of information science, such as visualization and data mining. These newly-detected domains could showcase the nuance and emerging topics of information science recently. Therefore, we believe that MFTACA could reveal more details and nuance in depicting scientific intellectual structures.

**Network Analysis**

Figures 2 and 3 show the scientific intellectual structures by using the two methods, ACA and MFTACA, where each node represents an author and the size of the node is proportional to the degree of the node in the given network. The distance between nodes are determined by ForceAtlas2 (Jacomy, Venturini, Heymann, & Bastian, 2014), a frequently used layout algorithm in Gephi. If two nodes lie near in the map, for instance, their relationship could be strong; and *vice versa*. For visualization, we employ Modularity algorithm (Blondel, Guillaume, Lambiotte, & Lefebvre, 2008), in which the nodes (authors) within the same colour indicate that their research interests are similar, while those in different colors show that their research interests could be distinct. The labels of the clusters are manually given by our reading literatures of the authors as well as browsing their personal websites. From Figure 2 we can see that four clusters are detected, bibliometrics, information retrieval, information behaviour, and library science/qualitative research. The results are similar to Jeong *et al.* (2014)’s result, where they also found four clusters, bibliometrics, information retrieval (I), information retrieval (II), and library science. On the other hand, Figure 3 detects six clusters; besides four clusters having been detected in Figure 2, it also finds two additional clusters, i.e. text mining/data mining and network-based information science. These two clusters reveal the nuance of the development of IS and are detailed sub-fields in IS. These indicate that our proposed MFTACA method could provide more details in knowledge domain maps and help better understand the domain.

![Figure 2. Knowledge domain map of traditional ACA method.](image)
Intuitively, the nodes within the same cluster lie nearer, and the nodes in different clusters lie farther in Figure 3 than in Figure 2. These indicate a better clustering performance in MFTACA method. Take Drs. K. W. McCain and R. Rousseau as examples. Both of them focus on bibliometrics during their main scientific careers. Specifically, they are both interested in ACA, where Dr. McCain (1990) gave a comprehensive overview of ACA and used ACA to map knowledge domain of IS field between 1972 and 1995 (White & McCain, 1998). Dr. Rousseau, as a representative in typical European bibliometricians, proposed several types of ACA by classifying them according to distinct requirements (Rousseau & Zuccala, 2004) and discussed whether Pearson’s $r$ should be used in ACA (Ahlgren, Jarneving, & Rousseau, 2004). Their positions in Figure 3 are nearer than in Figure 2, which shows that MFTACA could play a role of closing authors with similar research interests. Another examples come from Drs. A. Spink and B. Shneiderman, in which the former researcher is an expert in information seeking behavior (Spink, Ozmutlu, & Ozmutlu, 2002; Spink & Cole, 2005) while the latter has been concentrating on user behavior analysis (Shneiderman, 1978). Although the nodes representing these two authors are not closely with each other in Figure 2, they move nearer in the visualization of MFTACA method. However, the distance between Drs. Spink and McCain becomes farther in Figure 3 than Figure 2, indicating that our proposed MFTACA method separates authors sharing different research interests in knowledge domain maps. All of these facilitate the quality of maps in terms of the clustering performance.

**MDS-measurement**

In order to evaluate the performance of our proposed method quantitatively, we employ multi-dimensional scaling measurement (MDS-measurement) (Bu et al., 2016) to supplement our argument in “Network Science” section that in a quantitative way. Note that MDS-measurement is NOT the same as MDS. The basic principle of MDS-measurement is to calculate the MDS-measurement value ($\sigma$), which is equal to the ratio between the sum of the distance between the nodes within the same cluster ($c$), and the sum of the distance between the nodes in different clusters ($S$). Intuitively, a smaller $\sigma$ indicates a better clustering performance in knowledge domain maps in which nodes within the same cluster lie nearer while those in different clusters
lie farther. Table 3 shows the MDS-measurement result, where we can see that the MDS-measurement value ($\sigma$) of MFTACA is smaller than that of ACA, indicating a better clustering result in knowledge domain map. This confirms our observation in “Network Analysis” section.

Table 3. MDS-measurement results.

Conclusions

This paper proposes a novel method combining the number of mentioned times, the number of context words, and the published time of references into traditional author co-citation analysis (ACA), called MFTACA (metadata-in-full-text author co-citation analysis). The results show that compared with traditional method, our newly proposed method not only shows better clustering performance but also provides more details in knowledge domain mappings. Considering that this method does not need a large volume of input such as content-based ACA (Jeong et al., 2014; Kim, Jeong, & Song, 2016), we believe that our proposed method could be easily applied to various disciplines so as to depict scientific intellectual structures by involving more information and improving traditional ACA.

Besides the method itself and its advantages compared with traditional ACA, this study provides several implications to the future researchers. First, we use full-text data but not intend to analyse content-level information, which breaks the conventional thinking to use complex natural language processing technologies to mine content- or semantic-level (Bu, Huang, Ding, & Ai, 2017) data so as to map knowledge domains. Second, such idea enables to be applied into not only ACA but also other scholarly network analyses, such as author bibliographic coupling analysis (Zhao & Strotmann, 2008a) and coauthorship analysis (Ding, 2011b). Last but not least, this research supplements the framework of bibliometric elements proposed by Morris and Vander Veer Martens (2008), in which papers, paper authors, paper journals, references, reference authors, reference journals, and index terms are included. Our study provides “citing sentences” as a bridge between “papers” and “references”, and shows the potential detailed affiliations about “citing sentences” such as the number of mentioned times and the number of context words of references. These have offered significant foundations for future supplements of the bibliometric element framework when more full-text data are involved.

However, there are several limitations in this research. For example, we only used first authors’ information instead of all authors’. The accuracy could thus be negatively affected. Moreover, there are still many other types of metadata that are not used to involve in ACA in previous studies and this paper, such as the sequence of co-cited authors (He, Ding, & Yan, 2012) and the number of figures or tables (Lee, West, & Howe, 2016). We would like to focus on these in the future.

Abstract
On purpose of solving current limitation of patent citation analysis methods, we propose a new method named multiple technology topic paths method, which can capture more than one significant technology paths from patent citation network while patents from each path focus on certain technology topic. In more detail, this method uses text similarity between patents as weight of citation and applies dynamic programming for for technology paths searching in patent citation network, which gives rise to trajectories of main technologies development. As an empirical study, we take magnetic head of hard disk drive as example, the result shows the method can effectively generate whole picture of technological evolution process for magnetic head.

Conference Topic
Patent Analysis

Introduction
Technological evolution analysis is widely used within industry to support strategic decision and long-range planning. It provides access to exploring essential characteristics of technological evolution and examining relationships between different technologies, thus lies foundation for predicting future trends of emerging technologies.

Technological evolution analysis methods originated in 1940s, after development of almost 70 years, there are amount of members in this family, such as expert method, bibliometric methods, TRIZ (Russian abbreviation for Theory of Inventive Problem Solving), text mining method and so on. These methods help researchers to get insights into technological evolution from different viewpoints. However, at present all kinds of methods have their own limitations. Qualitative method such as the expert method is sensitive to subjective factors, quantitative methods can avoid this problem, but they have their own limitations, patent citation analysis is strongly dependent on citation network structure, data noise in network could lead to totally different technological evolution path, text mining method is proper for small dataset and TRIZ emphasizes its role in guiding specific innovation activity in engineering environment.

Under such condition, we propose a method to analyse technological evolution process in micro-level. This method applies text mining technique and dynamic programming algorithm on patent text and patent citation network for technological topic path searching. By extracting significant paths and combining them together, we can establish a network backbone which reflects the evolution process of significant technologies in target field.

In remainder of this paper, first we describe current development of technological evolution analysis methods based on patent citation as background knowledge in section 2. Second, the proposed method is explained in section 3. As an illustration, this method is applied to magnetic head of hard disk drive (HDD) in section 4. Finally, we conclude with a summary and briefly describe the further work.
Literature Review

Patent citation analysis

As the main outputs of R&D activities in companies, patents represent the direction and essential nature of technology development. Nowadays increasing researchers take patents as the main data source for technology management and intelligence analysis. Statistical data shows that 80% of the world's technological knowledge can be found in patent documents, furthermore, due to law procedure and commercial benefit, patent information is compiled rigorously under complete citation & audit mechanism, which not only leads to stronger correlation between citing patent and the cited one, but also the tendency in academic references has little impact on patent citations (Mitchell, 1991). Researchers have begun their efforts in patent citations since 1990s, while established a serial of indices based on patent citation, they proposed various methods for technological evolution analysis, within which the most representative one is so-called main path method. Compared to others, main path method evaluates one patent’s value by the structure of whole citation network and the position of this patent in it, which give rise to recognition for basic patents and milestone ones with high speed and low cost. Main path method was first proposed by Hummon and Doreian in 1989, this method takes importance inequality of citation relation into consideration, important citations act as main path for knowledge stream to go through, their remove will change the process of knowledge diffusion, while insignificant citation relations cause much less influence. In a sense, main path is the backbone of a citation network and it describes the most critical knowledge flow in it. Via main path method, researchers can focus on much fewer patents on main path, and achieve valuable result more easily. Main path method searches path by the following heuristic algorithm:

(i) Choose an index to measure significance of edges in citation network.
(ii) For each start point, pick the outward edge with maximal value among all outward edges from that start point. If more than one edge in the maximal value, take all them in.
(iii) Select the start points with maximal edge value among all start points in Step (ii). This is the start points of the main path.
(iv) Take the target nodes of the edges identified in the previous step. For each target node, pick the outward edges with maximal value from it. If these edges point to end points of the network, exit, else go back to Step (ii) and continue.

V. Batagelj (2003) first applied main path method on patent citation network with the background that patent citation network was one of few networks accessible at that time. Until 2007, B. Verspagen began to use main path method for technological evolution analysis, he noticed the original version of main path method uses greedy strategy for path searching, which can’t guarantee global optimum resolution. So he suggested a new version of main path method, which employs exhaustive strategy to ensure the result path to be global optimal. J. S. Liu called the original version of main path method as local main path method, and B. Verspagen’s version as global main path method, he suggested that it be useful to extract paths with top n weight by global path method, so more technological trajectories can be covered, he called this version as multiple Main Path method.

As a widely used approach, main path method has been integrated into popular network analysis software like Pajek. Although it provides efficient, and low-cost way to generate technology path, there are still some critical drawbacks in it which jeopardize its further application:

(1) Technology evolution is an uncertain process, it can develop in multiple possible ways and be implemented in various designs, these can be observed in patent citation network that multiple important technology paths occur simultaneously. Currently, both local main path
method and global main path method extract the “most important technology path” as output, which has drawback on technology coverage. Although B. Verspagen suggested extracting several technology paths to solve this problem, he did not implement it.
(2) Even technology path extracted by global main path method is more convincing than local main path, its time complexity is too high to tackle large-scale citation network.
(3) Indices based on network structure are sensitive to missing data and noise, which may cause significant change of result path.

**Methodology**

In order to solve main path method’s drawbacks, this paper takes topic into consideration and proposes a new variant of main path method which can extracts multiple main paths with each path focusing on a unique topic. So researchers can trace the evolution of different technologies conveniently. Furthermore, this method provides a way to observe relationship between different technologies. As patents in a main path belong to same topic, we named these new main paths as technology topic paths.

The whole process of this method is shown as below. First, searching patents and pre-processing them to build patent citation network. Second, taking patent abstracts as corpus and applying topic model to it to estimate model parameters, then calculating similarities between any pair of patent abstracts. Third, using proposed multiple main path method to generate candidate technology topic paths from patent citation network. Finally, sorting candidate technology topic paths by weight and generating technology topic backbone, the weakly connected components in technology topic backbone are the final technology topic paths.

**Data preparation**

After collecting relevant patents with their abstracts and citation information from patent database, data preparation includes two steps:

(1) Generating patent citation network by citation information;

(2) Pre-processing patent abstracts and building a corpus. Extract abstracts from patent dataset and run a series of pre-processing steps which include tokenizing, removing stop words, stemming, lemmatization and so on. Then use these cleaned patent abstracts to generate a corpus.

**Calculating semantic similarity between patent abstracts**

Apply topic model to the corpus to extract latent topics, and use these topics to represent every patent abstract. Compared with text of patent abstract, representation of patent abstract by topics can reduce number of features dramatically while maintaining necessary semantic information (Luo et.al. 2014). Furthermore, as patent abstract is short text, directly applying standard text similarity measure to patent abstracts measure always fails (Metzler, et.al. 2007) as a result of vocabulary mismatch problem (Furnas, et.al. 1987). However, since all topics occur in every patent abstract, patent abstract represented by topics can effectively avoid this problem. Here we choose the most widely used topic model--LDA (Blei, et.al. 2003) in our research, and calculate cosine similarity between different patent abstracts.

**Generation of candidate technology topic paths**

Intuitively speaking, main path with more significant topic should contain more patents and the semantic relationship among these patents should be tighter. Based on this, we create an indicator to measure path significance like this: calculating similarity of all possible patent pairs in a technology topic path, then summing all similarities as the weight of this main path. Main path weight is calculated by Eqs 1.
\[ W_{\text{path}} = \sum_{\text{node}_i \in \text{path}} \sum_{\text{node}_j \in \text{path}} \text{sim}(\text{node}_i, \text{node}_j) \]  

Where \( W_{\text{path}} \) indicates the weight of main path, and \( i, j \) are node IDs. \( \text{Sim}(\text{node}_i, \text{node}_j) \) indicates the semantic similarity between \( \text{node}_i \) and \( \text{node}_j \).

For example, there is a technology topic path shown as in Fig. 1, all node pairs on this path include (1,2), (1,3), (1,4), (2,3), (2,4), (3,4), therefore the weight of this path is: \( W_{\text{path}} = \text{sim}(1,2)+\text{sim}(1,3)+\text{sim}(1,4)+\text{sim}(2,3)+\text{sim}(2,4)+\text{sim}(3,4) \). Here we inverse the direction of citation to mark the direction of technology development.

**Figure 1. Technology Topic Path**

Given a patent citation network, the basic idea of candidate technology topic paths searching method is, start from a source node, traverse the citation network to find a path that has global optimal \( W_{\text{path}} \), in order to reduce this pathfinding algorithm’s time complexity, we use dynamic programming (Cormen, et. al. 2009) as search strategy.

In detail, candidate technology topic paths searching method is designed as below: taking a source node as start point and making breadth first traversal. Before cursor leaves current node, taking this node’s ID as key, taking a tuple, which consists of edge from start point to current node and this edge’s weight, as value and store the key-value pair into dictionary. After visiting all direct successors of source node, taking these successors as start points and repeat breadth first traversal. During traversal, if algorithm finds current node has been stored as key in dictionary before, it means there exists another path from the source node to current node that cursor has already traversed, then the algorithm will achieve this earlier path and compare its \( W_{\text{path}} \) with \( W_{\text{path}} \) of current path, if current path’s \( W_{\text{path}} \) is greater, the algorithm will create a tuple consisting of current path and its \( W_{\text{path}} \), then use it to replace the value corresponding to current node in dictionary, else keep the value unchanged and continue traversal process until the end. At last dictionary stores paths from the source node to all end nodes it can achieve, and every path is the global optimal one among all possible paths this path’s both end. We output path with largest \( W_{\text{path}} \) as result.

![Diagram of Technology Topic Path](image-url)
Figure 2. Patent Citation Network

In order to make the searching process clear, let’s assume that we have a patent citation network shown in Fig. 2, the semantic similarities between patent abstracts are shown in Table 1, here we show how to search candidate technology topic path in Fig. 3, the grid in each step presents dictionary’s content at that moment.

</tbody>
</table>

Figure 3. Technology Topic Path Searching Process
In step (1), from node 1 we begin breadth first traversal and achieve its successor nodes 2, 3, then we put nodes 2, 3 and their relevant information into dictionary. For example, we take node 2 as key, take tuple consisting of edge from node 1 to node 2 and its weight as value, and stores the key-value pair in dictionary; In step (2), we visit node 2’s successor node 4, according to Eqs 1, we get weight of path $1 \rightarrow 2 \rightarrow 4$, then take node 4 as key, take tuple including path $1 \rightarrow 2 \rightarrow 4$ and its weight as value and put them into dictionary; In step (3), we get node 3’s successors node 4, 5, since node 4 has been put into dictionary as key before, we need to calculate the weight of new path from node 1 to node 4, which is $1 \rightarrow 3 \rightarrow 4$, then compare it with the weight of earlier path, which is $1 \rightarrow 2 \rightarrow 4$, as earlier path’s weight is greater than new path’s, we keep node 4’s corresponding value unchanged in dictionary, but if earlier path’s weight is less than new path’s, we should replace node 4’s corresponding value with tuple consisting of path $1 \rightarrow 3 \rightarrow 4$ and its weight, then take node 5 as key, take tuple contains path $1 \rightarrow 3 \rightarrow 5$ and its weight as value, then add them into dictionary, and so on in step (4), (5). Eventually we find $1 \rightarrow 3 \rightarrow 5 \rightarrow 6$ as the path with highest weight and return it as the candidate technology topic path.

Generation of technology topic backbone

On basis of candidate technology topic paths, now we generate technology topic backbone. The process of generating technology topic backbone is, first we sort all candidate technology topic paths by weight, then we take the path with highest value as target network, and merge other topic paths into target networks in descendent order. After every mergence, record the snapshot of current target network, then we select a snapshot to be the final technology topic backbone. The intuition of selecting strategy is that technology topic backbone should highlight a few important technology topic paths, which are indicated by path’s weight, in the meanwhile, as paths merge into target network, paths with different topics may be connected, thus we have to balance number of highly weighed topic paths against number of weakly connected components in target network, and make an optimal choice from snapshots as technology topic backbone.

Illustrative example: Technology topic paths in HDD

The hard disk drive (HDD) technology field is selected as an exemplary study, because changes in technology of HDD have been much rapider than that in other fields, so it provides an opportunity of technological evolution analysis in a shorter time (Christensen, 2011). America is the birthplace of HDD and it keeps playing an essential role in propelling HDD technology move forward, major HDD companies have paid much attention to intelligence protection and filed amount of patent applications to protect their intelligence right since the beginning. Therefore relevant patents can be treated as a more representative and trustworthy data source for technological evolution analysis. Since the first appearance of HDD in 1956, HDD has undergone 3 generations which includes ferrite head disk drive, thin film head disk drive and magnetoresistant head disk drive (Christensen. 2011). As thin film head disk drive has endured the longest period of development, here we focus on thin film head which is a core component of thin film head disk, and collect bibliographic and textual information of patents on HDD from USPTO database.

Retrieving Patents

(1) Take (TTL//"thin film head" OR ABST//"thin film head") AND APD//1/1/1976->31/12/2013 as search query and run it on USPTO official website, we achieve 190 patents.
(2) With the assistance of ISTIC Patent Database supported by Institute of Science and Technology Information of China (data updated til 38th week in 2014), we retrieve patents
citing or cited by 190 patents. According to these patents’ USPC labels, we removes irrelevant ones and generate a dataset of 3503 patents.

(3) With citation information of 3503 patents, we generate a citation network consisting of 15 weakly connected components, among which the giant connected component contains 3193 patents. After removing invalidated patents, there are 2876 patents left. We use bibliographic and textual information of these 2876 patents for our exemplary study. As for patents in other weakly connected components, since their isolation, ignorance of them induces little negative effect on analysis result.

Calculating semantic similarities between patent abstracts

We use Python and NLP (Natural Language Processing) package Gensim (Redim, et.al. 2010), NLTK (Bird, et. al. 2009) to process patent abstracts. NLTK provides stop words list and term stemmer, Gensim provides tf-idf function, LDA model function and Cosine function to calculate similarities between patent abstracts.

After pre-processing patent abstracts as shown in previous section, we build a corpus and a vocabulary consisting of 4707 terms. According to perplexity curve generated by the corpus, we set topic number to be 110 and estimate parameters using LDA model. Finally, with representation of every patent abstract by these 110 topics, we calculate semantic similarities for every possible pair of patents.

Generating candidate technology topic paths

We implement technology topic path extraction algorithm using Python and package Networkx (Hagberg, et.al. 2008) which provides a series of basic network operation functions. After running technology topic path extraction algorithm on patent citation network, we get 828 candidate technology topic paths. A more detailed information of these paths is shown in Fig. 4, where the horizontal axis represents number of nodes contained in technology topic path, the vertical axis represents number of paths with same number of nodes. In order to show the changes of path counts as nodes of path increases, we smooth histogram by Gaussian kernel density estimation (KDE) and generate a blue line. From Fig. 4, we can see that most of the paths are concentrated in interval [4,9] with a few ones scattering at both ends of the curve.

![Figure 4. Distribution of Nodes in Technology Topic Paths](image-url)
Then we analyse the distribution of paths’ weight, due to the fact that path weight is calculated based on semantic similarity, which causes a fact that any two paths’ weight are seldom equal to each other, so we use KDE to smooth path weight distribution as before, and the result is shown in Fig. 5, where the horizontal axis represents path weight and the vertical axis represents number of paths falling in a weight interval. From Fig. 5 we can see most paths’ weight exist between interval (0,8]. As path weight increases, the number of paths shows a descendent trend.

Figure 5. Distribution of Weight for Technology Topic Paths

Generation of technology topic backbone

Based on 7 distinguished technology topic paths recognized in Figure 5, we establish technology topic backbone as Figure 6. We assign nodes on different path with different colour, as to some paths are crossed at one node, we assign any colour to the node from these paths. The labels besides node are patents number, and we use edges width to indicate texts similarity between patents.

Figure 6. Technology Topic Backbone
Result analysis

Detailed information about the 7 final technology topic path are shown in Table 2. We can see from 1972 to 2011, innovation activities of thin film head mainly involve 7 topics. In fact, according to relevant domain knowledge, major performance indices of HDD include areal density, absolute output, signal-noise-rate and resistance (Keiichi, et.al. 2006). The technology topic backbone indicates that innovators advanced HDD performance from two aspects: improvement of specific components and modification of the whole structure of technology. Path 2— innovations for layer of thin film head, path 4— innovations of read-write component for thin film head, path 7— innovations for magnetic core in thin film head belong to the first aspect, and Structure design of thin film head belongs to the second one.

Table 2. Information of Main technology topic paths

</tr>
</tbody>
</table>

Besides innovations focusing on advancing performance for HDD, other significant development of thin film head technologies includes path 5—etching methods in thin film head manufacture, which are used in manufacture process of thin film head. Also we can identify the tight relationship between thin film head and magnetoresistant head from path 3 and path 6. Actually the purpose for thin film head to integrate magnetoresistant components is to create a separate reading head, which enable to read very small magnetic features reliably (Mao. 2013). As to why related technologies of thin film head, such as etching method in thin film head manufacture and manufacture technology for layer of magnetic head, can keep on developing when magnetoresistant head has occupied dominant position in the market, the answer is that, as a result of structural inheritance between thin film head and magnetoresistant head, these technologies relevant to thin film head can be applied on magnetoresistant head and facilitate its development.

Conclusion and discussion

This paper proposes a new main path analysis method which takes topic into consideration comparing to previous methods of technological evolution analysis, it can produce multiple main paths each of which focuses on a unique technology topic. Thus apart from identifying major directions of innovation in a technology field, new method enable researchers to trace each direction’s evolutionary trajectory at micro level, in the meanwhile, with all multiple main paths put together, researchers have the opportunity to explore relationship between
different technology topics and get a deep understanding of technological evolution in a field. In addition, this method is domain-independent, in another research project we applied it to field of electric vehicle battery and precisely identified two most significant technology topics which includes cooling technology for battery module and monitoring technology for electric power of battery.

There are a lot of improvement for our method, such as the indicator used to measure significance of technology topic path. It’s probable that high value is caused by path with a large number of nodes in it, and it doesn’t necessarily reflect significance of this path. Vice versa, for some emerging technologies with tremendous potential, they may not be highlighted by path weight indicator as a result of a few patents involved. So in next step, we will focus on measuring the potential of emerging technologies.

Abstract
Patents signal a startup’s technological and innovative capability. Venture Capital (VC) investors can evaluate the true potential and behaviour of startups through their patents. While, there are many factors might have effect on the amount of VC financing. Some scholars have researched this question in other countries, but the detailed interaction between VC and patent activities in China is different and attractive. This paper tries to explore this relationship in the view of patent, growth stage, and industries by hypothetical test. We first propose four hypotheses about influence factors to VC. Then we use multi-source to get patent and VC data of listed companies. By descriptive statistics, univariate analysis and multivariate analysis, we try to verify our hypotheses. This research can provide advices to financers, investors, and policy makers by describing the relationship between technology innovation and VC.

Introduction
Innovation and its role as crucial carrier of sustainable national economic progress and competitive edge has been acknowledged to certain extent in formal writings since Schumpeter (Lazzarotti, Dalfovo, Hoffmann & Valmir, 2011). Many scholars argue that cost input is good for nurturing innovation (Gans, Hsu & Stern, 2002; Lerner, 2012; Chemmanur, Loutskina & Tian, 2014). However, some firms, especially new firms, can rarely rely on internal cash flows in their pursuit of innovation. Among the sources of external finance which may help to entrepreneurs, capital funding can provide not only the financial resources they require, but also assistance to enhance the design, development, and performance of portfolio companies (Schwienbacher, 2008; Cumming & Schwienbacher, 2005; Luukkonen, Deschryvere & Bertoni, 2013). Investment decisions largely characterised by the management thinking and quality of desired goals and objectives according to the current development state (Zacharakis & Meyer, 2000). For a commercial enterprise, quality is a state that can be reflected by employee’s skills, product or service designing for target customers, supply chain setup, proprietary rights, budgets, sale, income, marketing research and activities (Teece, 1993; Tripsas, 1997). Unlike
established firms that own many of these assets, new firms face a particularly strong challenge in securing complementary assets for their technology commercialization. Therefore, venture capital (VC) emerged and gives new firms more opportunities. After the world’s first VC firm being founded in 1946 in the US, VC begins its mature organization and institutionalization stage. This industry has changed the way of technological innovation in the US, which greatly promoted the sustained national economic growth (Yang, Wang & Wen-Jie, 2016). As to China, VC started in the 1990s and has gradually embarked on the development track after those years (Long & Liu, 2013). However, the relationship between new firms and VCs is characterized by information asymmetries because it is difficult for VCs to evaluate the true potential and behaviour of new firms (Baum and Silverman, 2004; Neher, 1999). Also, it is hard to estimate how the VC would influence on enterprises’ innovation output.

To give investors more significant information, some technology-based firms may utilize patents to communicate the quality of their underlying technologies to investors (Hsu and Ziedonis, 2013; Conti et al., 2013; Haeussler et al., 2014). Patent is an important output of firm innovation, and would lead to competitive advantage due to asset specificity. Patents signal a startup’s technological and innovative capability and have direct effects on VC financing. On the other side, many variables, such as VC funding, have been investigated that they have influence on patents’ effectiveness. Previous studies provide plenty theoretical explanation and empirical test through resource based view on these topics.

However, the exploration between VC and patents activity is few in China. China has a notable patents number in recent years, especially after the national strategy of “building innovation-oriented country” in 2006, and remains the biggest patent application country since 2011. The Derwent World Patents Index 3 estimated that by 2015, Chinese owned companies would be generating 500,000 patents, a number 25% more than the number of patents the US is expected to have. Even though, China’s market environment is different from that of other countries, how the VC and new firms’ technology innovation interacts each other is still not clear. Therefore, this paper tries to analyse their interaction in the view of different industries, bio-pharmaceutical and electrical & electronic. There are numbers of differences among industries, including government’s attitude and policy, global developing environments, the importance of technology innovation and investors’ opinion. To understand the different interactions of different industries’ process, we test several hypotheses using a sample of bio-pharmaceutical and electrical & electronics companies that seek VC. We analysis the VC data from PEDaily.cn [http://zdb.pedaily.cn/] and patent data from SIPO. Next section will introduce some theories and our hypotheses, then introduce the data and the method to test hypothesis, and results follow. Conclusions and discussion are in the last part.

**Theory and hypotheses**

*Technology innovation and patent*

Innovation is defined as the creation of new knowledge and ideas to facilitate business outcomes, processes and structures and creates new products and services (Du Plessis, 2007). Technology innovation refers to be a kind of improvements and modifications of existing technologies, and creating of new technologies. It is driven by the creation of knowledge and knowledge creation is perceived as one of major assets (Pei, 2008). Several measurement indicators of technology innovation have been proposed (Pakes and Griliches, 1984; Tseng, 2009; Coccia, 2014; Ayerbe, Lazaric, Callois & Mitkova 2014), including R&D, patents and new products. As a description of the fundamental nature of technology, or knowledge, and the strategic behavior of the firms when utilizing these technologies (Woo, Jang, & Kim 2015), patent is used as a major measure to elucidate technology innovation in this study for the following reasons (Tseng, 2014). First, patent data are easily accessible via the database, and don’t have problems of imprecise
definition and lack of comparability between firms. Second, patent data are accurately recorded and easily manipulated for more detailed analysis by technological field, patent inventors and assignees. Third, patents are an objective measure of technology innovation, since patents are examined and eventually granted by a single national patent office. Finally, in comparison with other sources, patents are often the only timely measure of rapid technological change, particularly in the context of global competition.

To judge whether there are relationships between technology innovation and VC, we propose the two hypotheses:

**Hypothesis 1.** Ceteris paribus, whether a startup has patents or not will make significant sense on the amount of funding money obtained from VCs.

**Hypothesis 2.** Ceteris paribus, the more patents a startup holds, the more funding money will be obtained from VCs.

*The growth stage of financing firms*

A study on China has proved that firm ageing has positive impact on organisation technology innovation outputs (Shi, Zhu 2014). To simplify our analysis, we consider the growth theory, instead of every-year age, to check the relationship between firm’s growth stage and its financing ability. Growth theory suggests that appropriate growth and capital capacity strategies vary at different stages of a firm’s growth (Anthony & Ramesh 1992), which consists of four stages: in the early, development, expansion and profit stage. Each stage exhibits significant differences in terms of situation, organizational strategy, structure, and decision-making style (Adizes, 2004; Miller and Friesen, 1984; Pashley and Philippatos, 1990). So, we get information of growth stage from our database and use 1~4 to respectively represent four stages: in the early, development, expansion and profit stage. So we propose this hypothesis:

**Hypothesis 3.** There are significant variations between the stage of growth and the amount of VC financing.

*Characters of different industries*

Every industry has its own character both on internal technology and external environment. In the view of internal technology, numerous complementary technologies are developed via different and diverse R&D lines in a complex industry, which increase the overall probability of creating a successful innovation (Bessen and Maskin, 2009). So, different industries have different attitudes to the relationship between technology innovation and patent, including the “innovative degree” contained by each patent in different industry, the importance of technology innovation to Return on Investment (RoI) and enterprise performance, which has direct influence on investors’ decisions. As to external environment, government usually holds different attitude and carries out various policies to different industries. At the same time, the maturity of development varies from industry to industry, which means their global marketing environments are also different. All these factors will work on investors’ judgement. Therefore, we decide to compare two typical and important industries, pharmaceutical industry and energy exploitation industry. Our second hypothesis is:

**Hypothesis 4.** In different industries, the number of startup’s granted patents, the growth stages of financing firms, investors’ funding amount, and VC series will have different characteristics.

*Data and sample*

*Data and sample description*

We study the role of information generated by corporation, especially patent, for VC financing in China. In this study, we choose listed companies as object of study. Because they will make more information (financial performance, corporation governance, the amount of VC funding,
and so on) public and it’s too difficult to find enough information of unlisted companies to analyse. The VC data is mainly collected from China Venture (https://www.chinaventure.com.cn/) and complementally from PEdata (http://www.pedata.cn/), both these two databases are relatively complete, widely used and have better reputations. The patent data is collected from SIPO (State Intellectual Property Office of the P.R.C., http://www.sipo.gov.cn/) and CSMAR (http://www.gtafe.com/), a professional database for research in China. Here we distinguish granted patent and applied patent (Haeussler, Harhoff, & Mueller 2009), cause only applied patent can’t evaluate technology innovation of a firm, while granted patent by SIPO can provide more reliable information about technology innovation.

**Measures**

There are two dependent variables in our analysis, whether obtained VC or not (VC_obtain) and the amount of VC funding (VC_amount). What’s more, invention patent, utility patent, and design patent have different characters and different degree of innovation. So, we will also distinguish the patent’s type and use them as independent variables. According to previous study (Hoenen, Kolympiris, Schoenmakers, & Kalaitzandonakes 2014), we firstly conduct univariate analysis by using whether applying and being granted patent (3 types) or not, the number of applied patents (3 types), the number of granted patents (3 types) to analyse whether these factors will have effect on getting financing or not.

</tbody>
</table>
Stage of lifecycle of financing firm, use 1~4 to respectively represent four stages: in the early, development, expansion and profit stage. The industry of financing firm.

Secondly, we will further add the stage of lifecycle of financing firm as independent variable to analyse how these variables operate on VC_amount. Table 1 describes these variables in detail. In this step, we will build a model to evaluate the influence of these variables on VC_amount by empirical test. We propose the model as follows:

\[ VC_{\text{amount}} = \alpha_0 + \alpha_1 \text{PATapply}_i + \alpha_2 \text{PATgrant}_i + \alpha_3 \text{INVapply}_i + \alpha_4 \text{INVgrant}_i + \alpha_5 \text{UTIapply}_i + \alpha_6 \text{UTIgrant}_i + \alpha_7 \text{DESapply}_i + \alpha_8 \text{DESgrant}_i + \alpha_9 \text{Stage} \]

Every \( \alpha \) is a regression coefficient of each independent variable. If \( \alpha \) is positive, it means its corresponding variable has positive effect on obtaining more financing amount.

Thirdly, we consider the function of control variable, the industry of financing firm (Industry). There are many studies, as well as foregoing analysis have proved the relationship between patent and VC is only obvious in A round (Conti, Thursby, & Thursby 2013; Zhou, Sandner, Martinelli, & Block 2016), so we choose all data about A round as a sub-database to continue our analysis. According to our now available database, fewer companies are included in each industry (provided by CSMAR), so we cleared up our data of A round, clustered and chose two industries, bio-pharmaceutical industry and electrical & electronic industry, to conduct later research.

Bio-pharmaceutical industry refers to economic activities of mass production of marketable drugs through the application in pharmaceutical industry of the research results of modern biotechnologies, such as genetic engineering, cell engineering, enzyme engineering, fermentation engineering and protein engineering. In many countries, bio-pharmaceutical industry has been identified as a key industry in the 21st century. In comparison, the bio-pharmaceutical industry is characterized with high-tech, high investment, high-risk, high-yield and long-cycle.

Intellectual property rights are essential to innovation and development of the bio-pharmaceutical industry. Only by establishing a sound intellectual property system, can the development of bio-pharmaceutical industry form the virtuous circle of “innovation-protection-innovation again”. Due to the lack of protection consciousness and talents, protection on intellectual property related with biomedical field is inadequate in China. Both the application of and the protection on patents of biomedical research achievements have a big gap with foreign countries, which result in some high value research results failed to properly obtain patent protection. Moreover, when cooperating with industrial companies, China’s biomedical research institutions often cannot accurately assess the value of their research achievements.

Analysis and results

Descriptive statistics

We searched VC and patent date from January 1st, 1999 to December 31st, 2016. After integrating the same type of data from different sources, matching VC records and patent records of the same corporations, cleaning fuzzy records, we finally got 19,115 records of companies’ applying patents and 2,757 events of VC of listed companies. It’s worthy to note that, in the view of corporations who obtained VC, the proportion of having patent is 15.05% and 20.38% of having no patent, which doesn’t have much special meanings cause the database of applying patent is relatively bigger than that of VC. The detail of all these data is shown in Figure 1. There are some corporations who have financed more than once, to get more valuable
samples, we use one event of VC as a sample. So, we get 4690 samples, including 2,757 VC events and 1,993 corporations who have patent but no VC funding.

1,993 corporations who have patent but no VC funding.
(18,577 records of corporations who have patent but no VC funding.)

353 corporations who have patent and VC funding.
(538 records of corporations who have patent and VC funding.)

1,732 corporations, 2,757 VC events
2,346 corporations, 19,115 records of applying patents

1,732 corporations, 2,757 VC events
2,346 corporations, 19,115 records of applying patents

1,379 corporations who have no patent but VC funding.
(2,219 records of corporations who have no patent but VC funding.)

Figure 1. Distribution of all VC data and patent data

Table 2 shows the result of descriptive statistics of main variables. The standard deviations of both the amount of VC funding and the number of patent are large, which illustrates that every firm’s technology innovation varies and the results of their VC financing are also significantly different. Among, Semiconductor Manufacturing International Corporation (SMIC) financed the most in one event, 7020.91 million RMB from Shenzhen Capital Group (SCGC), China Merchants & Fortune Assets Management Ltd, and Zhangjiang Hi-Tech Park in its A round financing. And ZTE Corporation has applied and been granted the most patents, 40,608 and 20,355 respectively. What’s more, a large number of top patent holders, including ZTE, Sinopec, Gree, PetroChina, BYD, Midea, JAC, Baosteel and many “successful” companies, have never financed for VC before, this might because they have good market performance and reputation to get enough capital flow. This also explains why the relationship between VC and patent is more obvious in A round and growth-oriented small and medium enterprises.

</table>

We finally get 538 records of corporations who have patent and VC funding. These records come from 353 listed corporations, including 5 types of financing rounds (as shown in Figure 2) 54 industries (top 10 industries are shown in Figure 3).
Among the whole 538 records (Figure 3), investments in mechanical equipment, hardware industry, communication equipment and other high-tech related industries dominate. On account that high-tech development is an exit to powerful nation, China has turned into the age of technology innovation. Besides, these technologies bring so much benefits to humans, which makes our life more convenient and fantastic. Manufacture is a big industry, which is closed to daily life. For example, we need furniture, vehicles, and other necessities. So, this industry also attracts so many investors, and industry pressure is not too small. The third one is pharmaceutical industry. This is a traditional, fast developing industry, for the reason that people are getting more concerned on health. Many new medicines will be created, even may change the word.

**Figure 2. Distribution of financing rounds**

**Figure 3. Distribution of top 10 financing industries**

*Univariate analysis*

To initially check whether a financing firm having patent (both applied and granted) will or not have influence on VCs’ decision (investing or not), we use univariate analysis to reach this goal. We divide all our data about 2,757 listed company into two group, have ever got VC, and never got VC. Then we use T test for independent-samples and the result is shown in Table 3. The Wilcoxon rank-sum test also shows there are differences among these variables at 0.01 significance level. Comparing to corporations who have never got VC, the corporations who have ever got VC usually have larger numbers of both proportions and amount of applying patents and granted patents, except the design patent. This illustrates that those corporations who have applied patents and been granted patents tend to obtain VC more easily from investors, as well as there is indeed close relationship between VC patent, which verifies Hypothesis 1. Therefore, we will further analyse how these variables work on the amount of VC financing by the method of multivariate analysis.

</table>

We can see that the VC_amount doesn’t have correlations with PATapply, PATgrant, INVapply, INVgrant, UTIapply, UTIgrant, DESapply or DESgrant. These results reject Hypothesis 2, which is opposite to previous study. By analysing our data and China’s situation, we find that all the patent data we got is about listed companies. While it is a signal that the company already has good performance, they can get enough capital flow through other ways, not only VC. What’s more, VC still doesn’t develop maturely in China and many investors tend to make their decisions without considering patents.

Other analysis

To test Hypothesis 3, we calculate the average of financing amounts of different growth stages of financing firms. The 538 records of corporations who have patent and VC funding are analysed and the result is shown as Table 5. We can see the averages are different and the amount is larger in earlier stage. This because venture capitalists are primarily engaged in nurturing innovation in small, nimble startups (Morgan, 2014). Therefore, a firm in early stage tends to get VC easily, which verifies Hypothesis 2.
As for different industries, pharmaceutical industry and energy exploitation industry, we analyze some dimensionalities and get the result shown in Table 6. We can see that pharmaceutical industry get less VC funding with more patents, which indicates pharmaceutical industry is more technology-oriented than energy exploitation industry. And this conclusion is also in agreement with the common sense that pharmaceutical industry will have more patents when creating new medicines. The distributions of growth stages of financing firms in these two industries don’t make big difference and both are focus on development stage and expansion stage. This might because these two industries have much risks in early stage and VC investors prefer other industries for risk averse, which also result that they have more series A in their development stage and expansion stage instead of early stage. While coming to these two stages means they have a promising market and they need more funding for further
expansion, in which time VC will play an important role. Therefore, the results verify Hypothesis 4 partly so we need further study in the future.

Conclusion
This paper first described the relationship of whole VC data and patent data, distributions of financing rounds and industries. Among all the corporations who obtained VC, the proportion of having patent is 15.05%. The mainly financing round is A round and high-tech related industries dominate. We put forward four hypotheses based on insights from earlier research. Hypothesis 1 is whether a startup has patents or not will make significant sense on the amount of funding money obtained from VCs, which is verified through the univariate analysis. Hypothesis 2 is the more patents a startup holds, the more funding money will be obtained from VCs. However, this can’t be verified which might because Chinese characteristic condition or our data’s problem, which needs further analysis. And there are significant variations between the stage of growth and the amount of VC financing by verifying hypothesis 3. Hypothesis 4 is verified partly, which means the number of startup’s granted patents, the growth stages of financing firms, investors’ funding amount, and VC series will have different characteristics among some, instead of between any two, different industries. So how the feature of different industries make influence on VC should also be studied.

We will make more analysis in the future research. First, in most present research, scholars usually use the number of different types of patents, even don't distinguish the type, to evaluate a firm’s technology innovation. It might be unilateral cause the quality of patent varies. We plan to add text-mining and more indicators of patents to the following research. Second, we will collect more VC and patent data of unlisted companies, who is in more need of VC and will get much more useful direction from this kind of research. Third, patent is only one pattern of manifestations of technology innovation, some other manifestations, such as software, are also innovation of a firm’s technology. So, it is also worthy to consider other patterns of technology innovation.

The choice of examiner citations for refusals: Evidence from the trilateral offices

Tetsuo Wada

Gakushuin University, Tokyo (Japan)

Abstract
As a comparative study between the EPO, the USPTO, and the JPO, this paper reports on (1) the discrepancies of X/Y patent citations (blocking patents), (2) overall trend of the discrepancies, measured by patent classification vector, and (3) how the discrepancies of X/Y patent citations relate to the characteristics of applications and longitudinal aspect of office actions. Blocking patents both in EP and US commonly show that the first action lag and the breadth of patent class of patent application are positively correlated with divergent refusal reasons, suggesting that costly examination leads to diversified X/Y patent citations for grant/refusal decisions.

Conference Topic
Patent analysis, Analysis on examiner citations, X/Y citations

Background
Patent citations have been widely utilized for empirical studies of patent systems, particularly for such issues as economic value and knowledge flows. Yet, there are numerous kinds of patent citations. Whereas the differences between examiner citations and inventor citations have received better understanding as a result of several empirical studies (e.g., Alacer and Gittleman, 2006; Hegde and Sampat, 2009; Cotropia et al., 2013), there exist few analyses concerning examiner citations specifically for issuing refusals.

Examiner citations for refusals, which are assigned special categories of “X” and “Y” at the European Patent Office (EPO) and at other offices such as the Japan Patent Office (JPO), have important meaning, in that examiners must indicate specific reasons to refuse patent claims, for example, due to lack of novelty. Applicants seek to know which prior art will be used by examiners for refusals, since initial claims are likely to pass through prosecutions to patent grants if examiners do not assign X/Y citations (i.e., if only “A” citations, or simply “relevant” prior art, are assigned). Thus, characteristics of X/Y citations has practical significance for patent prosecution strategies of applicants.

Furthermore, X/Y citations carry crucial piece of information in order to understand the institutional differences between countries. Statutory requirements of novelty and inventive step for granting patents are very similar among advanced economies. Therefore, the same invention described in the same claims and specification should theoretically invoke very close grant/refusal responses from patent offices. However, it is known that the decisions of patent grants and refusals by the trilateral patent offices (the EPO, the JPO, and the US Patent and Trademark Office, or the USPTO) often differ over the same content of triadic patent applications, as was studied by the Melbourne school (Jensen et al. 2005; Webster et al. 2007; Webster et al. 2014). X/Y citations have a clue in evaluating the mechanism by which examiners at the trilateral offices close the same case with different decisions. Yet, direct comparisons between citations for refusals have been challenging, since the US patent system does not provide citation category (such as “X” and “Y”) information. In other words, a novel data set on “blocking patents” in the US must be developed first.
Purpose
This present study takes advantage of a novel large-scale data set of “blocking patents,” obtained from refusal documents available as file wrappers on the Public PAIR database of the USPTO, to compare patent citations employed by examiners specifically as reasons for refusals. In other words, by way of approximating citation categories of X/Y for the USPTO, we are now able to measure technological divergence of individual refusal reasons used by the trilateral patent offices through family-to-family citations.

This proposal set three research questions: (1) the extent of technological discrepancies of patent citations for refusals (blocking patents) between the trilateral offices of the EPO, the USPTO, and the JPO, (2) whether we can find overall trend of the discrepancies, measured by patent classification vector, and (3) how the discrepancies of X/Y patent citations relate to the characteristics of patent applications and the longitudinal aspect of office actions, i.e., the dates on which refusals were presented to applicants.

Data source
We are in the process of developing a large-scale US blocking patent database by extracting patent numbers from the main text of “CTNF” (non-final rejections) and “CTFR” (final rejections) documents available on the Public PAIR database of the USPTO. These document types are different from “PTO-892” (Notice of references cited by examiners) from which US examiner citations are usually extracted, in that examiners state in the main text of CTNF/CTFR which prior arts they actually rely on to reject individual claims. Optical character recognitions and natural language processing are conducted by Guan-Cheng Li, who has also contributed to numerous patent data projects at the University of California, Berkeley. Attorneys at the AIPPI Japan (International Association for the Protection of Intellectual Property, Japan) have also been contributing for this blocking patent database through manual verification. To the best knowledge of the author, there is only one similar, yet separate, large-scale database project on US blocking patents, which is run by Jeffrey Kuhn, based on PAIR documents hosted by Google (Thompson & Kuhn, 2017). A preceding study on blocking patents used only smaller-scale data (Cotropia et al., 2013). Combined with the US blocking patent database, the EPO PATSTAT database (Spring 2016) has been used along with the OECD Triadic Patent database.

The domain of statistical analyses is the set of triadic applications through PCT and non-PCT (initially, 409,653 DOCDB family citation pairs) where their first priority year being between 2003 and 2010 in a patent family. Citing side is a DOCDB family (initially, 43,339 triadic families) where only single DOCDB family ID is observed and where blocking patents are added by all of the trilateral offices. Cited side is also a DOCDB family (initially, 367,054 blocking patent families).

All citation data are patent citations, because of the availability of DOCDB family-to-family citations. It is a weakness, though most observed examiner blocking citations are patents only. We combine citation date information from the EPO DOCDB back file and the USPTO Bulk PAIR data to relate the technological difference with the refusal timing within international patent prosecution processes of an international patent family.
Findings

Simple Discrepancies at the DOCDB family-to-family citation level
First, as Table 1 and Figure 1 show, the trilateral offices largely rely on their own reasons of prior patents (X/Y citations, or blocking patents) for refusals. Based on 409,696 DOCDB family citations found from 43,343 citing families which have single-DOCDB family IDs and priority year 2003-2010, we find surprisingly small share of overlapping refusal reasons, though after the cited patents are consolidated by DOCDB international patent families.

Figure 1. Small overlaps between X/Y citations (blocking patents)

One might wonder that the small overlap is attributable to the prosecutions conducted on non-PCT applications, because non-PCT applications do not carry information from ISRs, which could provide common information of prior art for the designated offices (DOs) conducting national prosecutions. However, as Table 2 shows, the distribution of the non-PCT sample is not much different from the combined sample of PCT and non-PCT. ISRs prepared at the Receiving Offices (ROs) for PCT applications may help searching activities at the DOs, but they apparently do not affect the choice of X/Y citations during national prosecution processes. Because the overlaps of X/Y citations at the trilateral offices are small, we then utilize technological distance measurement to evaluate the substantial differences between them.

Methodology for comparisons in technological discrepancies

Following Jaffe (1986), we use the cosine distance measurement (similarity index) between bundles of citations using the International Patent Classification (IPC), i.e.,

\[ \text{COS}(\vec{a}, \vec{b}) = \frac{\vec{a} \cdot \vec{b}}{|\vec{a}| |\vec{b}|} \]

where \(\vec{a}\) is a blocking patent family citation vector. An element of this vector is a count variable of all main class assignments of the X/Y citation, i.e., cited patent(s) of the cited DOCDB family, recorded on PATSTAT tis209 (application IPC). No duplicate counts occurred when several IPC subclasses, main groups or subgroups in a main class are assigned, whereas more than one cited family member may result in more than one element in a main class.

In contrast, \(\vec{b}\) is a global citation vector, where a bundle of all citations in the family are added and counted. All DOCDB family members of the bundle are included to count IPC main class, so an IPC main class as an element of the vector may increase when there are many patents cited by the originating application in the bundle, and also when a cited patent has more patent family members. In sum, this measurement indicates how similar a blocking patent family of an office is compared to globally cited (blocking and non-blocking) patents.

If the cosine distance is one, the technological vector of a particular blocking patent is identical with the technological vector of the bundle of all citations added to the same application worldwide. Figure 2 shows an example.

Figure 2. Blocking citation vector \(\vec{a}\) and global citation vector \(\vec{b}\) for a US blocking patent.
**Overall trend**

Utilizing the technology distance associated with a blocking patent, we describe the overall trend of the discrepancies. As is depicted by Figure 3 where vertical axis indicate the cosine similarity index, all blocking patents used by the trilateral offices have a slightly upward trend in recent years. It suggests that the improvement of prior art search technology leads to less heterogeneous blocking patents. Though the USPTO has relatively dissimilar vectors on the average compared to those by the EPO or by the JPO, the overall trend seems to be the same.

![Figure 3. Cosine distances of refusal reasons by the trilateral offices from all citation vector, by priority year.](image)

**Complexity, longitudinal distribution, and technological distances of blocking patents**

Unlike citations made on academic papers, examiner citations for refusals can be issued several times during a prosecution in response, for example, to amendments. In other words, examiner citations are produced in a dynamic process of bargaining between an applicant and an examiner. Therefore, longitudinal aspect of blocking citations should be an important factor as one of the determinant for technological distance, especially in the US where repetitive refusals are frequently observed. The US blocking patents are sometimes added by examiners up to ten times over more than ten year period from application in the same sample above.

Also, the discrepancies of X/Y patent citations may relate to the technological complexity of patent applications. This is because examiners at different offices might focus on diverse aspects of a patent application if the application is technologically complex and has a broad scope.

In order to explore the relationship between technological discrepancies in blocking citations and their longitudinal aspects further, linear regression analyses are implemented, taking the cosine similarity measurement as the dependent variable. Several explanatory variables are employed. The first group represents longitudinal aspects. The time lag in years between an entry of a triadic application into the US and the first rejection action by the USPTO is given by `us_firstaction_lag`. Similarly, the time lag in years between an entry of a triadic application into the EPO and the EP search report date is given by `ep_action_lag`. If an
application is technologically complex, this lag variables are expected to increase, and we expect these to be related negatively with the divergence of refusal reasons in the US and at the EPO, respectively, because examiners will focus on different features of the same application and will cite different prior arts. Following the first action, one or more additional office actions might take place at the USPTO. The lag in years between the first action and the following office action is given by \textit{repeated\_action\_lag}. Since repeated actions often occur within limited ranges of claim issues, and since the difference between offices decreases as examiners in different locations have similar information, we expect this to be positively related with the divergence of refusal reasons. Unfortunately, office action timing is not available at the EPO by PATSTAT and by DOCDB. Therefore, we are not able to define a similar variable for the EPO. Instead, we define \textit{ep\_us\_lag\_diff\_abs}, which represents the absolute time difference in years between the USPTO office actions and the EPO search reports. When this value is large, examiners at the USPTO and the EPO tend to face different information concerning the application. Therefore, we expect that there is negative relationship between this variable and the similarity index of blocking patents.

The technological complexity of a triadic patent application is represented by the number of 35 WIPO technological fields assigned to the application, or \textit{techn\_field\_nr\_counts}. We expect this variable to have negative relationship with the similarity of a blocking patent depicted by examiners. In addition to the explanatory variables, we employ control variables of other characteristics. Specifically, \textit{isr\_cited\_dummy} is a dummy variable indicating the blocking patent was shown in the preceding international search reports. Whether a blocking patent is used at other offices is coded as binary variables of \textit{ep\_xy} and \textit{jp\_xy}, which mean the blocking patent is also X/Y citation at the EPO and at the JPO, respectively. Patent grants ex post are controlled by three dummy variables of \textit{epo\_granted}, \textit{us\_granted}, and \textit{jpo\_granted}. In addition, priority years and technological fields are controlled.

As linear estimation results in Table 3 indicate, both the US and the EP blocking patents commonly show that the first action lag, the time differences between actions at the USPTO / the EPO, and the breadth of patent class of patent application (\textit{techn\_field\_nr\_counts}) are negatively correlated with divergent refusal reasons. It is consistent with an interpretation that costly examination leads to diversified reasoning for grant/refusal decisions. However, office action lag after the second action (\textit{repeated\_action\_lag}, where data is available only for the US at this time) shows the opposite, suggesting that repetitive refusals tend to be focused on a limited range of issues in terms of prior art. The results suggest that blocking patents at the EPO and the USPTO become more divergent as examination is more costly, which requires longer time for prosecution.

**Conclusion**

As a conclusion for the first question of the extent of technological discrepancies of blocking patents, we have found that the decision reasons used by examiners are very dissimilar between trilateral offices, if we define similarity by coincidences between DOCDB patent families of blocking patents. Secondly, concerning the second research question, overall trends in the similarity between blocking patents suggest that blocking patents become less divergent at the trilateral offices recently, possibly due to the advancement in search technology. Converging rejection reasons may lead to less divergent grant decisions between the trilateral offices. Thirdly, as a finding for the third question, we have found evidence which is consistent with an understanding that blocking patents at the EPO and the USPTO become more divergent as examination burden is heavier. This is consistent with Wada (2016) in that examiners are not free from the limitation in searching capability for prior arts, i.e., examiners are constrained in their information space.
Our understanding of the driving factors for the dissimilarity is still incomplete. For example, there are many other methods to measure the technological discrepancies (Wang, Thijs, & Glänzel, 2015), whereas this paper has utilized Jaffe’s cosine distance measurement only. Also, due to data limitation of office action timing, we have not been able to employ action lag data for the JPO. Although we have not obtained enough information about the details of patent applications and bias made by examiners, this paper has added knowledge to the understandings of limitations and biases of patent prosecution processes. We now have initial clues to analyse how examiner citations are produced and biased by way of measuring divergent blocking patent patterns.

Abstract

Detecting the technical information included in patent documents offers a window of opportunity for identifying current technology structures and tracing technological developments. In this paper, we attempt to build a basemap for the international patent classifications (IPCs) of USPTO citation data, with the aim that such a map might be used as a tool to benchmark and capture the changes in organizational innovation activities over time, or the patterns in technological changes for future investigations in other sectors. Additionally, we subdivided patent classifications into detailed technological fields, as opposed to the usual eight broad technical domains, then traced the direction of the information flow over time. Promising quantitative measures, based on the technological proximity of the specialization and integration of the classes, were introduced to further provide insights into the notable differences in technological change and knowledge fusion over the past 30 years. Our aim in constructing this interactive overlay, and tracing the evolution of these technological fields, is to understand the patent portfolios of countries, organizations, and new and emerging technologies in the context of the overall technological landscape.

Conference Topic

Mapping and visualization, Patent analysis

Introduction

Patents, as important carriers of technological knowledge, can be used to analyse patterns of invention by location, technology class, or organization. As compilations of large numbers of records for “landscaping”, patents provide both a macro perspective and the opportunity for in-depth, micro-analysis of a small number of patent documents (Trippe 2003). Examining the technical information included in patent documents offers a window of opportunity to identify current technology structures and trace technological developments. With keen observation, one may be able to spot the drift and development trends in many commercial sectors.

The visualization techniques that transform abstract and intangible data sets into something visible and concrete provide us the perceptual and cognitive ability to grasp the complexity and evolution of scientific and technological activity patterns more easily and more vividly than traditional scientific studies (Chen and Kuljis 2003). Among these techniques, the science overlay maps (Leydesdorff and Rafols 2009; Rafols et al. 2010) that identify scientific domains, analyze change in scientific frontiers, and inspire exploration of interdisciplinary scientific progress open up new avenues for understanding patent landscapes.

Technology classes are widely considered to be an appropriate unit of analysis for measuring technological proximity (Ejermo 2005). Technology-oriented applications often draw from patents in different hierarchical categories, and this subsequently leads to further diversity in patents that cite patents in these categories. There are three major classification systems: the International Patent Classification (IPC) system developed by the World Intellectual Property Organization (WIPO) in Geneva; the United States Patent Classification (USPC) system used by the US Patent and Trade Office (USPTO), and the European classification system (ECLA) refined by the European Patent Office (EPO) in partnership with WIPO and the Organization for Economic Cooperation and Development (OECD). The Cooperative Patent Classification (CPC) system, a new classification that covers all EPO and US classified documents, is
thought to be the most granular and precise classification system of the English versions (Montecchi et al. 2013). However, CPC and IPC are identical in the first four characters, while IPC is still the most widely used by most countries in the world.

Among national patents, the USPTO’s patents are considered the most accessible and yet also the most valuable. The availability of these data and the length of their history means they have been applied to many studies. Moreover, non-US firms have persistent interests in protecting their most significant innovations in the US because it is one of the most highly competitive markets for technologically advanced products (Criscuolo 2006).

In this paper, we attempt to build a basemap of IPC for USPTO citation data, with the aim that such a map might be used as a tool to benchmark and capture the changes in organizational innovation activities over time, or the patterns in technological change for future explorations in other sectors. Additionally, we subdivided patent classifications into detailed technological fields rather than the eight broad technical domains used in IPC, and then traced the direction of technological information flow over time. Promising quantitative measures based on the technological proximity of the specialization (S) and integration (I) of the classes were introduced to provide further insights into the notable changes in technologies and knowledge fusion over the past 30 years.

Data

To build this type of interactive patent overlay map, one of the toughest issues we faced was how to obtain high-quality patent data with equivalent citation patterns in appropriate quantities. Unlike the Web of Science categories applied in many science overlap maps, significant variations in the number of patents classified within each IPC classification level increase the challenges brought by the intensive quantity of patents in certain categories.

Our original patent data was collected from the National Bureau of Economic Research (NBER), a research group that has been working to make US patents widely accessible for research over the past decades (Hall et al. 2001). We selected the patents granted between 1976 and 2005 for this study, which resulted in 3,035,457 utility patents. Technical patents, design patents and genetic sequences were excluded. For the best visualization, and so as not to lose necessary detail or resolution of the technology landscape, we chose 4-digit classes that met the degree of detail in subject matter definition to represent network vertices. Ultimately, a dataset of 3,015,846 patents spanning 630 4-digit IPCs were selected as the classifications to benchmark in keeping with Leydesdorff et al. (2014) study.

The number of application patents and granted patents by publication year is presented in Figure 1. It can be seen that both the applications and granted patents show notable growth over the past several decades and that more and more patent assignees have been treating patent applications as an effective approach to protecting their intellectual property. The fluctuating number of patents granted and the relatively smoother trend for application numbers is another notable characteristic. The tremendous growth in patent applications has led to a noticeable delay in the examination process. Patent applications were granted relatively quickly before the 1990s, and, after 2001, a far smaller proportion of applications have been granted.
Even though 630 4-digit IPCs are more than adequate to compare the number of patents belonging to each subclass, classifications based on too much detail are meaningless in statistical analysis, and of course, classifications that are too broad would cover too many technologies to appropriately distinguish. One proposed solution for reclassifying the subclasses of patent categories is to fold these 4-digit categories up into higher levels of the appropriate number. However, in 1992, Fraunhofer ISI and the Observatoire des Sciences et des Technologies, in cooperation with the French patent office (INPI), developed a more systematic technology classification, called the ISI-OST-INPI classification, based on the IPC codes (Schmoch 2008). This classification system has been amended several times to keep pace with the revolution of IPCs, and new codes have been added. The latest edition from the WIPO Statistics Database includes 35 technological fields that cover and balance all possible IPCs (an Excel spreadsheet is available at: www.wipo.int/ipstats/en/statistics/patents). However, it is worth noting that these codes are exclusive to IPCs and quite distinct from each other.

The ISI-OST-INPI system provides a feasible manner for clustering our 630 4-digit IPCs into interactive overlap maps, but it has two main limitations. First, most IPCs are clustered at the subclass level as 4-digit IPCs, but some are clustered at a group level which sits even lower at the fourth hierarchical level of the system. Next, the number of IPCs in each different field are uneven, and this does not benefit the structure of the map. We took these 35 fields as benchmark technological fields and merged them into 29 optimized fields according to the following three rules: (1) All IPCs at a group level were upgraded to their subclass level. If different group levels belonged to different subclasses, we chose the one that contained the most groups. (2) Fields with less than 5 IPCs were merged into their most relevant field according to the strength of its citations. For example, A61K and A61P previously belonged to Pharmaceuticals but were merged into Medical Technology; B81B, B81C, B82B and B82Y were grouped into Chemical Engineering from Micro-structural Engineering and Nano-technology; G06Q (IT Methods for Management) was merged into Computer Technology; H01L (Semiconductors) was merged into Electrical Machinery, Apparatus, and Energy; H04L and H04W clustered under Digital Communication were merged into Telecommunications. The number of patents in each corresponding technological sector and field are provided in Table 1.

Methods

Constructing the basemap for the patent overlay maps

Patents that reference other patents in related technological fields have been suggested as a way of offering access opportunities to advance an area, whereas patent documents that contain references across diverse categories may offer the potential for radical innovation (Olsson 2005). In general, the IPC class of every patent might range from one to more than twenty, in exceptional cases. As the first step in constructing a basemap for patent overlap maps in our aggregated set, we used the cross-citation patterns of 630 4-digit IPCs of granted patents during the period 1976-2005. Given most patents relate to more than one field, co-classifications have been used more often than multi-classifications to measure the “technological distance” between classes (Breschi et al. 2003). However, citation networks are less sensitive to misclassifications than co-classification networks because they offer an additional degree of freedom compared to hierarchies. This means that the actual number of papers per overlay map depends on the breadth of the disciplinary category distribution (Rafols et al. 2010). As a result, we chose cross-citation rather than co-classification to build a
citation network, and reveal the structural patterns of technological information flow among the 630 4-digit IPCs.

Constructing this type of patent network requires a proper measure of the distance between different classes of patents in the patent classification system (Yan and Luo 2017). Therefore, the second data processing step involved normalizing the similarity matrix for the cross-citation IPC categories into an aggregated citation matrix. Initially, a correlation between the vectors representing the distribution of a firm’s patents in a set of technology fields was used as the index for technology mapping (Jaffe 1986). However, for co-citation patterns, Salton’s cosine measure (Salton and McGill 1986) is suggested instead of Pearson’s correlation coefficient, particularly if one aims to visualize the network’s structure, as in the case of social network analysis or multidimensional scaling (MDS) (Ahlgren et al. 2003). A cosine-normalized asymmetrical occurrence matrix provides the best visualization of vector space and is more consistent with consensus science mapping. The cosine-normalized approach uses conventional cosine similarity normalized by the square root of the squared sum. The cosine of the angle between the two vectors represents the citation distributions between two technology classes among all patent classes (Leydesdorff 2007). The formula can be presented as

\[
\text{Cosine} (i,j) = \frac{\sum_{k=1}^{n} C_{ik} C_{jk}}{\sqrt{\sum_{k=1}^{n} C_{ik}^2 \sum_{k=1}^{n} C_{jk}^2}}
\]

where \( C_{ij} \) indicates the number of citations referred from patents in technology class \( i \) to the patents in technology class \( j \) and \( k \) belongs to all the technology classes. The cosine value falls between \([0,1]\) and indicates the similarity of the knowledge bases of the two fields.

The remaining question that needed to be taken into consideration is which overlap toolkit to use. There are three main toolkits that offer a wealth of possibilities for the visualization of a comprehensive map and enable us to visualize portfolios as overlays: Pajek (http://vlado.fmf.uni-lj.si/pub/networks/pajek/), Gephi (https://gephi.org/) and VOSViewer (http://www.vosviewer.com/). Pajek and Gephi contain a suite of tools for network analysis and visualization, such as various decompositions, layouts, and visualization options. But, the advantage of VOSViewer is that further normalization within this toolkit does not disturb the maps on the basis of cosine-normalized matrices (Leydesdorff and Rafols 2012), and this feature drove us to choose VOSViewer as the benchmarking visualization platform. Technological fields are positioned in the map so that similar fields are situated nearby, and dissimilar components are situated at a distance.

**Mapping technological information flow among different fields**

The duality of citations and references is a central feature of citation processes. In terms of the direction of technological information flow, referencing is regarded as emission and the citations as reception. In order to map technological information flow among 29 different technological fields, rather than 630 4-digit IPCs and to distinguish the extent of the information flow, we introduced a new variable – citation link strength (CLS) (Zhang et al. 2009). The formula for the CLS between the technological fields \( i \) to \( j \) can be presented as

\[
\text{CLS}_{ij} = \frac{a_{ij}}{\sqrt{T Ci} \cdot TR_j}
\]

Here, \( i \) and \( j \) denote technological fields, \( TCi \) represents the total number of citations of the field \( i \), \( TR_j \) denotes the total number of references of the field \( j \), and \( a_{ij} \) denotes the number of citations the field \( i \) receives from field \( j \).
This indicator measures the strength of the citation links between two technological fields in an asymmetric matrix, which is directional as citations from field \(i\) to field \(j\) differ from citations from \(j\) to \(i\). Through this indicator, we can compare the emissions (the referencing) and the receipts (the citations) of an individual technological field, and can also detect some extremely asymmetric links between two technological fields. The footprints of the technological information flow among different fields also provide different dimensions for understanding the complex dynamics in innovation by providing different projections of those dynamics.

**Measuring specialization and integration in technology**

A large number of technologies represent combinations of different research fields and patented technologies, so it is important to examine the extent of diversity in the underlying research fields and the patented technologies to understand the inherent composition of these fields. We introduced two indexes, an integration index and specialization index, to measure the technological change in patents to more comprehensively navigate the evolution of a technology.

Traditionally, the interdisciplinary metrics of integration and specialization are based on ISI subject categories and measure the interdisciplinarity in an aggregated dataset of a country, institution or individual researcher (Porter et al. 2008; Porter and Rafols 2009; Porter et al. 2007). In this paper, we introduce a specialization score and an integration score, comparable to the Rao-Stirling’s diversity index (Rao 1982; Stirling 2007), to measure technological diversity in patenting. Likewise, the integration score can be used to examine the spread of references in a given technological fields to gauge the degree of integration across “bodies of specialized technology” reflected by the span of IPCs. The formula can be presented as

\[
\text{Integration} = 1 - \frac{\sum C_i C_j S_{ij}}{\sum C_i C_j}
\]

Here, \(C_i\) indicates the number of citations received by technology class \(i\), \(C_j\) represents the number of citations received by technology class \(j\), and \(S_{ij}\) is the technological similarity between categories \(i\) and \(j\). The integration score, ranging from 0 to 1, increases as a technological field cites more disciplines. Scores closer to 1 indicate more integration.

Specialization is operationalized differently from integration in important ways, reflecting the breadth of technology field distributions. The formula can be presented as

\[
\text{Specialization} = \frac{\sum F_i F_j S_{ij}}{\sum F_i F_j}
\]

Here, \(F_i\) indicates the frequency of technology class \(i\), \(F_j\) represents the frequency technology class \(j\). Specialization can reflect the breadth of technological fields over a certain time span.

**Results**

**Interactive overlay maps based on 630 4-digit IPCs**

The overlap patent basemap in Figure 2 is based on cross-citation relationships among the 630 4-digit IPCs of USPTO patents from 1976 to 2005. The 29 technological fields listed in Table 1 form the basis for color-coding these 630 categories. Labels and colours have been used to produce a reasonably clear map and facilitate its examination.
One good application for patent overlay maps is their use as benchmarking tools for companies or specific technological fields. To illustrate the application of patent overlay maps, a data set was created for patents granted on graphene, using data from the USPTO for the publication years 2000–2015. As shown in Figure 3, the subfields relating to graphene are mainly focused on Electrical Machinery, Surface Technology, Chemical Engineering, and Material Metallurgy. Hence, applying patent overlays to the analysis of technological subfields can help provide a better understanding of technologies involved in the development of a subfield.

Figure 2. The basemap of 630 4-digit IPCs

Figure 3. The patent overlay maps for graphene from the USPTO during the period 2000-2005
Note: The dataset is retrieved using the term “Graphene” in the fields of Title and Abstract in USPTO granted patents, and result in 1003 patents.

Technological information flows for 29 main technological fields

Compared to individual IPCs, analysis of the direction of information flows among different technological fields provides views at a macro-level. On the basis of the 29 technological fields defined above, we detected some distinct asymmetric links between different fields. To trace the evolution of technological flows among these different fields, we divided these patents into four time windows according to their publication year: 1976-1985, 1986-1995, 1996-2005, and 1976-2005. The thickness of the lines represents the intensity of the citations between two linked fields, and the size of the nodes is proportional to the number of patents in a given field. A pair of fields are considered as having strong asymmetric links if $\text{CLS}_{ij} - \text{CLS}_{ji} > 0.02$. The technological flows among these 29 fields can be viewed in Figure 4, generated from Gephi.

![Figure 4. The technological flow among 29 fields during four different periods](image)

During the late ‘70s and early ‘80s, patents in Electrical Machinery were somewhat dominant compared to others. The categories are relatively concentrated given they are typically related. In this era, four technological flows are remarkable: from Biotechnology to Organic Fine Chemistry; from Telecommunications to Computer Technology; from Organic Fine Chemistry to Medical Technology; and from Biotechnology to Food Chemistry.
From 1986 to 1995, due to advancements in technology and improved awareness of protecting intellectual property, most fields show an increased number of patents. Patents in Electrical Machinery and Medical Technology are still dominant over others. However, unlike before, there are more links among the fields, and some have links to more than three disciplines. Electrical Machinery shows expansive connections to other fields and is absorbing a great deal of knowledge from external fields, especially Materials Metallurgy. Computer technology was undergoing rapid development during this period, and Computer Technology also shows more and more connections with other fields, heavily relying on Audio-visual Technology. Moreover, Organic Fine Chemistry and Chemical Technology received many more citations than they emitted, while Chemical Engineering emitted many more than it received.

Between 1996 and 2005, the majority of patents were assigned to Computer Technology, Medical Technology, and Electrical Machinery. Electrical Machinery has far fewer links to other fields than before, implying a stronger independence and specialization. Computer Technology has become strongly related to Telecommunications. Most obviously, Biotechnology has become more aligned to Organic Fine Chemistry, Food Chemistry, and Measurement, revealing great advancements in biotechnology. Other knowledge flows between Organic Fine Chemistry and Medical Technology, and between Medical Technology and Materials Chemistry can also be observed.

In summary, throughout this entire period, most emerging patents were distributed in the Electrical Machinery, Medical Technology, and Computer Technology fields. Computer Technology and Electrical machinery relied heavily on other fields, which changed over time. Based on a correlation of the research, Chemical Engineering, Macromolecular Chemistry, Organic Fine Chemistry, Medical Technology relate to each other. A comparison of the citations between the different periods reveals several insights. First, we can trace the underlying development of emerging technology in some fields. For example, Computer Technology began to develop in the period 1986-1995, while Biotechnology has developed rapidly over the past decade. Second, we can identify changes in the basic fields that a technology relies upon. Computer Technology absorbed much knowledge from Control in 1976-1985, then relied more on Audio-visual Technology in 1986-1995, and Telecommunications in 1996-2005. In addition, Electrical Machinery transformed from high dependence to specialization over the period under study.

Technology specialization and technology integration among different sectors

We collected the IPCs for each record and counted them by publication year from 1976 to 2005. These data were represented as a vector denoting the number of IPCs assigned per year to five different fields – Chemistry, Electrical Engineering, Instruments, Mechanical Engineering and other fields. Using these vectors, we calculate the integration and specialization indexes at an aggregate level by patent publication year. Figure 5 summarizes the annual trends in technology specialization and the technology integration for all fields.

We derived two observations from Figure 5. First, the overall patent specialization index was stable at first, and increased slightly in the following years but always remained at a low level. This indicates that the IPCs involved in these patents are technologically distant. Second, the technology integration for all fields fluctuated before 1987, then exhibited a slightly decreasing tendency, which reveals a diminishing capacity to bring together technology from disparate fields.
To better distinguish between the technology integration and specialization among different sectors, we illustrated the annual trends of the technology specialization and technology integration in four different technological fields, as shown in Figure 6. This comparison shows several things. First, the annual specialization and integration scores both reveal fluctuating patterns in the Chemistry field. In the Electrical Engineering field, the specialization score increased rapidly, while the integration score declined slightly. Accordingly, Instruments reveals an increasing tendency in specialization and a drop in integration. As for Mechanical Engineering, neither score has changed much over time. Second, Mechanical Engineering shows a higher degree of integration and a lower degree of specialization relative to the other three fields across the given period. The most obvious difference in the index among the four fields is that patents in Electrical Engineering are more likely to specialize in fewer technological application fields.

Figure 5. The overall technology Integration and Specialization during the period of 1976-2005

Figure 6. Technology integration and specialization of four sectors during the period 1976-2005
Conclusion
The use of patent information increases the technical capabilities of obtaining competitive intelligence, and the patent mapping offers an approach to creating a graphical or physical representation of the relevant art pertaining to a particular subject area or novel invention. Interactive patent overlay maps can be an effective approach for understanding the overall landscape of technological areas and grasping the extent and evolution of technological activities over time.

This paper presents the preliminary results of a new patent visualization tool that has the potential to support policy decision making. The approach involves a two-step visualization process. First, we collected patent citation information and constructed a patent citation network that shows the technological distance among patent categories using USPTO granted patents published during the period of 1976-2005. Second, we overlaid the patent activity of specific technological fields over the fixed “backbone” of a patent map. Such patent overlay maps can be applied to benchmark organizations, regions or countries and form a general analysis of technological changes over time.

The strength of citation links among different technological fields in different periods reveal that technological information flows fluctuate, and the focal technological fields are transformed with the development of human society. Detecting the evolution of technological fields is beneficial for grasping the strategic intelligence required by analysts and decision makers.

Two advanced diversity measurements, specialization and integration, yield different implications when interpreting the interdisciplinarity (or diversity) of a given body of knowledge. A patent specialization score measures how much a developing technology is related to a particular technological application, and a patent integration score indicates how many technological fields have merged to navigate the innovation trajectories of a technology (Kwon et al. 2016).

Abstract
In two independent studies that were first presented at ISSI 2015 and recently published in PLOS ONE, Larivière & Costas (2016) and Sandström & van den Besselaar (2016) observe similarly that productivity among individual researchers is correlated with citation impact in large datasets from Web of Science (WoS). While the latter study draws the policy implication that productivity should be incentivized, the first study explains their finding by the Mertonian theory of cumulative advantages and maintains that research assessment should be qualitative and focus on research quality. Both studies are based on author name disambiguation and Web of Science data. As acknowledged by the authors, there are several problems with studying individual productivity by using author name disambiguation. In our study of the same general research question, we instead match Web of Science with national datasets that have information about the persons behind the author names. We know their age, gender, position and affiliation, as well as their former career and educational background in the higher education sector. We also have bibliographic information about all their peer reviewed scholarly and scientific publications – not only those covered by Web of Science. Our aim is to get deeper insight into the conditions that influence observable productivity differences among authors in Web of Science, and thereby to establish a firmer basis, both for understanding the correlations found in the former studies, and for expressing the implications for research policy.

Conference Topic
Science policy and research assessment; Studies on the level of individual scientists

Introduction
In two independent studies that were first presented at ISSI 2015 and recently published in PLOS ONE, Larivière & Costas (2016) and Sandström & van den Besselaar (2016) observe similarly that productivity among individual researchers is correlated with citation impact in large datasets from Web of Science (WoS). The policy implications drawn from this observation are different, however. Larivière & Costas (2016) frame their study within the increasing literature that warns against the possible adverse effects of quantitative research assessment and funding methods. They study whether the incentive to publish as much as possible leads to lower citation impact, but find, on the contrary, that higher productivity does not influence citation impact negatively. They explain the result as a confirmation of the Mertonian theory of cumulative advantages in research and nevertheless maintain that, in line with the Leiden Manifesto (Hicks et al., 2015), individuals are best assessed by qualitative peer review. Sandström & van Besselar (2016) also relate their discussion to the Leiden Manifesto and the policy discussion about a possible overproduction and decrease in research policy. Here, they take an opposing position and conclude that increased productivity in the research system is not a perverse effect of output oriented evaluation systems, but a positive development. Interpreting quantity as the number of WoS-articles and citation impact as quality, they found that there is no evidence that quantity and quality are opposed to each other. Instead, their view is that evaluation methods based on peer review of only a few publications “disadvantages the most productive and best researchers”.

In our research in progress, we will study persons, not only authors, to go deeper into the possible explanations for the observation that the two studies have in common, thereby securing a better basis for the interpretation of the phenomenon and for drawing policy implications.
A common feature of the two studies is that they identify individual researchers by using *author name disambiguation* within data from WoS, and that they do not go beyond this database for further information about the researchers. As an example, Lariviè re & Costas (2016) determine the ‘age’ of the researcher by the time the author name first appears in Web of Science, while Sandström & van den Besselaar (2016) determines the affiliation of a researcher by using disambiguated author addresses. Both studies discuss some of the problems with relying on WoS only: Most publications are co-authored between researchers who contribute in different roles and with varying degrees of efforts, and some of them may have shorter careers as authors. Productivity also differs by gender. In some fields, particularly in the social sciences and humanities, Web of Science does not represent the full productivity of researchers.

There may be other problems with the method as well: The type of institution and the position of the researcher may influence the time and resources available for research. Tenure and external funding can also make a difference. Co-authorship practices and productivity are variable within the five large research areas (applied sciences; natural sciences; health sciences; economic & social sciences) used for field normalization of productivity by Sandström & van den Besselaar (2016). The same is true for four large research areas (law, arts, and humanities; medical and life sciences; natural sciences; social and behaviour science) used to control for different publication patterns by Lariviè re & Costas (2016). Sandström & van den Besselaar (2016) are more advanced in controlling for average productivity in a field. They calculate *Field Adjusted Production* (FAP) with the so-called Waring method, but it has been documented to suffer from significant flaws in quite similar data representing all Swedish authors (Vetenskapsrådet, 2010).

We will try to come around as many as possible of such problems by selecting comparable data from WoS and replace the author name ambiguation method by matching the WoS data with two other data sources at a national level where the author names and addresses in the publications can be linked to real persons and institutions. From these other data sets we will also know the age, gender and position of the researchers, as well as their former career and educational background in the higher education sector. In addition, we will have complete bibliographic information about all their peer reviewed scholarly and scientific publications – not only those covered by WoS. This information is possible to gather at the national level in Norway by matching data from Web of Science to other datasets, as explained below and demonstrated in previous publications, e.g. Aksnes et al. (2013) and Zhang et al. (2017).

This is a research in progress paper because the large task of matching the data sets remains to be done. Our final results will be presented at ISSI 2017 if we are given the possibility to do so. However, our preliminary investigations, as demonstrated below, indicate the we will observe productivity and citation impact as correlated with mostly the same pattern and to the same degree as in the two above mentioned studies. Some of the methodological problems in the two former studies will be solved at the same time, thereby laying a firmer basis for empirically based conclusions.

As discussed above, the two former studies arrive at different policy implications. We believe that this may partly be due to the lack of data on the researchers as persons in both studies. With this data, we will get deeper insight into the conditions and factors that influence observable productivity differences among authors in Web of Science. The performances of researchers, as measured within Web of Science with bibliometric indicators after disambiguation of author names, may be interrelated in a complex way with what roles researchers actually take in research, what position they have, what resources are available, and what they achieve in their careers. We expect to be able to provide a better understanding of what the bibliometric measurement of productivity and citation impact might mean at the intermediate level, thereby providing a firmer basis for drawing policy implications from individual level studies.
Norway is mentioned by Larivière & Costas (2016) as a country with an institutional funding system based on bibliometrics, thereby as an example of a country where incentives for increased productivity may lead to lower research quality and other adverse effects. There have been several studies of the effects of the Norwegian system recently (e.g., Aagaard et al., 2015; Bloch & Schneider, 2016; de Rijcke et al., 2016; Sivertsen, 2016). None of these studies, however, have used individual level data sources with the same strategy as in our study. By using Norwegian data, we thereby also hope to enlighten the debate in which Larivière & Costas (2016) and Sandström & van den Besselaar (2016) draw their different policy implications.

Data

Our study depends on the matching of three data sets at the individual article and author/researcher level:

- **National Citation Report for Norway (NCR, 1981-2016)**, a data set provided by Clarivate Analytics with a representation of all articles in Web of Science with minimum one address in Norway, and their accumulated citation counts. This data set has the same field classifications and indicators that are present in the product InCites from Clarivate Analytics, but it is delivered as a database with all the basic data.
- **The Norwegian Science Index (NSI)**, a subset of the Current Research Information System in Norway (Cristin), with complete coverage since 2010 of all peer-reviewed scientific and scholarly publication output, including books, edited volumes, and conference series (Sivertsen & Larsen, 2012).
- **The Norwegian Research Personnel Register**, which has been updated since 1977 and has individual data for all researchers at public research institutions in Norway, including age, gender, educational background, affiliations and positions.

Publications from the five-year period 2010-2014, with citations until the end of 2016, will be selected in all fields from Norway’s four largest universities (Bergen, Oslo, Trondheim, Tromsø). The rest of the higher education sector is not included because researchers at other institutions on the average have less time and resources for research activities.

There are 34,417 research articles from the four universities in the NCR dataset (representing Web of Science) and 63,989 research publications from the same universities in the NSI dataset (representing all peer-reviewed publications in all fields). Our study is work in progress, and the three datasets still need to be matched. Before the deadline for ISSI submissions, we can only briefly describe our methods, present explorative results and conclude preliminarily.

Methods

Our study shares the general research question concerning the relation between publishing productivity and citation impact as studied by Larivière & Costas (2016) and Sandström & van den Besselaar (2016). Our data collection method is different, as explained above. Regarding the two Norwegian data sets on researchers, we will use a similar methodology as was used by Aknes et al. (2013). Within the data set representing WoS (NCR), we will delimit data and choose indicators that make our general findings directly comparable to the two former studies.

For the preliminary results presented below, the data collected by Zhang et al. (2017) is used. The data are derived from an earlier version of NCR (see the three data sets described above) and thereby only represents WoS, not the two other data sets. However, instead of author disambiguation, all researchers have been identified also in the NSI data mentioned above. Specifically, we adopt the following indicators for the preliminary study:

- **Number of Citations (NC)**: the number of received citations in a three-year citation window, starting from the publication year of an article.
• **Relative Citedness (RelCit):** This is a relative citation measure. According to the information provided by Clarivate Analytics, the supplier of NCR, the Relative Citedness of a document is calculated by dividing the actual count of citing items by the expected number of received citations for documents of the same document type (article, in our case), year of publication and subject area. When a document is assigned to more than one subject area an average of the ratios of the actual to expected citations is used. Here the term “subject area” refers to the WoS journal category of the article. For articles published in multidisciplinary journals, NCR uses a paper per paper assignment based on reference analysis.

• **Percentile of Citedness:** Percentile in which the paper falls in its category based on total citations. Indicates that the paper is in the top n% of papers in that category in that publication year - if a document is in more than one category, this is the percentile from the best performing category. We use the top 1% and 10% most cited articles as indicators, as is also done in the two former studies that we relate to and in most other studies.

• **CSS (Characteristic Scores and Scales) Classes:** “a parameter-free solution for the assessment for outstanding performance” firstly developed by Glänzel and Schubert (1988), which can be used to assign single publications in a field and publication year to meaningful impact groups. Characteristic scores are obtained from iteratively truncating samples at their mean value and recalculating the mean of the truncated sample until the procedure is stopped or no new scores are generated. According to Glänzel (2016), all papers could be classified into four groups: “poorly cited” (Class 1), “fairly cited” (Class 2), “remarkably cited” (Class 3) and “outstandingly cited” (Class 4).

**Preliminary explorative results**

Since the three data sets remain to be matched, we will only briefly present some explorative results based on a data sample comprising 899 Norwegian scientists active in the biomedical sciences, following the same data strategy as used in our previous study (Zhang et al., 2016). Our data set is thereby more homogeneous regarding field-specific productivity and publishing patterns than in the two former studies. Only records of the document type “Article” are included and the total number of unique publications (1992-2013) is 18,280. Their citations have been counted until the end of 2015.

As a first step, we calculated for each of different productivity classes the average number of highly cited papers (based on different citedness indicators). Figure 1 shows the relation between productivity and authoring top cited papers (using “outstandingly cited” papers in CSS classes as an example, and results based on other indicators have shown similar profiles). In general, the higher the productivity of a researcher, the more top-cited papers a researcher has.

![Figure 1. Average number of “outstandingly cited” papers (CSS) by productivity class](image-url)
Figure 2 presents the relation between top cited papers and total number of publications. As observed, the lower the citation threshold of the top cited papers, the higher the correlation.

In a second step, to concentrate on principle investigators, we removed the incidental co-authors with low number of publications. Only 564 biomedical scientists with at least 10 articles in the data sample are kept for a further analysis. We ranked the 564 researchers according to their average citedness respectively based on “number of citations (NC)” and “Relative Citedness”, evenly divided into four groups, hence each including 141 researchers. Group 1 stands for the most cited researchers, and Group 4 represents the researchers with least citedness. Although the groups are not exactly the same for the two different citedness measures, we do not find a systematical divergence between the two cases. We then calculated the average value of “total number of articles” for individual researchers in each author group, and the results are shown in Table 1. Interestingly, researchers in Group 1 are much more productive than researchers in Group 4 on average. A striking difference can be observed when Relative Citedness is used for grouping the researchers: Researchers in group 1 are twice as productive as researchers in group 4 on average. The researchers with highest citation visibility are also the most active researchers, and the least cited researchers are found to have the least productivity. However, this is a preliminary finding, and we do not yet know to what degree these researchers are comparable with regard to their backgrounds, positions, resources and roles in researches.

Our preliminary results are based on data representing the broad field of biomedicine, however with field normalization of citation indicators based on WoS journal categories. In our final study, we will combine this method, applied on all fields in WoS, with methods by which we use the matched data on the researchers and their complete publication records to field.
normalize also the expected productivity in WoS and to study also the factors influencing the productivity by being able to regroup the researchers also according to co-authorship practices, age, gender, position, other output, etc.

Conclusions (main hypotheses)

1. We expect to find similar correlations between publishing productivity and citation impact, as measurable within WoS with bibliometric indicators, as was found by Larivière & and Costas (2016) and Sandström & van den Besselaar (2016).
2. However, we also expect to establish a firmer basis for understanding these observable correlations by studying persons, not just authors, in relation to several factors that may influence productivity differences. Roles, positions, gender, resources, achievements, incentives and bibliometric performances in research are probably interdependent in a complex way and not separable as an interpreted causality (based on correlations) from which we can conclude on the possible effects of evaluation or funding regimes.
3. We find it interesting that the two former studies use a very similar empirical observation to conclude differently about the policy implications for evaluation and funding regimes. We instead expect to be able to enlighten the ongoing debate on the possible effects of such regimes by introducing a methodology not yet used in the several recent studies of the possible effects of the so-called Norwegian model.

Abstract
Titles of scholarly articles are generally a reflection of their content. They inform the reader about the methods, design, results or conclusion of the study, as well as on the context of the research. The mention of the name of a country, for example, provides a geographical contextualization of the article. In order to better understand the effect of these signaling devices on the reception of a study, this research in progress paper investigates the difference in citation rates of articles that mention a country in their title or abstract and articles that do not. It shows, using WoS-indexed papers published between 1996 and 2013, that mentioning a country in either the title or the abstract is associated with lower citation rates, and that this is observed for every country when all disciplines are combined. The gap in citation rates is also greater in Social Sciences than in other disciplines, which is likely due to their stronger focus on national issues.

Conference Topic
Research on local topics and issues, citation analysis, country-level studies

Introduction
The title of a research article play a central role in the scholarly communication process: it is usually the first point of contact with its potential readers (Diener, 1984; Gross, Harmon & Reidy, 2002; Salager-Meyer & Alcaraz Ariza, 2013). According to Yitzhaki (1994, p. 321), the “primary functions [of a title] are to draw a reader’s attention to a paper and to indicate its content from a short glimpse, thus contributing to its initial selection or rejection”. The title can be considered as the most important summary of a research article since it is “generally the first (and sometimes the only) information obtained from the published article” (Paiva, Lima, & Paiva, 2012, p. 509). It can also reflect the content of a paper by describing its methods, design, results or conclusion, or by revealing important contextual attributes of a piece of research. Similarly, we can posit that mentioning a country name in the title of an article constitutes a geographical contextualization of the article in question.

Several bibliometric studies have investigated the relationship between title characteristics and scholarly impact. Many studies found that articles with shorter titles were more cited (Gnewuch & Wohlrabe, 2017; Paiva et al., 2012; Subotic & Mukherjee, 2014), while others found the opposite (Habibzadeh & Yadollahie, 2010; Jacques & Sebire, 2010). Other studies found that the direction of the correlation between title length and citations differs between disciplines (van Wesel, Wyatt, & ten Haaf, 2014) or found no significant correlation (Rostami, Mohammadpoorasl, & Hajizadeh, 2014). Buter and van Raan (2011) found that the occurrence of at least one non-alphanumeric character in the title was associated with a higher impact, but the correlation strength varied by discipline and was in some cases non-significant or negative.
Titles containing a hyphen or colon (Jacques & Sebire, 2010; Rostami et al., 2014), and titles containing acronyms have also been associated with higher citations rates. According to Subotic and Mukherjee (2014), we should remain cautious when interpreting the results of these studies since “we are only beginning to understand how relevant title characteristics relate to each other in an integrative context” (p. 123). Indeed, “what is said probably matters more than how it is said” (p. 121).

We found five studies investigating the relationship between citations and the presence of a specific geographical region in articles’ title, which is the focus of the present study. Nair and Gibbert (2016) showed that context attributes of titles, such as reference to a specific country, company or industry name, had no significant influence on citations, yet the results of the four other studies point in the opposite direction. Indeed, titles referring to geographical feature were associated with fewer citations by Paiva et al. (2012), Rostami et al. (2014), Jacques and Sebire (2010) and Abramo, D’Angelo and Di Costa (2016). While most of these studies obtained a negative correlation between the geographical contextualization of a research and its scientific impact, they either used small samples (a few hundred publications) or focused on specific disciplines. The study by Abramo et al. (2016) attempted to overcome these limits by analyzing all WoS-indexed Italian publications published between 2004 and 2011. The authors divided articles in a “Country” group containing all publications mentioning “Italy” in their title, abstract or keywords (n=40,024), and a “No country” group including all the remaining publications (n=416,686). Despite being the largest study on the topic performed so far, its methodological design has serious shortcomings. For instance, factors other than the discipline that might affect the number of citations received by a paper were not controlled. Moreover, the “No country” group contains all publications that do not mention Italy, and therefore likely contains articles that mention other countries. Consequently, it is unclear how well the study isolates the effect of country mentions on citations. Another limitation of the research relates to its small geographical scope, both at the level of the researchers (the analysis is restricted to publications by authors affiliated to Italian institutions) and at the level of the research object (the analysis is restricted to publications mentioning Italy). This raises questions regarding the generalizability of their findings to other geographical and thematic contexts.

The present research aims to overcome these shortcomings by analyzing a large dataset of worldwide publication and controlling for article similarity. We also investigate how the amplitude of the citation (dis)advantage of articles naming countries in their title or abstract varies according to the country mentioned. More specifically, we provide answers to the following research questions:

1. What is the relation between the mention of a country in the title or abstract of articles and their relative number of citations?
2. How does this relation differ by discipline?
3. How does this relation differ by mentioned country?

Methods
We used all articles, notes and reviews published in Clarivate Analytics’ Web of Science (WoS) between 1996 and 2013, each assigned to one of four broad categories—Arts and Humanities (AH), Biomedical Research (BM), Natural Sciences and Engineering (NSE) and Social Sciences (SS)—based on the journal’s NSF classification. The twenty countries with the highest number of papers in the WoS over that period were chosen for this analysis (see Table 1). We searched for these countries’ names as well as their associated adjectives and demonyms to
create our “Country” dataset. For each article included in the “Country” dataset, we searched for the most similar article published in the same journal and year, but without any country mention (i.e., not limited to the twenty countries included in the analysis) in the title or abstract\(^1\). To measure the similarity between two articles, we computed the cosine similarity of their respective title and abstract (reduced to their constitutive noun phrases) as well as the Jaccard similarity of their references list (references to WoS source items only). We then ranked candidate pairs per these two criteria and, to ensure maximal proximity between the two articles, only cases where the same article was ranked first per both criteria were considered in the comparative analysis. Table 1 reports the resulting number of article pairs for each country and discipline. The group “Title” includes articles for which the country was mentioned in the title, and the “Abstract” group refers to articles for which the country was mentioned in the abstract, and did not appear in the title. Also, we decided to exclude Arts and Humanities from the analysis since the number of papers in the dataset was too small (a total of 1,456 and 2,161 articles in the “Title” and “Abstract” groups, respectively).

### Results

Figure 1 shows the average difference between the field-normalized citations rates (to enable the comparison of effect size between disciplines) of articles that mention a country in their abstract and their associated control article (i.e., the most similar article with no mention of a country). Four observations can be made. First, the results show that, on average, there is a

\(^1\) To identify mentions of other countries, we used a list of 593 country names, adjectives and demonyms, retrieved from: [https://en.wikipedia.org/wiki/List_of_adjectival_and_demonymic_forms_for_countries_and_nations](https://en.wikipedia.org/wiki/List_of_adjectival_and_demonymic_forms_for_countries_and_nations)
citation disadvantage for articles who mention a country either in their title or abstract. This is true for all countries when all disciplines are combined. Second, the citation disadvantage appears to be smaller when a country is mentioned in the abstract only, except for articles in BM that mention the United States or Germany or Sweden, and articles in NSE mentioning China or Sweden. Third, the citation disadvantage is generally higher in SS than in BM and NSE. Fourth, the citation disadvantage appears to be much higher for some countries than others. While this varies by discipline, we observe that the citation disadvantage is generally smaller for countries who have traditionally dominated the scientific front. There are however notable exceptions, such as papers in NSE mentioning China that appear to have the smallest citation disadvantage. In BM, articles mentioning the United States or Germany in their title also stand out, as they exhibit the opposite results than other countries and fields: they receive on average more citations than the control articles, and they are also more cited on average than articles who mentioned the country only in the abstract.

![Figure 1. Citation (dis)advantage when mentioning a country in the title or abstract by country and discipline.](image)

**Discussion and conclusion**

Our results show that articles mentioning a country in their title or abstract receive on average less citations than similar articles that do not mention a country and, thus, are coherent with those of Paiva et al. (2012), Rostami et al. (2014), Jacques and Sebire (2010) and Abramo et al. (2016). However, since we compared articles from the first group with their closest neighbour (based on the title, abstract and reference similarity), our method allows a better control for the research topic, and thus better isolates the “country effect” than previously used methods. Despite the unequivocal nature of the results, important nuances should be considered in their interpretation. For instance, while the appearance of a country in the title or abstract is likely to reflect the local relevance of an article—or at least its research setting—it is unclear to what extent the absence of geographical contextualization reflects its global relevance.
Consequently, it remains unclear whether the observed citation disadvantage is caused by a perceived lack of global relevance in the eyes of other researchers or by an actual lack of relevance of the articles for research in other geographical or global contexts. The greater citation gap—observed in Social Sciences—can be explained by the fact that research in these disciplines is more often contextualized within a specific region or nation, compared with Natural Sciences where research objects are often by definition international (Gingras & Mosbah-Natanson, 2010). Thus, it could be argued that in Social Sciences, mentioning a country in the title or abstract does act as the marker of a geographical or national context of the research, and that the results may in fact be difficult to transfer to other contexts. This raises a few questions. Is the citation gap caused by the title of the article, or by its content? Would removing the geographical location in title of articles with a local or national focus result in higher citations? Given that the title of a paper serves as a signalling device for those to whom it may be most useful, and that research on local topics is particularly relevant for local stakeholders (Stremersch, Verniers, & Verhoef, 2007), removing markers of geographical context from titles in an attempt to increase citations might come at the expense of other forms of impact.

This research in progress paper also shows that the amplitude of the citation disadvantage varies by mentioned country. Since some countries have a larger research output than others, this may be partially explained by the idea that researchers in a given country are perhaps more likely to do research on local topics, but also more likely to perceive articles mentioning their country as relevant. Moreover, given the importance of citations in research evaluation processes, even researchers in smaller and/or non-English speaking countries might be incentivized to work on research of local issues in larger English-speaking countries like the United States to get more citations (Larivière, 2014). This potential effect on citations might also be amplified by the overrepresentation of research published in the English language in the WoS database (Mongeon & Paul-Hus, 2016).

Further steps of this research will be to 1) extend our list of geographical markers to ensure that the “No country” group does not mention any location. It will also include the country of the authors in the analysis since research on local issues performed by local scientists may be of more local (and less global) relevance than topics that are studied by the global scientific community, which might also influence citation rates. Finally, there is empirical evidence that research focusing on local issues tends to be more interdisciplinary (Chavarro, Tang, & Rafols, 2014), and that interdisciplinarity is often associated with higher citation rates (Larivière, Haustein, & Börner, 2015). Thus, further research should also look at how geographical contextualisation of research is related to interdisciplinarity, and how this may affect citation rates.

Identifying Funding Allocation Gaps Within an Academic Domain: Case Study of Robotics Research

Cristian Mejia 1 Yuya Kajikawa 2

Abstract
In this paper, we compare the citation network of academic articles acknowledging financial funding, to the network of articles in the same research domain without funding acknowledgement. We found similar clusters in both networks, although with differences in publication intensity and academic impact. Other clusters were exclusive of any of the two networks, those only found in the network without financial acknowledgements represent funding allocation gaps. We applied our method to identify gaps in robotics research where we found topics like micro-robotics, spherical robots, and cloud-computing for robotics being underfunded. The proposed method may benefit two groups, researcher can identify topics receiving more attention, thus, having higher possibility of getting funds; and policy makers may monitor funding-independent clusters, born of researchers own curiosity, in order to consider those topics in future funding strategies.

Conference Topic
Methods and Techniques; Citation and co-citation analysis; Research funding

Introduction
The study of research funding is a growing field in bibliometrics. Large academic data bases like the Web of Science and Scopus now include funding information extracted from the acknowledgement section of the articles, opening up the possibilities for understanding the trends of funding across different countries or disciplines (Wang & Shapira, 2011). However, most of the research is focused on understanding the role of funding in relation to positive academic impact, usually measured by citations received by the funded projects (Gök, Rigby, & Shapira, 2016). While just few have pointed out the need of using maps of funding sources to understand gaps and new research trends (Rigby, 2011).

We take further steps in that direction, by trying to identify missing spots in the allocation strategies of funding organizations. To do so, we draw upon the literature on finding missing connections or common patterns by the comparison of two or more modes of knowledge representation. For instance, Shibata et al (2010) extracted commercialization gaps by comparing clusters in a citation network of patents with those found in a network of papers for the case of solar cells. Active clusters in the paper network, not linked to any cluster in the patent network were described as commercialization opportunity. Similar linkage strategy was followed by Ittipanuvat et al (2014) when connecting two different research domains, robotics and gerontology. While the focus in that research was not about missing connections, text similarity measurements proven to be able to stablish connections between two fields that are semantically different.

In this article, we take a different approach by adapting those methodologies within the same domain and type of documents. Although, this time two modes of the same type of documents are compared: the set of articles reporting financial funding and those which do not. We aim to provide a methodology for the identification of specific research topics not receiving funding,
and explore the academic landscapes created by the citation networks of funded and non-funded articles. We applied the methodology to the robotics research, which is known for its disciplinary breadth and funding support.

The rest of the paper is composed as follows. We describe the data extraction strategy and methodological treatment in the data and methods section. Characteristics of the data and findings derived from the citation network and text linkage is shown and discussed next. We conclude by summarizing those findings.

Data and Methods

An overview of the proposed methodology is represented in figure 1. Data were retrieved from the Web of Science. We searched for articles on the topic “robot” from 2009 to 2016, obtaining 76,209 records. The selection of 2009 as starting year was determined by the availability of funding acknowledgements in the database (Paul-Hus, Desrochers, & Costas, 2016). We split the records in two parts, those mentioning at least one funding organization, and those without funding acknowledgment. The former accounted for 21,142 records (27.7%), and the latter for 55,067 (72.3%). The two datasets were normalized and compared in terms of year frequency, participating countries, and target research categories.

Each of these data sets received the same following treatment. We created a direct citation network (de Solla Price, 1965) where the articles are treated as nodes, connected to other nodes according to the cited references found in each article. This type of networks is known for generating accurate taxonomies of scientific knowledge (Klavans & Boyack, 2017), and for detecting research fronts (Shibata, Kajikawa, Takeda, & Matsushima, 2009). Direct citation networks have been applied to map global scientific landscapes, and specific research domains. Once the network is created, the direction of the citations is neglected and the largest connected component extracted.

Following, we identified tightly connected communities of nodes by applying a non-fuzzy, topological algorithm based on modularity maximization (Newman & Girvan, 2004). This algorithm looks for the best partition by contrasting the network to a random graph generated from the features of the original one, thus, the number of clusters is automatically defined by the natural structure of the network. Then, we used the large graph layout (Adai, Date, Wieland, & Marcotte, 2004) to visualize the network. The size of nodes was set to zero, and clusters are depicted by the edges only. At this point we have two networks, one representing the knowledge derived from articles that acknowledge funding, and one without funding acknowledgement. Finally, we compared the communities in both networks in term of text similarity. For each cluster, we obtained the set of keywords that best represent them by weighting them using the term-frequency/inverse-document-frequency adapted to cluster level (i.e. inverse-cluster-
frequency), those keywords were translated to a vector space model and the cosine similarity was computed. Cosine similarity ranges from 0 to 1, being 1 the exact match. We regarded clusters to be similar if they score a similarity of 0.5 or more.

Once similar clusters were connected, we identified three types of clusters: a) Clusters that exist in both networks; b) clusters exclusive to the network with funding acknowledgements; and c) Clusters exclusive of the network without funding acknowledgement. The third type represents the funding allocation gap. In this article, allocation gaps are defined from a bibliometric standpoint only, being the clusters of knowledge not receiving funding. In practice, their interpretation varies from those areas overlooked by funding agencies, to ideas explored without the need of grants.

**Results and discussion**

Academic articles on robotics research were obtained and classified according to the funding information provided. 27.7% acknowledge at least one funding organization. This proportion is in line with the general proportion of articles reporting funding in the Web of Science’ Core Collection (Paul-Hus et al., 2016). After normalizing the data, we compared them in terms of year frequency, and participating countries as shown in Figure 2. Robotics is an ever-growing field. Before 2012 shares of articles reporting, or not, funding were balanced. However, in recent years the difference is getting noticeable. 2016 has the largest share of articles reporting funds, while 2015 is the largest for articles without acknowledgement. In the case of participating countries, USA and China are the largest contributors. Some countries like China and South Korea have larger shares when it comes to acknowledged funding, while Iran and India show an opposite behaviour. England and Australia have similar proportions in both scenarios.

![Figure 2](image.png)

**Figure 2. (a) Normalized frequency per year (b) Top 15 participating countries.**

There are differences regarding specific research categories within robotics. Figure 3 depicts such difference in an overlay map (Rafols, Porter, & Leydesdorff, 2010), plotted using VOSviewer (Van Eck & Waltman, 2010).

While surgery is present in both sets, there is a clear intensification of funding in robotics for medical sciences, particularly neuroscience and rehabilitation. Multidisciplinary science is also benefited from funding, and so is intensified the region of applied sciences. The social sciences and humanities are underrepresented.
Figure 3. Target research categories within robotics for articles (a) not reporting funding, and (b) reporting funding.

Figure 4 shows the citation networks for the two data sets. Clusters were labelled by inspecting the relevant keywords, and the title and abstract of the most cited papers within them. We compared the clusters by using cosine similarity and found 17 highly similar pairs of clusters, which top ten are characterized in table 1. Clusters from the network without funding acknowledgement have an average year that is younger than their counterparts in 13 of the cases, although by a small difference. On the other hand, the performance measured in terms of cites received per articles within each cluster, is clearly better for the network reporting funding, except for the most similar connection about the topic of transoral robotic surgery.

The remaining clusters were found of little similarity between the two networks. However, several clusters were of small size, so that we focused only in the largest clusters that accounts for the 80% of articles in each network. Exclusive clusters are shown in table 2. Again, clusters from the network reporting funding show better performance in terms of citations received. By exploring the robotics research separately, we could find similarities and gaps between the two networks structures, however the two sets of articles do not exist in isolation. Articles with and without funding cite each other forming the complete academic landscape of a domain. A simpler method to evaluate the presence of funding is to create a citation network of all papers, obtain the clusters, and compute the proportion of articles reporting funding within each cluster, expecting to find some of them ranging from purely funded to not funded at all. That practical and straightforward method may serve as indicator of funding; however, it leads to a different interpretation to that aimed in this article. We created the citation network by using all the data on robotics, obtaining a network split in 460 clusters. 18 of them aggregated 90% of the articles.
The proportion of articles acknowledging funding within each of them was rather stable, having a mean 33.3%. This suggests that the specific topics in robotics are receiving funding in a proportion close to the global average. Moreover, we did not find any relevant cluster without presence of funding. Finally, we compared the 4 clusters without funding shown in Table 2, to the clusters in the merged network. Articles from the micro-robotics cluster were found in the merged network, forming a new cluster along with Nano-robotics having 42% of funding presence. Articles from the other 3 clusters were scattered into several clusters in the merged network. Therefore, our proposed methodology generates clusters that are fine grained, and can inform about network structures that are independent of funding.

Finally, challenges exist when using acknowledgements as proxy of funding. The proposed methodology depends on the reliability of rightly acknowledging the funding sources, and this presents two limitations. First, authors willingly or unwillingly may omit an acknowledgement. The reasons may vary from cultural and political as discussed in Rigby (2011), or because some funding bodies, private specially, prefer to be omitted as mentioned by Wang and Shapira.
Second, data providers as the Web of Science may fail to rightly recognize the entities written in the acknowledgement section when using automated tools to populate the article metadata. In regard of these limitations, experiments realized in the field of cancer research, a field known for its intense funding activity, have demonstrated that less than 3% of papers in the corpus omitted any of the sponsors involved in the research; and that the Web of Science reach a precision and recall above 90% when converting the acknowledgment text to funding metadata (Grassano, Rotolo, Hutton, Lang, & Hopkins, 2016). Therefore, the use of acknowledgement can be associated to patterns of funding, particularly for the study of general trends as proposed in this article.

Conclusion

We took advantage of the financial acknowledgement information provided in academic articles to separate the corpus of research reporting and not reporting funding. From these sets of records, we build citation networks that allowed us to explore the academic landscape of funded and unfunded research. The comparison of these networks leaded us to three categories. The first one, specific topics that exist in both networks, as is the case of robotics for medical science, particularly related to robotic surgery and rehabilitation, this group also brought to surface the relation between funding and academic impact. Except for research on transoral surgery, clusters with common topics had better citation per paper ratio in the network of funded articles, this result agrees with the bibliometric literature arguing that the presence of funding leads to more citations (Lewison & Dawson, 1998). The second group, are clusters only present in the network of funded articles, here we found swarm robotics, temporal logic and neural network algorithms, and robots for harvesting. The final group are those clusters that appeared in the network of articles without funding acknowledgements, thus, representing funding allocation gaps. These underfunded topics were micro-robotics, spherical robots, and cloud computing for robotics. It also appeared a cluster of general concepts about robotics technologies. The methodology proposed in this article allows the identification of topics receiving high or little attention from funding organizations. The study of landscapes of research funding may facilitate the creation of research strategies, by understanding the trends of funding. However, the assessment of relevance of the funding gaps, or its typology (e.g. basic vs applied, breakthrough vs conventional) is still subject of future research.

By applying the proposed method researchers get a picture of specific topics in an academic domain that are receiving higher attention and attracting funding, while allows them to avoid those with little possibilities of getting grants.

A Logical Comparison of Citation Wakes and Generations

David Friggens

david.friggens@mbie.govt.nz
Ministry of Business, Innovation and Employment, Wellington (New Zealand)

Abstract
We provide an empirical comparison of two indicators – the citation-wake-score and the $fp^k$-index – for measuring an article’s influence by counting all of its direct and indirect citations, i.e. its citations, citations of citations, and so forth. The indicators are compared for the small field of mathematical logic, but articles from all fields in the Scopus database are used for the calculations. We find that the two indicators are very similar. Furthermore, the use of a general bibliometric database raises different questions for future investigation than previous results using field specific data sets.

Conference Topic
Indicators; Citation and co-citation analysis

Introduction
Most citation-based indicators in bibliometrics consider only direct citations between articles (Waltman, 2016), though there are approaches that consider indirect citations (Fragkiadaki & Evangelidis, 2014). Recently, Klosik & Bornholdt (2014) and Fragkiadaki & Evangelidis (2016) have independently proposed new indicators that count all of the direct and indirect citations of an article, i.e. an article’s citations, citations of citations, citations of citations of citations, and so on, each level being a new generation. The collective generations of citations form an article’s citation wake. Both indicators are similar, with differences in the ways they weight the age of an article and the generation of a citation. Additionally, the choice of a manual parameter differs too: the first parameterises the generation weighting and the second limits the number of generations counted.

In this study we provide two contributions: first by comparing the two indicators, and second by providing new empirical data. Both previous studies used field-specific data sets, from the physics journal Physical Review and the computer science database DBLP, respectively. We look at one field – mathematical logic – but consider indirect citations from any field in the Scopus database. The choice of a mathematics subfield was in part as it is commonly used as an example of a field with low citation rates (e.g. Waltman, 2016, Section 6); are indirect citations a more important indicator of an article’s influence in a field with low citations?

Indicators
We consider two indicators: the wake-citation-score of Klosik & Bornholdt (2014) and the $fp^k$-index of Fragkiadaki & Evangelidis (2016); we shall refer to them (both indicator and reference) as KB14 and FE16, respectively.

First, let us define some concepts and a generalised indicator. For a given data set of publications and their citation network, let $P(y)$ be the number of publications published in year $y$. For a specific publication $p$, let $G(p, g)$ be size of generation $g$ – the number of publications whose shortest citation path to $p$ is length $g$. Thus, the number of direct citations is $G(p, 1)$.

Here we follow the terminology of FE16. KB14 term “generation $g$” as “neighbourhood layer $g - 1$.”
For a given publication \( p \) published in year \( y_p \), we can define a generalised indicator \( \mathbb{I}(p) \) to assess the impact of \( p \) as the sum of the generation sizes, up to a given limit, and weighted by a damping factor for each generation; a constant is added, and the result is normalized based on its age. Formally, we write:

\[
\mathbb{I}(p) = c + \sum_{g=1}^{\text{lim}} (\text{df}(g) \times \mathbb{G}(p,g)) \over \text{an}(y_p)
\]

The values of the components for each of the two specific indicators are shown in Table 1, and discussed in more detail below. Each indicator has a configurable parameter, so actually defines a family of indicators. For KB14 it is \( 0 \leq \delta \leq 1 \) in the damping factor, for FE16 it is \( \lambda \geq 1 \) to limit the number of generations counted. Note that we have deliberately used different notation from both KB14 and FE16 to avoid confusion and make the commonalities clearer.

### Table 1. Components of the two indicators

<table>
<thead>
<tr>
<th>Component</th>
<th>Description</th>
<th>KB14</th>
<th>FE16</th>
</tr>

<td>age normalization</td>
<td>( \sum_{i=y_p}^{y_{\max}} \mathbb{P}(i) )</td>
<td>( y_{\max} - y_p + 1 )</td>
</tr>
</tbody>
</table>

**Damping Factor**

FE16 note that later generations should count less than earlier ones, and propose that the count should be divided by the generation number. KB14 propose a configurable damping factor, allowing for all generations to be counted equally (\( \delta = 1 \)) through to only counting direct citations (\( \delta = 0 \)); they report experimental results primarily with \( \delta = 0.9 \). Figure 1 compares the two approaches, and shows that the reductions are not comparable.

**Age Normalisation**

Older publications have had more opportunity to receive citations than younger ones, so direct comparisons would be unfair. FE16 simply divide by the age, starting from 1 in the year of...
publication. KB14 divide by the theoretical maximum citation wake possible – the count of all publications in the data set from the year of publication onwards. The latter approach could have different effects based on the data set used, but in the Scopus database between 2002 and 2015 the two approaches are very similar, as shown in Figure 2.

**Generation Limit**

KB14 assume all generations of indirect citations should be counted. FE16 propose limiting the depth, and report experimental results for $\lambda = 3$.\(^2\) In practice, lower values of $\delta$ with KB14 may be equivalent to limiting the generations counted. If we assume that a dampened generation count less than 1 is equivalent to being excluded, then Table 2 shows the values of $\delta$ that match $\lambda$ under different maximum generation sizes.

</tr>
</tbody>
</table>

**Data**

In this study we used a full 14 year extract from the Scopus database (Elsevier, 2016), spanning 2002 to 2015 and containing 24,964,475 publications of type “article” or “conference paper”, with 208,583,913 citations between them. We calculated indicators for the 13,354 publications from sources classified with the ASJC code 2609 (Mathematics; Logic).\(^3\)

In comparison, Klosik & Bornholdt (2014) used a data set spanning 116 years (1893-2009) from a single physics journal (*Physical Review*) containing 438,000 publications and 4.5 million citations. Fragkiadaki & Evangelidis (2016) used a data set from DBLP containing 20,000 computer science publications and roughly the same number of citations.

**Results**

**Generations**

There were 13,354 publications from mathematical logic classified sources, of which 8,367 had citations. This group received direct citations from 34,692 publications, and indirect citations from a further 2,439,601 publications. Taking the logic publications as generation 0, there are 23 more generations, peaking at generations 7 and 8, as seen in Figure 3. The publications come from all 27 ASJC top-level fields. Figure 5 plots the percent of each field across all generations versus the percent in the whole data set. Sources can receive multiple field classifications, so the totals add up to more than 100%.

For individual publications, the maximum generation ranges up to 31, as shown in Figure 4. Most publications have smaller generation ranges: 28% only have 1 generation, 58% have no more than 3 generations, 87% have no more than 8, and 99% have no more than 20

\(^2\)“This number has been chosen based on the authors’ sentiment that three generations (similar to friends of friends of friends in social networks) are enough to illustrate the usability and validity of the indicator under different circumstances.” (Fragkiadaki & Evangelidis, 2016, p670)

\(^3\)To be clear, Scopus classifies the source (e.g. journal) rather than the article. Some included articles may not actually be about logic (if the source covers multiple subfields) and, conversely, some logic articles may not be included, as their source has a broader mathematics classification or is multidisciplinary (e.g. *PLoS ONE*).
generations. The size of each generation per publication is mostly small – 13% contain only one indirect publication – but they range up to nearly 277,000 in one case. 48% have up to 10 publications, 79% up to 100 and 94% up to 1,000.

Figure 3. Size of generations from set of logic publications

Figure 4. Number of generations for each logic publication, darker parts of the bar indicate older publications

Figure 5. Comparison of field distribution in logic generations vs whole data set

**Indicators**

Figure 6 shows comparisons between five indicators: the average citations per year (CPY), the Mean Normalized Citation Score (Waltman et al., 2011), FE16 with $\lambda$ values of 3 (used by the authors) and 31 (the maximum in this data set), and KB14 with $\delta$ of 0.9 (used by the authors). The figure displays Pearson and Spearman correlation coefficients, and a scatter plot to visualise the relationship between each of the ten pairs of indicators.

The most striking result is how similar the two full generation indicators are. Another observation is the L shape of the bottom left scatter plots, which results in low Pearson
correlations. The direct citation indicators favour young publications with relatively high citations that are unlikely to be sustained, but these are not favoured by the new indicators. The limited FE16 indicator appears visually more correlated to the direct indicators, but has a higher rank order correlation with the other two indirect indicators.

![Matrix of pairwise comparisons of five indicators, showing scatter plots, and Pearson and Spearman correlation coefficients](image)

Figure 6. Matrix of pairwise comparisons of five indicators, showing scatter plots, and Pearson and Spearman correlation coefficients

An alternative comparison is to consider the top 10% of publications, ranked by each indicator. Figure 7 contains an UpSet (Lex et al., 2014), an alternative to a Venn diagram, visualising the overlapping rankings. Only 3.3% of the publications were ranked in the top 10% by all five indicators.
Discussion

Our results show that the two indicators proposed independently by Klosik & Bornholdt (2014) and Fragkiadaki & Evangelidis (2016) are quite close, and with similar configuration produce very similar results. Further research is needed to investigate if there are situations where one approach has a clear advantage, but for mathematical logic the differences are much less than they may appear at first glance.

The biggest difference between the two indicators is the choice of parameter: count all generations and tune the damping factor, or place a fixed generational limit? We have shown that there may be equivalent configurations, so the main practical concern may be ease of computation.

Computing these indicators using a broad data set like Scopus raised new questions that remain to be investigated, especially about field normalization. So far the indicators have been used to look at publications from a single field – do we need to divide by expected values for cross field comparison as with MNCS? Even for a small field like mathematical logic the wakes include publications from all fields, so perhaps this is unnecessary? Alternatively, perhaps field normalization needs to take place within the counting of the indirect citations at each generation?

A novel analysis on global environmental quality research in the last two decades based on bibliometric modeling indicators

Dron Lha¹, Lihe Chai²

Tianjin University, Tianjin (China)

Abstract
A novel analysis on the global environmental quality research (EQR) during the last two decades is conducted based on bibliometric modeling indicators. Four aspects of findings are obtained. (1) From the subject categories distribution and the co-words network, we elucidate the global EQR involves both natural aspects and social aspects. Small world (c=0.17 and L=3.042) of co-words network highlight the underlying strong relations between most topics. (2) For the cooperative network, a large clustering coefficient (0.367) and a small average path length (1.909) indicate very accessible cooperation between any countries during the EQR. Power-law distribution of node degrees implies that led by USA and China, all over the world is involved in EQR by a self-organized way. However a large slope (α=-3.958) means many countries have not yet sufficiently played their roles. (3) The Zipf’s distribution for citations, Bradford’s distribution for journals and Lotka’s distribution for funds reflect the self-organized information transmission in the global EQR. Bradford’s distribution suggests the participations of wider scopes of journals in EQR are expected. Lotka’s distribution for funds with α=-1.9 implies the funding agencies distribution is too concentrative. (4) By elucidating the underlying pattern of global EQR, some coping strategies are proposed.

Introduction
The interactions between the environment and the activities of all living beings in the world are very strong (Green et al. 2000). During past years, there were extensive environmental quality research (EQR) from global scientists with diverse scopes involved. Some researches were conducted from agricultural perspectives by relating natural resources protection to environmental quality improvement (Cassman et al. 2003), by relating resource use efficiency to environmental quality (Fan et al. 2011), by analyzing the impact of soil erosion on environmental quality (Lal 1998) and the impact of crop residue removal on environmental quality (Blanco-Canqui & Lal 2009), and by aimed at developing an integrated environmental risk assessment and management (IERAM) framework for enhancing the sustainability of such MPAs (Xu et al. 2015). There were also studies about environmental quality and potential evolution from the view of animal populations (Charmantier & Garant 2005; Rose 2000). Brasington & Hite (2005) and Mitchell et al. (2007) conducted EQR from the view of indoor environment in a small angular space. Farzin & Bond (2006) analyzed
democracy and environmental quality to illustrate the relations between social
environmental quality and economical environmental quality. Le et al. (2016)
elaborated the relationship between trade openness and environmental quality. In
addition, there were also lots of researches focusing on other numerous scopes, such
as climate impact of Russia (Frijters & Van Praag 1998), environmental quality in
Taipei (Tzeng et al. 2002) and the local environmental quality or life-satisfaction in
German (Rehdanz & Maddison 2008), and so on.

Doubtless, it is very necessary to uncover the underlying pattern of EQR from a large
scale of literature of EQR. This paper attempts to conduct an intensive bibliometric
modeling indicative anatomy on the pattern of global EQR.

Methods and data sources

Methods

The paper adopts statistical analyses on subject categories distribution to reveal the
connotation of EQR from a macroscopic view. By constructing co-words network and
calculating its dynamic parameters from complex network theory, the connotation of
EQR is revealed from microscopic keywords. In this way, the connotation of EQR
can be strictly explored from the new perspective of complex network by detailed
parameter calculations (e.g. small world phenomena). By constructing cooperation
network of countries and calculating its dynamic parameters from complex network
theory, the global cooperation actions on EQR can be rigorously elucidated by a
detailed calculation of the network parameters (e.g. small world phenomena,
scale-free degree distribution). Some other factors (i.e., citation dynamics, journal
dynamics and funding dynamics) on the global actions of EQR can be analyzed by
utilizing three prime indicators of bibliometrics: Zipf’s distribution for citation,
Bradford’s distribution for journals and Lotka’s expression for funding agencies
distribution. Finally, based on the findings from the bibliometric modeling indicative
results, the corresponding coping strategies can be proposed.

Data sources

The data were retrieved from Web of Science with the search term “environmen*
quality” from the topics, abstracts, and keywords of all publications related to EQR
during 1998-2015. A total of 6819 publications of EQR were obtained. As shown in
Figure 1, journal articles increased year by year, reaching a peak in 2015. Moreover,
proceedings and reviews had the most publications in 2012 and 2015, respectively.

We analyze dynamic characteristics of the data. We consider the empirical Logistic
correlation for the relationship between accumulative publications \(y\) and time \(x\)

\[
y(x) = \frac{k}{1 + ae^{-bx}}. \quad (1)
\]

In Eq. (1), \(k\), \(a\) and \(b\) are coefficients. \(k\) represents the theoretical maximum possible
accumulative publications that EQR could achieve. \(b\) is related to growth rate. That is,
\(b\) relates the time of reaching the theoretical maximal publication accumulation: the
smaller \(b\) corresponds the longer time. By the correlations between the accumulative
publications and time as shown in Figure 2, it is clear that Logistic formula is
generally met, which means the accumulative publication output of EQR holds Logistic growth pattern. That is, generally, accumulative publication output of EQR would undergo a near exponential growth at initial stages, and reach a maximum growth rate at $x=(\ln a)/b$ with $y=k/2$, and then would be gradually close to a stable theoretical value $k$ at a constantly decreasing growth rate. From Figure 2, we $k=8290$, $b=0.23$. The large $k$ and small $b$ well validate that in current phase (1998-present), the EQR is still in the early stages of a rapid development as an emerging discipline. Our data source from the current phase (1998-present), which is characteristic of early and rapid developing movements, is enough for our analyses on the pattern of global EQR, including what is EQR, and how we cooperate to address the issues of global EQR.

![Figure 1. The publication output](image1)

![Figure 2. The Logistic growth of publication output](image2)

**Results and discussions**

*The connotation of environmental quality research (EQR)*

We first uncover “what the connotation is” from the EQR’s emergence and the process of reaching the consensus by analyzing the publications of EQR. This can be done from the distribution of macroscopic subject categories and the evolutionary co-words network of microscopic keywords.

(1) EQR’s connotation from the distribution of macroscopic subject categories

Since each publication can be assigned a subject category, the stable distribution of subject categories that have formed during a long time can reflect what the agreed connotation of a discipline and how the scientists reach the consensus during the emerging movements or efforts of developing a discipline.

In this study, EQR covers 177 subject categories in SCI-E and SSCI. By statistical calculations, a logarithmic scale radar chart is obtained as in Figure 3. We can see EQR covers a wide range of subjects, including environmental science, agriculture, economy, architecture, computer science, transportation, administration, medicine, psychology, etc. The scientists have gradually reached the consensus that the connotation of EQR includes not only the natural aspects (air, water, soil, physics, chemistry, biological life, etc), but the social aspects (economy, culture, psychology, education, etc). Environmental science is dominant in EQR, followed by engineering and agricultural science, economics and architecture, etc. In Figure 4, we analyze the dynamic trends of the top 6 subject categories. Environmental science ecology held a relative stable growth, reaching a peak in 2015. Engineering, agriculture and business
economics sometimes had downward trends, which reached the peaks respectively in 2012, 2008 and 2009. Starting from 2006, construction building technology had a most obvious growth trend. Water resources showed a steady growth from 2010. During past years, EQR flourished in environmental science ecology. Construction building technology had a greater growth than engineering, agriculture and economics. According to the accumulative publications of the top 6 subjects, Logical growths of Eq. (1) are correlated as in Figure 5. A deep understanding on the subjects can be obtained by comparing its parameters $k$ and $b$. Large $k$ and small $b$ mean that the vitality of the subjects in EQR. Environmental science ecology ($k=4869.26$ and $b=0.23$) has a high growth vitality. Agriculture ($k=693.79$ and $b=0.26$) and business economics ($k=658.47$ and $b=0.31$) have a relatively low growth vitality (i.e., easy to be saturated). In EQR, the most flourishing subject seems to be environmental science ecology.

Figure 3. The subjects distribution Figure 4. The annual variations of the top 6 subjects

Beyond qualitative understanding, we here use the detailed data to clarify the connotation of EQR by elucidating the distribution of EQR’s subject categories that have formed during past years. This can partly reflect the agreed connotation of EQR resulted from the emerging movements or efforts in EQR.

(2) EQR’s connotation from microscopic co-words network

The keywords of a publication can accurately interpret the microscopic content of a
With keywords as nodes and co-occurrence of two keywords as the edges between nodes, a co-words network can be constructed. By the analysis of a co-words network, i.e., its topological structure or clustering and networked parameters, we can uncover what connotation of an issue is agreed by scientists, and how scientists gradually reach the consensus on the issue during the emerging movements or efforts of developing a discipline. Thus, besides the distribution of EQR’s subject categories, which provide an understanding on EQR’s connotation from a macro viewpoint, we here further use co-words network to reflect what the agreed connotation is, and how we reach the consensus of EQR’s connotation from a new flavor.

As shown in Figure 6, the co-words network pattern is composed of 998 nodes (keywords) and 7294 edges (connections between keywords). From the classified color areas, the indoor environment, the sustainable environment, water quality and heavy metal are the centers of proliferating domains, suggesting that they dominate the connotation of EQR during past years. As Figure 6, water quality-centered keywords include monitoring, sewage, eutrophication, nutrient, phosphorus, agriculture, land use and management, and so on. With heavy metal as the center, the most closely related keywords are metal, soil, sedimentary pollutants, risk assessment, biological monitoring, water framework indicators, etc. Environment-centered keywords have closest relations with sustainable development, environmental Kuznets curve, indicators, climate change, China, model, geographic information systems, risk, environmental policy, water and air pollution, and so on. The keywords that are closely related to indoor environment include health, indoor air quality, indoor environment, comfort, energy consumption, energy, temperature and schools.

Figure 6. The co-words network pattern of EQR
Doubtless, during past years environmental quality was largely changed by mankind’s activities. These changes even endanger human living and development. The Earth we live together is facing big challenges. By a large number of actual movements and studies on environmental quality from all angles, a lot of publications on EQR appeared. These efforts from all aspects were embodied in the evolutionary keywords (i.e., co-words network). From a new flavor, Figure 6 can partly illustrate what efforts were made, what the agreed connotation is, and how we reach the consensus of EQR’s connotation.

A hotspot in a discipline neither merely consists of a single keyword, nor assembles a group of keywords with poor correlations. The connections of the co-words network are complicated. For example, pollution is related to both heavy metals and water quality or environment, but its connections with the heavy metal are closer. By calculating the parameters of the co-words network, we can learn more quantitatively the connections and then more accurately understand the agreed connotation of EQR. Co-words network is a complex network, we have to calculate the main parameters related to dynamic characteristics, namely average clustering coefficient $c$, average path length $L$, average degree $k$, network diameter $D$ and network density $p$.

The parameters of the co-words network are calculated, as shown in Table 1. For comparisons, we establish random network (with 998 nodes and links probability of 0.146) and calculate its parameters, as also shown in Table 1. From the comparable data, we find the average clustering coefficient of the network is 0.17, much larger than the average clustering coefficient 0.007 of corresponding random network. However, the average path length of the network is 3.042, smaller than that of corresponding random network. These results show that the co-words network exhibits evident small world phenomena (Strogatz 2001). This finding is meaningful. In one way, we can say small world phenomena that widely exist in other types of networks may hold well for co-words network. In other way, this result can help us to better understand the connotation of EQR: We can draw that the EQR discipline is currently at rapid development stage; The relationship between factors within disciplines is very close, holding strong correlation between keywords and the great co-occurrence chance.

In a word, above by obtaining the subject categories distribution and calculating the
dynamic parameters of co-words network, we can strictly verify that generalized EQR involves both natural aspects and social aspects. The quality of the natural environment contains physical aspect, chemical aspect, biological aspect, and so on. The quality of the social environment can be divided into social-economic aspect, psychological aspect, education aspect, cultural aspect, and so on. Indeed, environmental quality, as a measure of the suitability of human survival and social or economic development, reflects the comprehensive requirements of humanity, including both natural and social demands. The calculated parameters of co-words network, especial its small world characteristics \((c=0.17\) and \(L=3.042\)), show that the connections between all aspects within the discipline is very close, holding strong correlation between the keywords and large co-occurrence chance. The pursuits for a better understanding on environmental quality must be integrated to include various aspects of EQR.

Global cooperation actions on environmental quality research (EQR)

(1) General characteristics

From the connotation of environmental quality, environmental quality is not a problem of one person or one country, but is related to the whole Earth and all humankind. We need a deep cognition on human global cooperation actions on EQR. Here we make a detailed analysis on 5154 publications that remove the articles lack of author addresses information. The results show that nearly 105 countries have conducted EQR. With countries as nodes \((N)\) and cooperation of the countries in a publication as the edge \((M)\), a cooperative network is obtained as in Figure 4, in which the size of nodes and thickness of the edges indicate the number of publications by collaboration between countries. Figure 4 visualizes the patterns of the cooperation between all countries. To quantify the characteristics of the global cooperation actions on EQR, we calculate the parameters of the network: the average clustering coefficient \(c\), the average path length \(L\), degree \(k\) and others, as listed in Table 2. The average clustering coefficient of the network has a large value (0.367), indicating the close relationship between the various countries. The average path length is 1.909, which means that on average, one country can cooperate with anyone country by no more than one intermediate country in the actions on EQR. In addition, the cooperation network has network diameter 5 and network density 0.186, indicating that global actions on EQR by cooperation between the countries is very accessible.

(2) Degree distribution: characteristics of the global cooperation network on EQR
The larger the degree of a country is, the more the number of countries that cooperate with it is. From 7, the degree of USA has a largest value (80), followed by China (77) and Italy (67). The average degree of the entire network is 19.314. To reveal more underlying characteristics of the global cooperative, it is useful to study the degree distribution of the network. With \( f \) as the degrees of the countries and \( r \) as the ranks of the countries (a decreasing order), we fit the degree distribution of the network by Zipf’s equation

\[
f = c \cdot (r + m)^{-a}.
\]

The results are shown in Figure 8. \( R^2 = 0.981 \) means power-law distribution of degrees is satisfied, which implies that led by USA and China, the whole world is involved in EQR by a self-organized way. In addition, a large slope (with \( a=-3.958 \)) suggests that the number of countries with low degrees is relative large. That is, many countries have not yet sufficiently exploited their capacities in the cooperative actions on EQR.

![Figure 8. The degree distribution for all countries](image)

(3) Characteristics of cooperation between different countries and regions
In order to further understand detailed cooperative relations between different countries and regions, we here select the top 11 productive countries for our analyses.
In Figure 9, the cooperation between USA and China is most frequent, issuing 211 publications of EQR, followed by the cooperation between USA and Italy (99), USA and UK (87). USA also has wide partnerships with Canada, Spain and Brazil. Among the top 11 productive countries, in addition to China and Brazil as developing countries, the rest are all developed countries (developing countries and developed countries are identified according to the standard of 2015 United Nations). We conduct the calculations on the publications of without international cooperation (SP), international cooperation (CP) and first author (FP). The top 5 countries are still USA, China and European countries (Italy, Britain and Spain). USA accounted for 33.99% of TP, 27.74% of SP, 38.63% of CP and 22.62% of FP, followed by China (20.14% of TP, 11.57% of SP, 26.77% of CP and 12.96% of FP). Canada and Germany rank No. 6 and No. 7 in SP, higher than Brazil. Canada and France have same ranks in CP. In general, the cooperation patterns show that: a) The developed countries are led by USA and the developing countries are led by China, and both of them made much EQR. The cooperation between USA and China dominated the global patterns. b) Next to USA and China, the European countries (Italy, Britain Spain, etc) made much EQR, and there was also close cooperation between the countries. c) Brazil from South America and Canada from North America also made lots of efforts on EQR, and cooperated with many countries.

Figure 9. The cooperation of the top countries

Figure 10. Zipf’s distribution for citations

Some other factors on the global actions of EQR: citation, journal and funds

Regarding the global actions on EQR during past years, some other factors also play important roles. Here, we mainly conduct our analyses on the dynamics of citations, journals and funding agencies.

(1) Citation dynamics

In order to reveal how citation tendency and dynamics affect the global actions on EQR during past decades, we analyze the citation distribution of all 4778 articles, which is expressed by the relationship between citation times \( f \) of a publication and its rank \( r \) (the larger \( f \), the higher the rank \( r \)). We correlate the expression by a well-known generalized Zipf’s law as Eq. (2) and the results are shown in Figure 10. \( R^2=0.996 \) shows a generalized Zipf’s law or a power law distribution is well met for the citation pattern. That is, a small number of publications obtain most citations, just as the metaphor of “2/8 or 20/80 principles”. For the global actions on EQR, a
generalized Zipf’s law means the some publications can first get attention and be cited, and then they will get much more attention or be more highly cited by preferential positive feedback. Gradually a power law distribution with different citation grades will form. The preferential citation tendency and dynamics hidden in a generalized Zipf’s distribution for citation intuitively reflects the self-organized information transmission in the global actions on EQR during the past decades.

(2) The dynamics of generalized Bradford’s journal distribution

As the main exhibiting place of EQR’s publications, journals’ status, quality and distribution pattern must partly affect the global actions on EQR during past decades. In order to reveal the effect of journals on the global EQR’s actions during past decades, we analyze the journals distribution. Bradford’s law holds that the journals for scientific papers in a field have a concentration and dispersion distribution (Meadows 2002). When the journals are ranked by the number of publications in a descending order, the separation of a core area and the subsequent several areas will appear. Here we consider a generalized Bradford’s journal distribution. Taking the logarithm of the ranks of journals as horizontal axis, and the corresponding cumulative number of publications as the longitudinal axis, we have a generalized Bradford’s journal distribution for the curved portion of the figure as

\[ R(n) = an^\beta \quad (1 \leq n \leq c), \quad (3) \]

and linear portion of the figure as

\[ R(n) = k \ln\left(n \frac{N}{s}\right) (C \leq n < N). \quad (4) \]

We correlate our data using Eqs. (3-4), and the results are yielded as in Figure 11. \( R^2 = 0.992 \) and 0.998 imply that our sample well meet generalized Bradford’s journal distribution. Figure 11 shows that the journals of EQR have already included wide range of scopes. However, as an emerging interdisciplinary discipline, the participations of wider scopes of journals in dealing with EQR are still expected. In addition, since Bradford’s law expresses a centralization and decentralization journal distribution that implies a cumulative advantageous process of journal’s attraction to the submissions, we may hold the cumulative advantageous tendency hidden in a generalized Bradford’s distribution for journals reflects the self-organized information transmission in the global actions on EQR during past decades.

![Figure 11. The Bradford’s distribution](image1)

![Figure 12. The Lotka’s distribution for funds](image2)
The dynamics of funds
To some extends, fund is financial base of the global publications on EQR during past years, being an important factor for analyzing the global actions on EQR. We give the distribution dynamics of funding agencies to analyze its effect on the global EQR’s actions during past decades. We correlate the relation between the number of funding agencies \( f \) (percentage) and the number of publications \( x \) by Lotka’s expression

\[
f(x) = \frac{C}{x^{\alpha}}.
\]

In Eq. (5), \( C \) and \( \alpha \) are coefficients with different values depending on the statistical data of samples. Here, we use double-logarithmic coordinates for \( f \) and \( x \), and the results are shown in Figure 12. The slope \( (\alpha=-1.9) \) of the line for our sample basically satisfies the Lotka’s equation, which means the number of funding agency is inversely proportional to the number of publications. It is clear that Eq. (5) is another power law, which demonstrates the dynamic self-organization during the EQR from the perspective of the distribution of funding agencies. Though it is a fact that a small number of funding agencies contribute lots of efforts on EQR, the slope of the line with \( \alpha=-1.9 \) in Figure 12 means the distribution of funds is too concentrative and lots of low frequencies funding agencies have not sufficiently played their roles in the actions of EQR. Funding dynamics reflects the global actions on EQR.

Some coping strategies
The above findings can offer us some important coping strategies. Based on the connotation of EQR, since EQR lies in a small world \( (c=0.17 \text{ and } L=3.042) \), to realize a better understanding on environment quality, we should not only integrate both natural factors (water, air, soil, etc) and social factors (economy, culture, psychology, etc), but also deal with the close relationship between different aspects of EQR and strong correlation or co-occurrence between different factors. In term of the characteristics found for the global cooperative network on EQR, we should reduce the number of countries with low degrees, and make more countries be able to sufficiently plunge into the cooperative actions on EQR. Steps should be taken to improve their enthusiasms, financial supports and research capacity or efficiency. This will effectively decrease the slope of power-law distribution of degrees (currently \(|\alpha|=|-3.958|=3.958 \text{ is too large}).

As for some other factors on the global actions of EQR, we would like to stress the adjustments on the generalized Bradford’s distribution for journals and Lotka’s distribution for funding agencies. That is, EQR, as an emerging interdisciplinary discipline, should encourage wider participations of journals. The Lotka’s distribution for funding agencies with \( \alpha=-1.9 \) is too concentrative. We should encourage more low frequencies funding agencies to sufficiently play their roles in the actions of EQR, effectively decreasing the slope of Lotka’s distribution or funding agencies (currently \(|\alpha|=|-1.9|=1.9 \text{ is absolutely too large}).

Abstract
It is increasing important to identify automatically thematic structures from massive scientific literature. The interdisciplinarity enables thematic structures without natural boundaries. In this work, the identification of thematic structures is regarded as an overlapping community detection problem from the citation-link network. Thus, the overlapping thematic structures can be detected from citation-link network with a mixed-membership stochastic blockmodel, armed with stochastic infer algorithm. Experimental results on the astro dataset indicate that it is feasible to extract overlapping thematic structures.

Conference Topic
Social Network Analysis, Mapping and Visualization

Introduction
It is increasing important to identify automatically thematic structures (topics or fields) from massive scientific literature, which is a pertinent problem of science studies in general and bibliomerics/scientometrics in particular. Last two decades witnessed significant progress in the field of the detection of thematic structures ever since van Raan (1996). Several major technologies have been developed, such as citation-link approaches (Klavans and Boyack 2011; Waltman and van Eck 2012; van Eck and Waltman 2017), lexical approaches (Leydesdorff and Welbers 2011; Yau et al. 2014), and hybrid approaches that combine citation-link and lexical techniques (Glänzel and Thijs 2011; Glänzel and Thijs 2017).

As we all know, due to intrinsic difference between these methods, they usually detect somewhat different topical structures for the same dataset. To the best of our knowledge, there is no benchmark dataset public available with known structures until now. Therefore, it is still not clear that whether the thematic structures found by these methods are indeed representative of knowledge structures in science, merely artefacts resulting from the used methods, or something in between. Though it is very difficult to answer this question, topic extraction challenge pioneered by Gläser, Glänzel and Scharnhorst (2017) as a first step in this direction tries to provide some general understanding of properties of different approaches and thematic structures they deliver.

Meanwhile, interdisciplinarity enables thematic structures without natural boundaries, which has been shown in bibliometric research (Zitt, Ramanana-Rahary & Bassecoulard 2005). So, increasing attention has been paid to detect overlapping structures from direct citation, bibliographic coupling, or co-citation networks with community detection methods in recent years (Havemann et al. 2012; Havemann, Glänzel & Heinz 2017). For more elaborate and detailed surveys on overlapping community detection we refer the readers to Xie, Kelley & Szymanski (2013).

This paper also regards the identification of thematic structures as an overlapping community detection problem from citation-link network. A mixed-membership stochastic blockmodel, armed with stochastic inference algorithm, is utilized to detect the overlapping thematic
structures. From the experimental results and comparisons with each other, it makes clear that it is feasible to discover the overlapping thematic structures.

**Mixed-Membership Stochastic Blockmodel**
Mixed-membership stochastic blockmodel (Airoldi et al. 2008; Gopalan & Blei 2013) is a variant of the stochastic blockmodel, in which each node can belong to multiple communities. Given an observed direct citation network \( \{y_{ij}\} \) (including links and non-links), hidden community/thematic structure can be discovered by estimating its conditional distribution. This model can be described by its probabilistic generative process of a network with \( K \) communities as follows. One can associate each node \( p_i \) with a multinomial distribution vector of community membership \( \theta_i \).

In order to generate an overlapping community network, this model takes into account each pair of nodes. For each pair \((i, j)\), two community indicators \( z_{i \rightarrow j} \) and \( z_{i \leftarrow j} \) are drawn from the vector \( \theta_i \) and \( \theta_j \), respectively. If these two indicators point to the same community, that is, \( z_{i \rightarrow j} = z_{i \leftarrow j} \), then it links nodes \( p_i \) and \( p_j \) with high probability \( \beta_{z_{i \rightarrow j}} \); otherwise, they are likely to be unconnected.

The above generative process defines a joint probability distribution over the node-wise community memberships \( \{\theta_i\} \), the pair-wise community indicators \( \{z_{i \rightarrow j}\} \), and the observed network \( \{y_{ij}\} \). Given an observed network \( \{y_{ij}\} \), conditional distribution (posterior) of the latent community structure \( p(\{\theta_i\}, \{z_{i \rightarrow j}\} | \{y_{ij}\}) \) gives a decomposition of the nodes into \( K \) overlapping communities. As for many interesting Bayesian models (Blei, Ng & Jordan 2003; Xu et al. 2014), however, posterior inference cannot be done exactly in this model. A variety of algorithms have been used to approximate the posterior of Bayesian models, such as variational inference (Jordan et al. 1999), Markov chain Monte Carlo (Andrieu et al. 2003), and stochastic variational inference (Hoffman et al. 2013). In this work, stochastic variational inference is used, since it can easily scale to real-world-sized citation-link networks.

**Experimental Results & Discussions**

**Dataset**
The astro dataset (Gläser, Glänzel and Scharnhorst 2017) is used in this work, which was extracted from the Web of Science (WoS) bibliographic database. It includes all publications of the document type article, letter, and proceedings paper published between 2003 and 2011 in 59 journals assigned by the Journal Citation Report to the subject Astronomy and Astrophysics. The number of publications in the dataset is 111,616. Of the 4,311,953 cited references provided in the publications of the dataset, 929,364 ones point to publications in the dataset.

Due to computational problems (Waltman & van Eck 2012; van Eck and Waltman 2017), direct citation relations ignoring directions are used here. That is to say, an undirected network is considered in this study. In the meanwhile, self-citation relations are removed (e.g., a publication citing itself). There are 659 connected components totally in the network. This work only keeps the giant component, which includes 924,750 citation relations involving \( n = 101,831 \) publications.

Before extracting the overlapping thematic structures, we want to get a first idea of the sparsity degree of the network. Let \( a_i \) denote the number of connections of node \( p_i \), and \( T = \sum_{i=1}^{n} a_i \). One can sort the \( \{a_i\} \) in the ascending order, and then let \( b_i \) represent the \( i \)-th ordered element. Gini index (GI) (Goswami, Murthy & Das 2016; Hurley & Rickard 2006) is formally calculated as follows.
\[
\text{GI} = \frac{\Delta(A)}{\Delta(A + B)} = 1 - 2\Delta(B) = 1 - 2 \left[ \sum_{i=1}^{n} \frac{b_i(n - i + 0.5)}{n} \right]
\]

Here, \(\Delta(\cdot)\) represents the area of the resulting polygon (ref. Figure 1). It is easy to see that this index is normalized and lies between 0 and 1. It measures the extent of inequality in distribution of degrees among all nodes. When GI closes to 1, it means that there are several dominant nodes in the network. For our case, GI = 0.48858 indicates that the distribution of degrees is not so skewed.

Figure 1. Gini Index of direct citations network in the *astro* dataset.

**Experimental setup**

The software *svinet*, which can be available at https://github.com/premgopalan/svinet, implements stochastic inference algorithm for the mixed-membership stochastic blockmodel. Hence, it is utilized to extract overlapping community/thematic structures from the direct citations network. The number of overlapping communities is set to \(K = 20, 30, 40\) and \(50\). The link sampling is chosen as the sampling strategy, and the prior \(\epsilon\) on network strengths is learned from the direct citations network (i.e., the option \(\text{eta-type}\) is set to \(\text{fromdata}\)).

**Overlapping thematic structures**

Table 1. Statistics for the different clustering solutions

Figure 2. The distribution for the number of memberships of nodes in the *astro* dataset.
Four clustering solutions are obtained with the different values for $K$. Table 1 reports the statistics for the different clustering solutions, such as the number of clusters, the number of publications in the smallest and largest cluster, and the average number of publication per cluster. From Table 1, it is not difficult to see that, regardless of the value of $K$, the distribution of publications over clusters is quite even. The distribution of the number of memberships of nodes illustrated in Figure 2 make clear that about 40% publications only belong to one theme, and about 30% and 17% publications belong to two and three themes, respectively. This indicates that it is very common for publications to cover multiple themes. In order to get an impression of the discovered thematic structures, let’s take the solution of $K = 50$ as an example. Figure 3 visualizes the top themes with Gephi (Bastian, Heymann & Jacomy 2009) that links to the high cited publication (its degree is 1439): First-year Wilkinson Microwave Anisotropy Probe (WMAP) observations: Preliminary maps and basic results. This publication bridges several themes. Each node is sized by their bridgeness (Nepusz et al. 2008), an inferred measure of their impact on multiple themes. Several publications with large bridgeness is also labelled in the Figure 3.

![Figure 3. The overlapping thematic structures in a subgraph of the astro dataset.](image)

**Solution comparisons**

Due to the fluidity of cognitive structures in science, and the multiplicity of reference frames (Gläser, Glänzel and Scharnhorst 2017), it is not easy to compare two solutions in the presence of multiple, inaccessible ground truths. But if one solution is treated as “ground truth”, then the other is seen as the solution to evaluate, and vice versa. Thus, some external measures for clustering comparison, such as pair-counting based measures, set-matching based measures, and information theoretic based measures, can be used here. Of course, the symmetric measure (switching two solutions will return the same score) should preferred. For more elaborate and detailed surveys, we refer the readers to Xu et al. (2013). Here, adjusted mutual information (AMI) (Vinh, Epps & Bailey 2010) is adopted, since it accounts for the
fact that the mutual information (MI) is generally higher for two clusterings with a larger number of clusters, regardless of whether there is actually more information shared. Table 2 shows the AMI values between our solutions, in which each publication is assigned to the theme with the highest probability. It seems that the four solutions have obvious difference, though the same clustering algorithm is used. It is very possible for AMI to evaluate the performance of overlapping thematic structures. Hence, modification of the partition coefficient (MPC) (Dave 1996) is also calculated in the last row of Table 2. The values of MPC indicate that the four solutions give similar performance.

Table 2. Adjusted mutual information and modification of the partition coefficient.

Conclusions

Based on the astro dataset, we can conclude that the stochastic inference algorithm for the mixed-membership stochastic blockmodel can indeed scale to real-world-sized network, such as citation-link network. This approach can detect the overlapping thematic structures from massive scientific literature, and is able to identify the publications bridging several themes. What’s more, regardless of the number of themes, the distribution of publications over clusters seems to be quite even. Though the overlapping thematic structures can be discovered, the results are still not readable. We will try to label the themes with relevant phases in the next step. Additionally, in this work, only direct citation relations are utilized. We will investigate the usability of bibliographic coupling and co-citation relations in the near future.

Abstract
Bootstrap methods are increasingly accepted as one of the common approaches in constructing confidence intervals in bibliometric studies. Typical bootstrap methods assume that the statistical population is infinite. When the statistical population is finite, a correction needs to be applied in computing the estimated variance of the estimators and thus constructing confidence intervals. We investigate the effect of overlooking the finiteness assumption of the statistical population using a dataset containing all articles in Web of Science (WoS) for Delft University of Technology from 2006 until 2009. We regard the data as our finite statistical population and consider simple random samples of various sizes. Standard bootstrap methods are firstly employed in accounting for the variability of the estimates, as well as constructing the confidence intervals. The results unveil two issues, namely that the variability in the estimates does not decrease to zero as the sample size approaches the population size and that the confidence intervals are not valid. Both issues are addressed when accounting for a finite population correction in the bootstrap methods.

Methods and techniques.

Introduction
The bootstrap (Efron, 1979) has become one of the most well-known statistical methods, despite the futility implied by the ‘bootstrap’ action, that is, of lifting oneself by using the bootstraps only. Nonetheless, the expressive terminology has been chosen to suggest a process done without external help. Starting from the data at hand, which is regarded as a sample from a statistical population, one is able, by resampling the data, to provide confidence intervals and means of measuring the accuracy of the sample estimates. Since the bootstrap was firstly proposed and studied, constant effort was put into improving the techniques, relaxing the assumptions and accounting for the particularities of the data at hand. This, together with the enhanced computational capabilities lead to the current popularity of the bootstrap.

Bootstrap methods are increasingly accepted as one of the common approaches to construct confidence intervals in various science fields, including citation analysis and bibliometric studies. Chen, Jen & Wu (2014), Rahman et al. (2016), Fairclough & Thelwall (2015), Williams & Bornmann (2016), Bornmann & Daniel (2007), Waltman & Costas (2013), Costas, Zahedi & Wouters (2014) are just a few recent publications that have included bootstrap methods in their analysis. Bootstrap methods are also used in accounting for the variability in the research output in the Leiden Ranking (Waltman et al., 2012).

The standard bootstrap methods, as well as various other standard statistical tools rely on the implicit assumption that the data at hand is a sample from an infinite population. “The idea of infinite hypothetical population is, I believe, implicit in all statements involving mathematical probability” (Fisher, 1925), and therefore in statistics. This is however rarely mentioned in practice by statisticians. This of course has to do with the purpose of the statistical analysis.
and the nature of the target population, as emphasized in Nane (2016) as a comment to Williams & Bornmann (2016).

Though implicit, numerous statistical populations in citation analysis are assumed to be infinite, albeit data on publications or researchers. The target population can also be regarded as a underlying stochastic process, whose realizations are observable and constitute a statistical population, see, for example Claveau (2016). The concept of super-population emerges therefore naturally.

Finite target populations arise in numerous applications, for example in survey analysis, biology, management, etc. When the target population is finite, the statistical methods need to be adapted. Hajek (1960, 1981) has initiated the work on the finite population statistics and provided important asymptotic results, as well as advanced the idea of sampling within finite populations. This study follows the discussion on the paper of Williams & Bornmann (2016). In the comment, Nane (2016) drew attention on the particularity of the data at hand, that is the finite population and the necessary correction implied by this assumption.

The purpose of this study is twofold. First of all, several techniques of performing bootstrap are considered. Results are investigated and conclusions are drawn based on the variability of the estimates and confidence intervals with respect to length and accuracy. Secondly, we will investigate the effect of not taking into account the finiteness of the population and we will, in turn, account for the finiteness of the population at hand.

The study relies on the Delft University of Technology (TU Delft) data, that is all the articles from Web of Science (WoS) for which at least one author is affiliated to TU Delft, as collected for Leiden Ranking 2011/2012. We will perform a simulation study where the data at hand will act as the statistical, finite, population and various samples, using a simple random sampling without replacement will be drawn from this population. The 6224 articles in our data have been published between 2006 and 2009 and their citations have been counted until the end of 2010. The citation performance of the articles are evaluated using two well-known indicators, MNCS and PP(top 10%). MNCS is the average of the field-normalized citation score of each publication. PP(top 10%) accounts for the proportion of publications that are in the top 10% most cited in their field. More details about the indicators can be found in Waltman et al. (2012). The population MNCS is 1.275, that is the average of the field-normalized citation scores of the TU Delft publications is 1.275, which is higher than the world average and the PP(top 10%) is 13.7%, which asserts that 13.7% of TU Delft’s publications are in the top 10% most cited publications in their field. These values will be regarded as the true parameter values and compared with estimates and confidence intervals resulting from various bootstrap methods.

The paper is organized in three subsequent sections. The following section describes the methods used for our analysis. It includes and compares standard bootstrap methods, as well as the bootstrap methods which account for the finite population. The main results of the analysis are presented in the subsequent section. Finally, the conclusions are drawn and the discussion is carried.

**Methods**

We investigate the effects of the finite population setting on the estimation of two well-known citation indicators, MNCS and PP(top 10%), as well as on the construction of confidence intervals. Standard bootstrap methods will be reviewed and compared in the following subsection. The adjustments entailed by the finite population setting will be considered and integrated in bootstrap methods.
**Bootstrap methods**

Bootstrap has become a standard statistical method for providing a measure of variation for sample estimates and computing confidence intervals. Since it was first advanced by Efron (1979), numerous bootstrap methods have been proposed.

Given an independent and identically distributed sample \( s = \{x_1, x_2, \ldots, x_n\} \) from an unknown distribution \( F \), we are interested in estimating the parameter \( \theta \) of the distribution \( F \), typically the mean. The estimate of \( \theta \) is denoted by \( \hat{\theta} \), the sample mean estimate of the mean of the distribution. \( B \) samples, denoted \( s_1^*, s_2^*, \ldots, s_B^* \), are drawn, with replacement from the initial sample \( s \). These samples represent the bootstrap samples and the size of each bootstrap sample is equal to \( n \). A bootstrap parameter \( \theta_i^* \) is computed for every bootstrap sample \( s_i^* \), for \( i = 1, \ldots, n \).

The variance of the estimator \( \hat{\theta} \) is estimated by the bootstrap variance estimator. In turn, the bootstrap variance estimator has been shown to converge asymptotically to the sample variance of the bootstrap estimator.

This bootstrap methods is also referred to as the nonparametric bootstrap, since no parametric distribution is assumed for \( F \). Assuming a certain parametric family for \( F \) and drawing the bootstrap samples from a parametric distribution where the parameters have been estimated from the sample \( s \) are often referred to as the parametric bootstrap. We will not include the parametric bootstrap in our analysis.

The standard approach for computing confidence intervals is based on the central limit theorem, and uses the sample variance bootstrap estimator and quantiles of the standard normal distribution. These confidence intervals will be called asymptotic confidence intervals. Confidence intervals can also be constructed based on the percentiles of the bootstrap distribution, suggestively named percentile confidence intervals. The percentiles confidence intervals can be quite inaccurate in the case of skewed distributions. A bias corrected version (BCa) of the bootstrap has been proposed to compute confidence intervals (Efron, 1984). DiCiccio & Efron (1996), for example, provide a detailed theoretical analysis of the accuracy of these bootstrap confidence intervals.

Though implicit, standard bootstrap methods assume that the statistical population from which the data at hand was sampled is infinite. In the following section, we will see that, in practice, bootstrap methods fail to provide adequate results when this assumption is violated.

**Finite population correction**

The finite population correction assumes that the population size is known. Let \( N \) be the population size and let \( n \) be the sample size. Then the sampling fraction is defined as \( f = n/N \) and the finite population correction is given by \( 1 - f \), see, for example, Davidson and Hinkley (1997). If the variance of the bootstrap estimator is denoted by \( V^* \), then the finite population correction of the variance estimator is \( (1 - f)V^* \), from where it becomes obvious that it converges to zero, as \( n \to N \). A straightforward bias-adjusted variance estimator is given by

\[
V^{**} = \frac{N - n}{N - 1} V^*.
\]

When estimating means, the standard error of the mean for finite populations is given
\[ \frac{\sigma}{\sqrt{n}} \sqrt{\frac{N-n}{N-1}} \]

The second term of the product is often referred to as the finite population correction factor (fpc) and is also used in deriving the standard error of the proportion for finite populations. Finally, it needs to be emphasized that the finite population correction depends on the sampling design. As mentioned beforehand, the employed sampling scheme here is simple random sampling without replacement. If a different sampling design is chosen or has been already employed when collecting the data, then the finite population correction needs to be adjusted accordingly.

The question is of course when does the finite population make a significant difference. Davidson and Hinkley (1997) advise to use the finite population correction when \( f \geq 0.1 \). That is to say, if \( f < 0.1 \), then \( n \) is relatively small compared to \( N \) and the correction factor can be ignored.

**Bootstrap methods for finite populations**

Several methods have been proposed in the literature for the bootstrap while taking into account the finiteness of the population. Mashreghi, Haziza & Léger (2016) have recently provided a survey of bootstrap methods for finite populations in the context of survey data and for various sampling techniques. We will investigate two bootstrap methods, namely the pseudo-population bootstrap and the direct bootstrap for simple random sampling without replacement.

The pseudo-population bootstrap method creates, by resampling, a pseudo-population with the same size as the actual finite population. Bootstrap samples, equally sized as the original sample are subsequently drawn from the resulting pseudo-population. By employing the same sampling design in drawing the bootstrap samples from the pseudo-population as for drawing the initial sample, the method ensures that the bootstrap variance estimator encompasses the finite population correction factors. The pseudo-population method has been first proposed by Gross (1980) and several adaptations have been developed ever since. We will employ in our analysis the method proposed by Booth, Butler & Hall (1994).

For comparison reasons, we have also employed the direct bootstrap method for finite populations. Direct bootstrap methods are grouped in a category that does not employ the creation of the pseudo-population but mimic the idea and adjust the original proposal of Efron (1979), where bootstrap samples are directly drawn from the data at hand. The adjustments are made “so that the bootstrap variability reflects the sampling variability of the original sample design” (Mashreghi, Haziza & Léger, 2016) while accounting for the finite population setting. In the direct method proposed by Sitter (1992), resamples of smaller size are taken from the initial sample without replacement for a number of times that depends on the size of the original sample and the resample and the finite population correction factor. The bootstrap sample is constructed by concatenating all these resamples. The motivation and technical details, along with two other direct methods are extensively studied in Mashreghi, Haziza & Léger (2016). A comparison between the direct bootstrap methods and the standard bootstrap proposed by Efron (1979) shows how Efron’s bootstrap method, in the absence of a finite population correction factor, leads to an overestimate of the variance.

Confidence intervals can be constructed using the same techniques as when using the standard bootstrap methods. Parametric confidence intervals will be constructed, as well as bootstrap-t confidence intervals. The bootstrap-t confidence intervals use quantiles of the bootstrap
distribution \((\hat{\theta} - \theta)/\sqrt{\hat{V}}\), where \(\hat{V}\) is an estimate of the variance of the estimator \(\hat{\theta}\) instead of quantiles of the standard normal distribution. Moreover, we will employ standard percentile confidence intervals that make use of the bootstrap distribution of \(\hat{\theta}^*\). As noted by Mashreghi, Haziza and Léger (2016), it is worth mentioning that, in practice, the percentile confidence intervals over-cover the true parameter \(\theta\). This is generated by the overall high dispersion of the bootstrap estimators \(\hat{\theta}^*\) compared to the dispersion of \(\hat{\theta}^* - \theta^*\) that is used in computing the bootstrap-t confidence intervals.

**Finite population in statistical software packages**

The assumption of finite population is usually contained within the survey analysis of the statistical software programs. The finite population correction is included in various statistical software programs as Stata, SAS and R. In Stata, it is included as an option in the survey design functions. SAS also has the finite population correction factor contained within the survey function PROC SURVEYMEANS. R has various packages that account for finite population correction, including survey and PracTools. In Stata, the variance estimation and confidence intervals for finite population are obtained using bootstrap procedure proposed by McCarthy & Snowden (1985) and Rao & Wu (1988) in the class of direct bootstrap methods. The differences between the two methods and the method of Sitter (1992) employed in our analysis are quite technical and can be found in the survey of Mashreghi, Haziza & Léger (2016). To the best of our knowledge there are no bootstrap methods for finite populations implemented in SAS. In R, the survey package also the direct bootstrap method of Rao & Wu (1988). To the best of our knowledge, the pseudo-population bootstrap and the direct bootstrap method that we used in our analysis have not been implemented yet in a package in R or elsewhere.

**Results**

This section includes the analysis of the standard bootstrap method for various sample sizes, as well as two bootstrap methods that allow for the finite population assumption.

**Standard bootstrap methods**

To study the sample estimates and to compare the different 95% confidence intervals, a sample of size \(n = 100\) has been drawn from our statistical population. The table below shows the results for the two indicators, MNCS and PP(top 10%).

<table>
<thead>
<tr>
<th>Estimate</th>
<th>Variance of Estimator</th>
<th>Asymptotic CI</th>
<th>Percentile CI</th>
<th>BCa CI</th>
</tr>
</thead>
<tbody>
<tr>
<td>MNCS</td>
<td>1.22</td>
<td>0.21</td>
<td>(0.88;1.71)</td>
<td>(0.91;1.74)</td>
</tr>
<tr>
<td>PP(top 10%)</td>
<td>12.58%</td>
<td>0.03</td>
<td>(6.44%;18.89%)</td>
<td>(6.69%;19.12%)</td>
</tr>
</tbody>
</table>

The sample MNCS is 1.22 and the estimate for PP(top 10%) is 12.58%, which are relatively different from the true values of MNCS is 1.275 and PP(top 10%) is 13.65%. The variance of the two estimators is estimated using the bootstrap method. As expected, the variance for the MNCS is significantly higher than the variance for the PP(top 10%).
difference reflects the robustness of the PP(top 10%) as compared to the MNCS. The three confidence intervals are rather wide, showing the high uncertainty around the estimates. Finally, it is notable that all confidence intervals contain the true values. Obviously these results depend on the particular initial sample, so an analysis of the bootstrap has been performed by repeating the bootstrap procedure for a large number of times. Specifically, for 1000 times, a sample of size 100 has been drawn. The MNCS and PP(top 10%) estimate has been computed, along with the variance of the estimators and the bootstrap confidence intervals for the 1000 samples. The results are depicted in Table 2.

Table 2. Average length and coverage of the true value for asymptotic, percentile and BCa confidence intervals (CI) for MNCS and PP(top 10%) based on a sample n=100 and B=1000 bootstrap samples.

</tbody>
</table>

The average of the estimated variance of the estimator has been obtained by averaging the estimated variances of the two estimators over the bootstrap samples. We note small differences from the estimated variance of the estimator using one sample in Table 1. The average length provides the average over the length of the confidence intervals obtained from applying the three bootstrap methods. Furthermore, we computed the coverage probability of the confidence intervals. That is, we checked whether the true MNCS and PP(top 10%) values were contained in each resulting confidence interval. We concluded that, for example, the true MNCS values was contained in 907 out of 1000 percentile confidence intervals. Similarly, 958 times was PP(top 10%) true value contained in the BCa confidence intervals. Since we computed 95% confidence intervals, we expect a 95% coverage of the confidence intervals. The results in Table 2 show that the 95% confidence intervals are mostly under-covering the true values. This effect is highly likely to be due to the small sample size. We will hence investigate the coverage probability, as well as the average length and average of the estimated variance of the estimator for larger samples, namely for \( n = 1000 \).

Table 3. Average length and coverage of the true value for asymptotic, percentile and BCa confidence intervals (CI) for MNCS and PP(top 10%) based on a sample n=1000 and B=1000 bootstrap samples.

The results in Table 3 show a rapid decrease of the variance of estimators and average length of the confidence intervals as the sample size increases. The average of the estimated variance of the estimators has decreased to less than a half. The average length of the confidence intervals has also decreased considerably. Finally, we notice an increase in the confidence intervals coverage. The high coverage values, which might be interpreted as a very good performance, show that the confidence intervals are conservative and over-cover the true parameter.

It also raises a question on the validity if the confidence interval. A confidence interval is said to be valid if the coverage of the interval converges to the true coverage (of 95% in our case) for a very large number of repetitions of the procedure. When repeating the procedure for a number of times, the coverage probabilities have slightly changed.

Furthermore, when repeating the bootstrap methods for increasing sample sizes, the variance of the estimators and the length of the confidence intervals decreases. Since the asymptotic confidence intervals are derived using the variance of the estimator, we will investigate the influence of the sample size on the length of the asymptotic confidence intervals. Figure 1 below depicts the length of the confidence intervals for sample sizes until 4000 observations and for a sample size equal the statistical population of 6224 observations.

![Figure 1. Length of asymptotic confidence intervals for MNCS for different sample sizes using the standard bootstrap method (left) and length of 100 MNCS confidence intervals using a sample size equal to the population size (6224).](image)

The two plots show that, although decreasing, the variance of the MNCS estimator and hence the confidence intervals do not decrease to zero, even when the sample size equals the size of the statistical population, as depicted in the right plot. When the sample is, in fact, the statistical population, the estimate is as a matter of fact the true parameter and has zero variance. Nonetheless, this is not reflected by the right plot of Figure 1. The reason why the variance and hence the length of the confidence intervals is not decreasing to zero is because the sample is assumed to be drawn from an infinite population. A finite
population correction therefore needs to be applied. The bootstrap methods that account for finite populations are employed in the following subsection.

**Bootstrap methods for finite population**

We will use the pseudo-population and the direct method described in the previous section for constructing asymptotic, bootstrap-t and percentile confidence intervals for the MNCS and PP(top 10%) estimators. The results for a simple random sample of size 500 are included in Table 4.

We observe similar results in terms of the average length of the intervals for the two bootstrap methods. The coverage of the confidence intervals suggest, in general, a better coverage for the PP(top 10%) than for MNCS. When using the pseudo-population bootstrap, the MNCS seems to be under-covered by the confidence intervals, where the highest coverage probability is 94.9% for the percentile confidence intervals. Using the direct method produces confidence intervals that cover the true MNCS value close to the nominal coverage. For PP(top 10%), the coverage probabilities for the pseudo-population confidence intervals are closer to the nominal value. The closest coverage probabilities to the nominal value, for both MNCS and PP(top 10%), and for both bootstrap methods are obtained by the percentile confidence intervals.

Table 5 shows the analysis for a simple random sample of 1000 observations. The average length is decreasing when comparing with Table 4. Nonetheless, the coverage probability fluctuates around the nominal coverage probability of 95%, sustaining the validity of the confidence intervals produced. Once more, the percentile confidence intervals are the closest to the true coverage probability.

To investigate the change in the length of the confidence intervals with respect to the sample size, we performed simulations for sample sizes varying from 100 to the entire statistical population.

Figure 2. Length of asymptotic and percentile confidence intervals (CI), for n=100, 500, 1000, 2000, 4000 and 6224 using the direct bootstrap method (left), pseudo-population bootstrap (middle) and the percentile confidence intervals produced with boot.ci function in R (right).

Figure 2 above shows the length of the asymptotic and percentile confidence intervals using samples with size varying from 100 (leftmost) to 6224, the size of the statistical population. For each sample size, the direct method of Sitter (1992), the pseudo-population of Booth, Butler & Hall (1994) and the standard bootstrap method from Davidson & Hinkley (1997) implemented in the statistical R package boot are used to compute confidence intervals. As expected, the length of the confidence intervals decreases as the sample size increases. It is notable however that the standard bootstrap method used by the boot.ci function in R does not decrease to zero.

Conclusions and discussion

The purpose of this study is to draw attention and provide a detailed analysis for the finite populations when bootstrap techniques are employed. The confidence intervals constructed using standard bootstrap techniques have been shown to over-cover the true parameter as the sample size increases. The over-coverage appears for sample sizes of less than 16% of the statistical population. The over-coverage poses serious questions on the validity of the confidence intervals, which need to have a coverage around the
nominal value of 95%. The main reason for this phenomenon is that the variability in the estimator does not take into account the finiteness of the population. The analysis shows that the estimated variance of MNCS and PP(top 10%) estimates decreases as the sample size increases. Despite small, the estimates of the variance of MNCS and PP(top 10%) influence significantly the coverage of the confidence intervals.

Finite populations depend on the choice of target population and can definitely occur in citation analysis. An example at hand is the use of the bootstrap methods to compute the stability intervals in the Leiden Ranking (Waltman et al., 2012). All publications of universities in WoS are regarded as the (finite) target population from which samples of size 1000 are drawn, with replacement, in order to compute the stability intervals. It is notable that the widest stability intervals are encountered for universities with the smallest output, of around 1000 publications. On the other hand, for these universities, the samples are the largest with respect to the population size, which should translate into smaller variation of the indicators and hence smaller stability intervals. A finite population correction for the variability of the indicators, as well as bootstrap methods for finite population would account for the relationship between the sample size and the population size.

The results suggest that the finite population correction needs to be incorporated in any proper analysis. Nonetheless, the scarce and limited availability of bootstrap methods for finite populations make the process difficult. Despite the large application of these techniques, they are contained in packages and functions devoted to survey analysis. Though far from exhaustive, the bootstrap methods presented in this study are theoretically accurate, as presented by Mashreghi, Haziza & Léger (2016). We need to emphasize though that a large number of variations of the bootstrap are available, depending on the focus of the analysis and the data at hand.

First of all, the sampling procedure itself can lead, in the case of finite populations to different bootstrap methods. In our study, we used simple random sampling without replacement. Other methods are available, including mirror-match bootstrap and superpopulation bootstrap. The details of these methods can be found in Sitter (1992) and Davidson & Hinkley (1996). All in all to show that finite population sampling is not a trivial matter and the effect of the sampling design should be accounted for. In practice, researchers can opt for stratified sampling, unequal sampling, etc. The study of the effect of the sampling design on the variability of the bibliometric indicators would be of interest.

An important assumption of the methods presented is that the data at hand are independent and identically distributed. It has been frequently shown that the independence assumption is unrealistic and one can argue that, in this analysis, the citation counts of the publications at TU Delft are not independent. Bootstrap methods are available for dependent, though identically distributed data (Gonçalves & Politis, 2011) and it would be very interesting to investigate the existing dependencies and also the effect of those dependencies on the estimates and confidence intervals.

Last, but definitely not the least, we reinforce the concepts of statistical sample and statistical population. A very important question evidently aims for the target of the analysis and therefore target population. As emphasized in Nane (2016), the target population triggers the analysis and therefore the validates the use of finite population correction and bootstrap methods of computing the confidence intervals.

Abstract
In this article we continue our study of power structures, providing further examples of dominance structure in a directed acyclic network. We calculate the D-measure, a measure expressing the degree of dominance in a network, when nodes are added to an existing simple network. This was done for “moving from a hand to a line”, and for a citation network consisting of the ego (the original article) with n references and m received citations. When n=m the network is symmetric and the D-measure is 0.5; when the article did not yet receive a citation the D-measure is n/(n+1). When the article has no references then the D-measure is 1/(m+1).

Keywords: dominance structure; power; digraph; citation graph

Introduction
The universe is often viewed in a dual fashion: where there is high there is low; where there is left there is right; where there is yin there is yang; where there is dominance, there is subdominance. Yet, each of these two opposing principles are usually not present in equal amounts. We will explain that these notions can be expressed in mathematical terms using zero-sum arrays (Liu, Rousseau & Egghe, 2017). More specifically, these zero-sum arrays will be used to study dominance and subdominance.

It goes without saying that network theory is an essential part of informetrics; the best known networks in the field being direct citation networks, co-citation networks and other co-occurrence networks such as co-word or co-assignation networks. These networks reveal key aspects of the structure of science and as such studies of their characteristics belong to the core of informetrics. Among the many characteristics of networks we consider here dominance, defined in detail further on. Scientific disciplines benefit if networks making part of the discipline are studied from many angles, dominance and sub-dominance being one of the many aspects. As science is a formal as well as an informal structure also on this higher level, it includes dominance structures, which may change when top scientists change affiliations.

Power structures are indeed ubiquitous. Blogs and information systems are modern forms of social power (Wei, 2009; Liu et al., 2013; Lu et al., 2015; Nord et al., 2016), while universities and systems of education too can be described as power structures (Clark, 1987; Van de Graaff et al., 1978). Power structures among academics may influence scholarly impact in research (Truex et al., 2009). Empowerment of women, in academia, in industry, in politics and in daily life is another topic that has lately received quite some attention (Gutierrez et al., 2000; Pacardo-Mercado, 2013; Oreglia & Srinivasan, 2016). Yet, the majority of these studies are qualitative in nature. Hence, a quantitative framework for measuring power is necessary. This is provided in (Liu et al., 2017). In this earlier work we discussed local and global dominance as special network structures. Next we focused on dynamic aspects of dominance structures (Liu & Rousseau, 2017). In this investigation we continue our study of dynamic aspects of dominance structures adding nodes in a network one
at the time. Studying dynamic aspects of networks is essential for potential applications. We recall that in our previous studies and also here the focus goes to structures, not elements or single nodes.

**Zero-sum arrays**

A zero-sum array is defined as follows: If $X = (x_1, \ldots, x_N)$ is a real-valued array, i.e. an $N$-tuple, such that $\sum_{i=1}^{N} x_i = 0$, then $X$ is called a zero-sum array. The set of all zero-sum arrays is denoted as $\mathbf{Z}$; its subset of arrays of length $N$, namely $\mathbf{Z}_N$, is denoted as $\mathbf{Z}_N$. The array $Y_1 = (4,3,-7)$ is an example of a zero-sum array and so is $Y_2 = (4,3,0,-7)$. In accordance with the theory developed in (Liu et al., 2017) all arrays studied in this article must be ranked from highest to lowest value.

Constructing a pseudo-Lorenz curve for zero-sum arrays.

Given a zero-sum array $X$, we set

$$I_+(X) = \{i \in \{1,\ldots,N\} \text{ such that } x_i > 0\}$$
$$I_0(X) = \{i \in \{1,\ldots,N\} \text{ such that } x_i = 0\} \text{ and}$$
$$I_-(X) = \{i \in \{1,\ldots,N\} \text{ such that } x_i < 0\}.$$

As in (Liu et al., 2017) we assume that $X$ is not the trivial zero-array. This implies that $I_+(X)$ and $I_0(X)$ are always non-empty. This requirement also implies that $N > 1$. When it is clear about which array we are talking or when it does not matter we simply write $I_+, I_0$ or $I$. We note that $\sum_{i \in I} x_i = -\sum_{i \in I} x_i$. Next we put $\Sigma_+ = \sum_{i \in I_+} x_i$ and $\forall i = 1,\ldots,N : a_i = \frac{x_i}{\Sigma_+}$. With each zero-sum array $X$, we associate a corresponding $A$-array, denoted $AX$, and equal to $AX = (a_1, \ldots, a_N)$. We will further need the array $Q_X$, with $(Q_X)_i = q_i = \sum_{k=1}^{i} |a_k|$. Clearly $q_N = 2$.

Liu et al. (2017) developed a new curve, referred to as the D-curve (D for dominance), which does not decrease when the corresponding D-array has negative values, but, instead, rises further to the value two. Let us recall this construction of a D-curve.

A D-curve of a zero-sum array $X$ is defined as the polygonal line connecting the points:

$$(0,0) \rightarrow \left( \frac{1}{N}, a_i \right) \rightarrow \ldots \rightarrow \left( \frac{i}{N}, \sum_{j=1}^{i} a_j \right) \rightarrow \ldots \rightarrow \left( \frac{|I_+|}{N}, 1 \right) \rightarrow \left( \frac{N - |I_-|}{N}, 1 \right) \rightarrow \ldots \rightarrow \left( \frac{k}{N}, \sum_{j=1}^{k} |a_j| \right) \rightarrow \ldots \rightarrow (1,2)$$
where $i \in I_+, k \in I_-$. We see that a D-curve is partly concave and partly convex, see Fig.1., representing the D-curve of the array $(4,2,0,0,0,-1,-1,-4)$.

Moreover, this curve can be described as a function, denoted as $D_X(t)$: for $t \in [0,1]$, we have:

$$D_X(t) = \begin{cases} 
Na_i t, & t \in [0, \frac{1}{N}] \\
\sum_{k=1}^{i} a_k + Na_{i+1} \left( t - \frac{i}{N} \right), & t \in \left[ \frac{i}{N}, \frac{i+1}{N} \right], \quad i = 1, \ldots, N-|I|-1 \\
\sum_{k=1}^{i} |a_k| + Na_{i+1} \left( t - \frac{i}{N} \right), & t \in \left[ \frac{i}{N}, \frac{i+1}{N} \right], \quad i = N-|I|, \ldots, N-1 
\end{cases}$$

![Figure 1. An example of a D-curve](image)

Similar to Lorenz curves, also D-curves introduce a partial order, called the dominance relation.

**Definition:** the dominance relation $\preceq_D$ in $\mathbb{Z}$

Let $X$ and $Y$ be zero-sum arrays, not necessarily of the same length, then we say that $X$ is D-smaller than $Y$ (or $Y$ is D-larger than $X$), denoted as $X \preceq_D Y$ (or $Y \succeq_D X$) if, for each $t$, $D_X(t)$...
The array \( X \) is strictly \( D \)-smaller than the array \( Y \), denoted as \( X \prec_D Y \), if, for each \( t \) \( D_X(t) \leq D_Y(t) \) and there is at least one point \( t_0 \), hence infinitely many, where \( D_X(t_0) < D_Y(t_0) \). The relation \( \leq_D \) determines a partial order in the set of all equivalence classes (all arrays with the same \( D \)-curves) of zero-sum arrays. Formally we write:

\[
X \leq_D Y \quad \text{if and only if} \quad \forall t \in [0,1]: D_X(t) \leq D_Y(t)
\]

As the dominance relation \( \leq_D \) is only a partial order, some arrays cannot be compared: they are said to be intrinsically incomparable.

The area between the \( D \)-curve and the line \( y = x \) is denoted as \( AR_D(X) \). For any zero-sum array this measure takes values on the interval \( ]0,1[ \). We will refer to this measure as the \( D \)-measure. The \( D \)-measure is denoted \( AR_D \) and is calculated as:

\[
AR_D(X) = \frac{1}{N} \left( \sum_{i=1}^{N} q_i \right) - \frac{N+2}{2N}
\]

(1)

where the \( q \)-values are the components of the array \( Q_X \): \( (Q_X)_j = q_j = \sum_{k=1}^{j} |a_{jk}| \). For further information on \( D \)-curves we refer the reader to (Liu et al., 2017; Liu & Rousseau, 2017).

It was shown in (Liu et al., 2017) that this zero-sum theory can be applied in directed, acyclic networks. We briefly recall its main features.

The number \( \alpha_j^+ \) of edges in the digraph \( G \) having node \( j \) as their initial node is called the out-degree of node \( j \). Similarly, the number \( \alpha_j^- \) of edges in \( G \) having node \( j \) as their terminal node is called the in-degree of node \( j \). We put \( \alpha_j = \alpha_j^+ - \alpha_j^- \). This parameter characterizes the flow through node \( j \). Since every edge is outgoing from a node and terminating at another, the number of edges in \( G \), denoted as \( \varepsilon \), is related to the degrees of its nodes by the following equation:

\[
\varepsilon = \sum_j \alpha_j^+ = \sum_j \alpha_j^- \quad \text{or} \quad \sum_j \alpha_j = 0
\]

where the summation is over all nodes of graph \( G \). Hence the sequence \( (\alpha_j) \) forms a zero-sum array derived from the network and we can apply the \( D \)-theory explained above. In this contribution we will, however, not study local flows but focus on global flows and the corresponding global dominance theory, explained below.

In global dominance theory, GDT in short, arrays of the form \( \Sigma = (\sigma_1, \sigma_2, \ldots, \sigma_N) \), are used, defined as follows:

\[
\sigma_i^+ = \text{the sum of the lengths of the chains that start in node } i
\]

\[
\sigma_i^- = \text{the sum of the lengths of all chains that end in node } i
\]

\[
\sigma_i = \sigma_i^+ - \sigma_i^-
\]
From these definitions we see that also $\Sigma$ leads to a zero-sum array and hence also here we can apply the zero-sum theory developed in (Liu et al., 2017). This zero-sum array will be referred to as a global flow array and consists of global flow numbers.

**Modelling: the need for examples and case studies**

When a new measure is proposed one usually derives theoretical properties and explains the possible benefits of using such a measure. This has been done in (Liu et al., 2017). Studying dynamic aspects of networks and their corresponding dominance measures is essential for potential applications in fields such as business management, politics and social interactions. We provided examples in politics (Sales, 1991), universities and systems of education (Clark, 1987; Van de Graaff et al., 1978). We further mentioned the important case of changing power structures when two companies merge.

**The global D-measure: Two case studies**

We next determine and study the global D-measure for two interesting dynamic structures.

**Case I. From a hand to a line**

We consider a hand with $N-1$ fingers, i.e. with $N$ nodes in total. This hand evolves to a line as shown in Figure 2. We will calculate values of the D-measure for the cases a), b) and c).

![Figure 2. From a hand to a line, illustrated for $N = 6$.](image)

Case studies are considered with $N$ nodes in total; the one on top has global flow value $f_1$ and then further numbered downwards.

Case (a). This “hand” leads to a maximum D-graph. It is shown in (Liu et al., 2017) that the corresponding D-measure is equal to $(N-1)/N$.

Case (b). With at least 3 nodes.
Top: $f_1 = 2(N-2) + 1$

Middle (split): $f_2 = (N-2) - 1 = N-3$

Rest: $f_3$ till $f_N$ (N-2 nodes in total): -3 each

The positive part is: $3N-6$ (if $N>2$)

$|A|\text{-array: } \begin{pmatrix} \frac{2N-3}{3N-6} \frac{N-3}{3N-6} \frac{3}{3N-6} \end{pmatrix}_{(N-2) \text{ times}}$

$Q\text{-array } = \begin{pmatrix} \frac{2N-3}{3N-6}, \frac{1}{3N-6}, \frac{(3N-6) + 3i}{3N-6} \end{pmatrix}_{i = 1,\ldots,N-2}$

$AR_{D}(X) = \begin{pmatrix} 1 & 1 \\ \frac{3N-6}{N} & \frac{N+2}{2N} \\ \frac{N}{3N-6} & \frac{9N^2 - 23N + 12}{2N} & \frac{N+2}{2N} \\ \frac{9N^2 - 23N + 12}{2N} & \frac{(N+2)(3N-6)}{2N(3N-6)} \\ \frac{6N^2 - 23N + 24}{6N(N-2)} \end{pmatrix}$

Case (c). With at least 4 nodes.

Top: $f_1 = 3(N-3) + 2 + 1 = 3N - 6$

Second: $f_2 = 2(N-3) + 1 - 1 = 2N-6$

Node at split: $f_3 = -3 + (N-3) = N-6$

Rest: $f_4$ till $f_N$ (N-3 in total): -6 each

The positive part is: $6N-18$ (if $N>5$; other cases are not included here)

$|A|\text{-array: } \begin{pmatrix} \frac{3N-6}{6N-18} \frac{2N-6}{6N-18} \frac{N-6}{6N-18} \frac{6}{6N-18} \end{pmatrix}_{(N-3) \text{ times}}$
Q-array = \left( \frac{3N-6}{6N-18}, \frac{5N-12}{6N-18}, \frac{1}{6N-18}, (\frac{6N-18}{6N-18})^i \right), i = 1, ..., N-3

\text{AR}_D(X) =
\begin{align*}
\frac{1}{N} \frac{1}{6N-18} \left( \frac{3N-6}{6N-18} + (5N-12) + (6N-18)(N-2) + \frac{6(N-3)(N-2)}{2} \right) - \frac{N+2}{2N} \\
= \frac{1}{N} \frac{1}{6N-18} \left( 3N-6 + 5N-12 + 6N^2 - 18N - 12N + 36 + 3N^2 - 15N + 18 \right) - \frac{N+2}{2N} \\
= \frac{1}{N} \frac{1}{6(N-3)} \left( 9N^2 - 37N + 36 - (N+2)(3N-9) \right) = \frac{9N^2 - 37N + 36 - 3N^2 + 3N + 18}{6N(N-3)} \\
= \frac{3N^2 - 17N + 27}{3N(N-3)}
\end{align*}

\text{Case (d). With at least 5 nodes.}

\text{Top: } f_1 = 4(N-4) + (3 + 2 + 1) = 4N - 10

\text{Second: } f_2 = 3(N-4) + (2+1) - 1 = 3N-10

\text{Third: } f_3 = 2(N-4) + 1 - (1+2) = 2N - 10

\text{Node at split: } f_4 = -(3+2+1) + (N-4) = N-10

\text{Rest: } f_5 \text{ till } f_N \text{ (N-4 in total): } -(4+3+2+1) = -10 \text{ each}

\text{The positive part is } 10N-40 \text{ (if } N>9; \text{ other cases are not included here)}

[A]-array:
\begin{bmatrix}
4N-10 & 3N-10 & 2N-10 & N-10 & 10 \\
10N-40 & 10N-40 & 10N-40 & 10N-40 & (N-4) \times \\
\end{bmatrix}

Q-array = \left( \frac{4N-10}{10N-40}, \frac{7N-20}{10N-40}, \frac{9N-30}{10N-40}, (\frac{10N-40}{10N-40})^i \right), i = 1, ..., N-4
$$\text{AR}_D(X) = \begin{cases} 
\frac{1}{N^2} & \frac{1}{10N - 40} \left( 4N - 10 + 7N - 20 + 9N - 30 + 10N - 40 + \frac{10(N - 4)(N - 3)}{2} \right) \\
- \frac{N + 2}{2N} & 
\end{cases}$$

$$= \frac{1}{N^2} \frac{1}{10N - 40} \left( 4N - 10 + 7N - 20 + 9N - 30 + 10N^2 - 70N + 120 + 5N^2 - 35N + 60 \right)$$

$$= \frac{1}{N^2} \frac{1}{10N - 40} \left( 15N^2 - 85N + 120 - \frac{N + 2}{2N} \right)$$

$$= \frac{15N^2 - 85N + 120 - (N + 2)(5N - 20)}{10N(N - 4)} = \frac{15N^2 - 85N + 120 - 5N^2 + 10N + 40}{10N(N - 4)}$$

$$= \frac{10N^2 - 75N + 160}{10N(N - 4)} = \frac{2N^2 - 15N + 32}{2N(N - 4)}$$

**Case II. An example in citation analysis**

One can consider a citing article to be in a dominating position with respect to the article which receives a citation. This idea is now illustrated with an article that has four references and which receives step by step more and more citations, making the structure more and more top-heavy. The different steps are shown in Table 1.

**Table 1. A short citation history of an article with four references**

<table>
<thead>
<tr>
<th>Number of citing articles</th>
<th>N</th>
<th>Array</th>
<th>Value of global D-measure</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>5</td>
<td>(4,-1,-1,-1,-1)</td>
<td>0.8</td>
</tr>
<tr>
<td>1</td>
<td>6</td>
<td>(9,3,-3,-3,-3)</td>
<td>0.708</td>
</tr>
<tr>
<td>2</td>
<td>7</td>
<td>(9,9,2,-5,-5,-5,-5)</td>
<td>0.621</td>
</tr>
<tr>
<td>4</td>
<td>9</td>
<td>(9,9,9,9,9,0,-9,-9,-9,-9)</td>
<td>0.5</td>
</tr>
<tr>
<td>8</td>
<td>13</td>
<td>(9,9,9,9,9,9,9,9,9,9,9,9,9,9,-4,-17,-17,-17,-17)</td>
<td>0.357</td>
</tr>
</tbody>
</table>
It is possible to derive a general formula for the global D-measure in the case that the original article has \( n \) references and received \( m \) citations, hence \( N = n + m + 1 \). The corresponding array is:

\[
X = \begin{pmatrix}
1, 2, \ldots, 1, 2, \ldots, (1, 2), \ldots, (1, 2) \\
n \text{times} \\
m \times n \times n \times m \times m \times m
\end{pmatrix}
\]

If \( m \geq n \) then the \(|A|\)-array is:

\[
\begin{pmatrix}
1, 2, \ldots, 1, 2, \\
m \times n \times n \times m \times m \times m
\end{pmatrix}
\]

and the Q-array becomes:

\[
AR_d(X) = \frac{1}{N} \left( \sum_{i=1}^{N} q_i \right) - \frac{N + 2}{2N}
\]

One can easily check that, if \( m = n \), the value of \( AR_d(X) \) is equal to 0.5. If \( n = 0 \), corresponding with an article without references, then the result is \( 1/(m+1) \). This clearly is a decreasing power structure for increasing \( m \).

If now \( m \leq n \) then the positive part is equal to \( n(2m+1) \) and we have:

\[
AR_d(X) = \frac{1}{N} \left( \sum_{i=1}^{N} q_i \right) - \frac{N + 2}{2N}
\]

One can easily check that, if \( m = n \), the value of \( AR_d(X) \) is equal to 0.5. If \( n = 0 \), corresponding with an article without references, then the result is \( 1/(m+1) \). This clearly is a decreasing power structure for increasing \( m \).
\[
\frac{1}{m+n+1} \left( \frac{m(m+1)(1+2n)}{2n(1+2m)} + 1 + n + \frac{n+1}{2} \right) - \frac{m+n+3}{2(m+n+1)}
\]

\[
= \frac{1}{m+n+1} \left( \frac{m^2(2n+1) + m(6n^2 + 8n + 1) + 3n(n+1)}{2n(1+2m)} \right) - \frac{m+n+3}{2(m+n+1)}.
\]

Also here the expression becomes equal to 0.5 when \(m = n\). If \(m = 0\), corresponding with an article that has not been cited yet, then the result is \(n/(n+1)\), as we already know.

**Discussion and conclusion**

In this article we provided some further examples of dominance structure in a directed acyclic network. Then we calculated the D-measure when nodes are added to an existing simple network. This was done moving “from a hand to a line” and for a citation network consisting of the ego (the original article) with \(n\) references and \(m\) received citations. When \(n=m\) the network is symmetric and the D-measure is 0.5; when the article did not yet receive a citation the D-measure is \(n/(n+1)\). When the article has no references then the D-measure is \(1/(m+1)\). We consider our contribution as an aspect of the “hardening” of the social sciences.

Abstract
International research collaboration is an important form of Science and Technology (S&T) research and is attracting an increasing attention from researchers. While other studies have examined collaboration using publication and patent data, this paper examines funded research collaborative project data by selecting collaborators affiliated with units outside Mainland China. Among a total of 320,000 National Natural Science Fund of China (NSFC) projects conducted from 2006 to 2016, 17,624 projects involving international research collaboration were extracted and included in our empirical analysis. Using the bibliometric method, this paper quantitatively analyses three aspects of the collaboration currently happening in Mainland China: collaboration activity, relative research efforts, and subject field of collaboration. The results demonstrate that among all 78 countries and regions of collaboration, the top fifteen account for
94.73% of all projects on record. The USA is the most important collaboration partner, but the number of research collaborations between the US and Mainland China is around the average of the top fifteen partners. Collaborations with Australia and Netherlands show an increasing trend, while collaborations with Japan and Germany decreased from 2006 to 2016. Of eight fields included in this analysis, the highest number of collaboration projects deal with health sciences, information science or management science.

Introduction

As an essential form of S&T research, international research collaboration is vital to a country’s growth, particularly that of developing countries (Finardi and Buratti 2016). Since 1978, when China adopted a policy of reform and opening-up, the government has encouraged research cooperation with many different countries. According to the administrator of the National Natural Science Fund from the Central Government, the NSFC will continue to increase international research funding in its thirteenth Five-Year Plan for the development of the National Natural Science Fund. International research collaborations enable researchers to share scientific knowledge, create networks of scholarly communication and generate new ideas; they also lower research costs and increase productivity (Katz and Martin 1997; Beaver 2001). Therefore, the study of international research collaboration in China is becoming more and more significant. A better understanding of the existing collaborations will make it possible to make specific recommendations about the establishment of collaborative relationships with other countries in the future.

International research collaboration in China has attracted attention from many researchers. Existing studies mainly focus on specific research collaboration partners or collaboration in specific fields. Some studies examine Chinese research collaborations with specific countries, such as the USA (Wagner et al. 2015), the UK (Zhou et al. 2013) or Germany (Zhou and Bornmann 2015), or with groups of countries, such as BRICS (Finardi 2015; Finardi and Buratti 2016) or G7 countries (He 2009). These partner studies analyse overall collaboration on the macro level. These studies usually conclude that partner countries
have different distributions of collaboration output numbers and collaborate on different subject fields, and the growth trends in collaboration with different countries vary over the given time span. However, some studies on collaboration in some specific areas take a focused micro approach. Generally, the traditional basic disciplines such as mathematics (Zhou and Tian 2014), physics (Zhou and Lv 2015), food and agriculture (Zhou et al. 2013), and cutting-edge technologies like healthcare science and services (Chen et al. 2016) and nanotechnology (Wang et al. 2012; Tang and Shapira 2011) have received the most attention. Most studies examine specific growth, the strength of collaborations, amount of collaboration activity and citation performance. Most studies have concluded that a gap exists between China and other countries and regions in these specific areas.

Most previous studies have used a bibliographic method to study collaboration via publication data (Coccia and Wang 2016), patent data (Guan and He 2007) or a combination of both (Zheng et al. 2012). Publication data is usually extracted from several journal indexes: Thomson Reuters’ Science Citation Index (Expanded)/Social Science Citation Index (SCI/SSCI) (Zhou and Lv 2015; Barth et al. 2014; Leydesdorff et al. 2014), which is the most commonly cited dataset; Elsevier Scopus (Finardi and Buratti 2016); Journal Citation Reports (Yan and Guns 2014) and other minor journal indexes. Patent data is usually retrieved from the United States Patent and Trademark Office (USPTO) database.

Publication data and patent data are the most commonly used data because they are readily available. Many meaningful, extensive conclusions have been reached using these data sources. However, the selection of collaboration databases from different sources is just a method for analysing collaboration from different perspectives. Project collaboration is another kind of collaboration, but it has only been included with other types in collaboration studies. This type of data has many special features which make collaborative project data appropriate for analysing collaboration.

1) Firstly, it is a feasible and reasonable way to analyse collaboration. This is because collaboration project data is itself a kind of direct collaboration, and it contains information not only on the project applicant but the
participants.

2) Secondly, this data reflects collaborations in real time, with no time lag. This is because the collaboration is created the moment the collaborative project is approved. It commonly takes several months to one year or more for articles to be published and patents to be approved.

3) Finally, this type of data enables a more comprehensive analysis of collaboration. This is because collaborative projects result in diverse types of output, so the study is not limited to publications and/or patents.

This paper combines data about collaborative projects in Mainland China with that of other countries and regions to analyse the current status of international research collaboration in Mainland China. This empirical analyses uses the NSFC data on funded international collaborative projects. Using the bibliometric method, we quantitatively analyse three aspects of current collaboration: collaborative activity, relative strength of collaboration and collaboration research efforts in each field. Based on this analysis and a discussion of it, some conclusions are reached on the international collaboration between Mainland China and other countries and regions.

**Data and Methods**

*Data sources*

The data used in this paper was extracted from the NSFC dataset of funded projects. From a total of 0.32 million NSFC projects from 2006 to 2016, 17,624 projects involving international research collaboration were extracted as our research dataset. The extracted dataset includes the personnel and project information. The dataset includes 17,624 collaborative projects with 22,655 persons from 78 countries and regions (including Hong Kong, Macau and Taiwan). Each project involves one applicant and one or more participants. This is why there are more people than projects. Each project includes people from different countries or regions (including Hong Kong, Macau and Taiwan) in addition to Mainland China. Table 1 shows the sample for one project.
People from Hong Kong, Macau and Taiwan are included in the datasets. As Special Administration Regions of China, Hong Kong and Macau are much more international than Mainland China (Wang et al. 2013). For historical reasons, Taiwan also differs from Mainland China in many aspects, such as education and culture.

Data processing
Before analysis, the data was processed using the following steps.

Firstly, the data was cleaned. This includes filtering out records with null fields, uniquely identifying each person and implementing name disambiguation for each person’s unit or units of affiliation. For detailed information on name disambiguation, please refer to Yan and Sugimoto (2011).

Secondly, the affiliated units were allocated to the countries or regions where they are belonged to.

Finally, the collaborative projects were assigned to one of eight subject fields according to the area of application. The subject field was divided into eight categories corresponding to the eight scientific departments at NSFC. The eight subject fields are Mathematical and Physical Sciences (MPS), Chemical Sciences (CS), Life Sciences (LS), Earth Sciences (ES), Engineering and Materials Sciences (EMS), Information Sciences (IS), Management Sciences (MS) and Health Sciences (HS). Moreover, some special projects, such as Emergency projects and Director Fund projects, did not fit into any of the eight subject fields due to their specificity. These were categorized as Other and will not be analysed in this paper. Of a total of 17,624 collaboration projects, 17,503 projects were allocated to one of the eight subject fields, and the remaining 121 projects were classified as Other.

Results and Discussion

This section addresses three aspects of international research collaboration between Mainland China and other countries all over the world: collaborative activity, relative research effort and subject field of collaboration.

Collaborative activity

This section provides an overview of the collaboration between Mainland China and other countries and regions. It shows the total absolute collaboration numbers and the growth in collaborative projects from 2006 to 2016.

Table 2 shows detailed information about the total number of persons and projects in specific countries and regions. The top ten countries and regions account for 90.48% of the total 17,624 collaboration projects, and the top fifteen account for 94.73%. The number of people and projects collaborating with researchers from Mainland China varies widely from country to country. Forty-five point sixty-seven percent of the collaboration projects in Mainland China involve collaboration with the USA. Even within the top fifteen, there is a huge gap between countries in the share of international collaboration projects. South Korea, Macau and Denmark are each involved in less than 1% of the total projects. We conclude that nearly 95% of international research projects involve collaboration with the top fifteen countries and regions, and almost half of the collaborations are with the USA.

</table>
To clearly illustrate the profile of international research collaboration between Mainland China and the top fifteen countries and regions, Table 3 shows the number of collaborative projects in each country for each year from 2006 to 2016. Before the results are discussed, the application limit issued in 2012 by the NSFC on General Projects should be mentioned. This limit forbade re-applications by researchers who had applied for but not received General Project funding in the past two consecutive years. This application limit affected the number of the project applications, as reflected in the numbers shown in Table 3. In every year, more projects involved collaboration with the USA than any other country, and collaboration with the USA grew rapidly before 2012. The number of collaborations with the USA reached its maximum of 1,123 in 2012 and has stayed over 1,000 since then, despite a slight decrease. Collaboration with Hong Kong experienced a similar upward trend from 2009 to 2012, but decreased rapidly in 2014. The UK and Australia witnessed a steady increase from 2006 to 2016. A similar situation happened in Canada and Japan; collaborations with both countries grew steadily before 2012 and then decreased slightly. Overall, 2012 is a turning point for trends in collaborative projects. From 2006 to 2012, collaborations with nearly all of the top fifteen grew, while collaborations with over half of the top fifteen decreased after 2012. Although the absolute number of other countries and regions collaborating with Mainland China is far smaller than that of the USA, the number of collaborations still show an upward trend, which means that China has a propensity to collaborate.

Relative research effort

This section analyses the relative research effort of specific countries and regions collaborating with Mainland China. The absolute number of collaboration projects between Mainland China and a specific country or region depends on the country’s size and its propensity to collaborate (Luukkonen et al. 1993). The Activity Index (AI) is a relative indicator which was first proposed by Frame (1977) and was used by Bujdoso and Braun (1983). The AI was later defined in detail by Schubert and Braun (1986) as characterizing the relative effort a country devotes to a given subject field (Schubert and Braun 1986; Kumar and Garg 2005). It can eliminate the effect of country size when comparing the absolute number of collaborative projects. Many researchers have modified and developed this definition (Garg and Padhi 2001; Kumar and Garg 2005; Garg et al. 2006; He 2009).
Here, \( AI = (P_{ij} / P_{ii}) / (P_{cj} / P_{ct}) \)

where \( P_{ij} \) is the number of collaborative projects between Mainland China and country or region \( i \) in the given year \( j \); \( P_{ii} \) is the number of projects between Mainland China and country or region \( i \) from 2006 to 2016; \( P_{cj} \) is the number of projects between Mainland China and all countries and regions \( c \) in the given year \( j \); \( P_{ct} \) is the number of projects between Mainland China and all countries and regions \( c \) from 2006 to 2016; and \( i = 1, 2, \ldots, 15; j = 2006, 2007, \ldots, 2016 \).

If \( AI = 1 \), the country or region’s research effort in the given year corresponds to the average effort of the top fifteen countries and regions; \( AI > 1 \) reflects an above-average effort; \( AI < 1 \) indicates a below-average effort.

In this way, the relative effort of each country or region in any year can be compared. For example, we can compare the USA’s relative research effort in 2007 to that of Japan in 2015.

Figure 1 shows the AI distribution profiles for the top fifteen countries and regions collaborating with Mainland China. To
clearly show the distribution profiles, the top fifteen are divided into four parts, (a) (b) (c) (d), in Figure 1, according to their similar or adverse variation characteristics over time. Figure 1(a) shows that research efforts toward collaboration between Mainland China and the USA, Hong Kong, the UK or Canada were near the average of the top fifteen countries from 2006 to 2016 (AI = 1). After diminishing the effect of country size, research efforts for these countries decrease to the average. Although these four countries and regions among the top five in absolute number of collaborative projects with Mainland China, they seem to show no preference for research collaboration with Mainland China.

Figure 1(b) shows two different growth trends. The research efforts of Mainland China with Japan and Germany decreased steadily, from around 1.5 to 0.7, and collaboration efforts with Australia and The Netherlands increased gradually, from 0.5 to nearly 1.5. This means that Australia and The Netherlands demonstrate a growing desire for collaboration, while Japan and Germany demonstrate an opposite trend. The reason for this should be determined, and policies should be established to provide these countries with more incentive for collaboration. These policies could include financial grants, granting more collaborative project, and providing more support for exchange students.

In contrast to Figures 1(a) and 1(b), Figures 1(c) and 1(d) display an irregular, jumpy variations over time. The difference between Figure 1(c) and Figure 1(d) is the fluctuations in the size of the variations. In Figure 1(c), AI varies less than in 1(d).

To summarize, from 2006 to 2016, research effort in the USA, Hong Kong, the UK and Canada is around the average of that of the top fifteen. Australia and The Netherlands show an overall rising trend in research collaboration efforts with Mainland China, and collaborations with Japan and Germany are decreasing. The other countries and regions in the top fifteen show random variations in collaborative efforts.

**Collaboration field**

In the first two sections, all projects are compared without considering the subject fields they address. In fact, after many
years of development, there are significant differences and imbalances between subject fields in different countries and regions. However, an analysis of collaboration subject fields in different countries and regions is critical for a thorough understanding of collaborative projects in Mainland China. Therefore, Table 4 shows the number of collaborative projects in each subject field in the top fifteen countries and regions.

As the bottom row of Table 4 demonstrates, the absolute number of collaborations in each subject field is quite different. Of 17,624 projects examined, the most projects (4,293) are in the field of HS, and the fewest (566) are in CS. The most common fields for collaborative research are HS, IS and MS. MS accounts for 15.98% of total projects in this study and is the third most common field. However, of the total 0.32 million NSFC projects from 2006 to 2016, only 4.38% deal with MS, and it is the least common field of research overall. This big difference in total and collaborative MS studies means that this field is quite popular for international research and shows a kind of propensity.

The USA has the most collaborative projects in all subject fields. The bar chart in the last column in Table 4 illustrates the wide variation in the number of collaborative projects between Mainland China and the top fifteen in different subject fields. There is a great deal of variation and imbalance in the numbers of collaborations in different subject fields in all countries and regions. HS, IS and MS are the most common fields for collaboration, sharing nearly 60% of all collaborative projects. Moreover, there is a great deal of international research in MS. This kind of difference and unbalance may be partly caused by the dominance of certain disciplines in some countries, such as HS in the USA.

A comparison of the absolute number of collaborative projects does not allow for differences in country size or the propensity of a country or region when collaborating with Mainland China. Hence, the International Collaboration Index (ICI) is adopted to measure the relative research effort of the top fifteen in each field. ICI is an improved internationalization index and was defined by Garg and Padhi (2001).

Here, \( ICI = \left( \frac{P_{ij}}{P_{it}} \right) / \left( \frac{P_{cj}}{P_{ct}} \right) \)

where \( P_{ij} \) is the number of projects on which country or region \( i \) collaborates with Mainland China in the given subject field \( j \); \( P_{it} \) is the number of projects on which country or region \( i \) collaborates with Mainland China in all subject fields; \( P_{cj} \) is the number of projects on which all the countries and regions \( c \) collaborate with Mainland China in the given subject field \( j \); and \( P_{ct} \) is the number of projects on which all the countries and regions \( c \) collaborate with Mainland China in all subject fields.

For the eight subject fields, Table 5 shows the highest and lowest ICI and the corresponding countries and regions collaborating with Mainland China for eight subject fields. Denmark ranks first in CS and LS but last in MPS and IS. France ranks first in MPS and last in CS and HS. In the field of EMS, the USA has the lowest effort with Mainland China, while Japan has the highest effort. Hong Kong has the highest collaboration effort in MS, and Japan has the lowest effort. The biggest effort gap occurred in Singapore; of eight fields, the lowest effort is 0.18, for ES, and the highest is 2.05, for IS. It can be concluded that no one country or region ranks highest or lowest in all subject fields. The top fifteen countries and regions vary in each research field, and there are no obvious trends. Contrasted with the absolute advantage in the number of collaborative projects with the USA, the USA’s research efforts are below the average in six fields, and its effort in EMS is the lowest effort with Mainland China.

Conclusions
Mainland China has established international research collaboration with many countries and regions in the past 40 years, and it has continuously attached great importance to international research collaboration. Therefore, it increasingly important to have an overall understanding of existing collaboration. This paper analyses three aspects of international collaboration with Mainland China: collaboration activity, relative research effort and subject field of collaboration. Several conclusions can be drawn.

1) Of the 78 collaborative countries and regions in this study, the top fifteen account for 94.73% of the total 17,624 collaborative projects. The USA has the most collaborative projects with Mainland China. A trend turning point occurred in 2012. Collaborations with nearly all of the top fifteen increased before 2012, and collaborations decreased with over half of the top fifteen after 2012. Although the absolute number of other countries and regions collaborating with Mainland China is far less than that of the USA, they still show an upward trend, which indicates a propensity to collaborate.

2) From 2006 to 2016, the research effort of the USA, Hong Kong, the UK and Canada is around the average of the top
fifteen (AI=1). Collaboration effort between Mainland China and Australia and The Netherlands shows an overall upward trend; Japan and Germany show a downward trend. Other countries and regions show random variation in collaboration effort.

3) There are significant differences across the eight subject fields, and there are no obvious trends in different countries and regions in subject fields. HS, IS and MS are the top three fields, accounting for nearly 60% of all collaborative projects. MS is a popular subject for international research collaboration. No one country or region ranks the highest or lowest in all subject fields. The USA ranks first in total numbers in all these fields, but the USA’s collaboration efforts are below average in six fields, and the USA’s collaborative effort in EMS is the lowest effort with Mainland China.

Future studies on collaboration should include different data sources, such as publication data and patent data (which are widely used) as well as applied project data. The integration of different data sources would provide a more comprehensive understanding of international research collaboration with Mainland China.

Acknowledgments
This research has been supported by grants from the National Natural Science Foundation of China (71425002, 71640007), the Special Fund Project of the Qinghai Province for the Transformation of Scientific and Technological Achievements (2016-GX-109), and the Youth Innovation Promotion Association of the Chinese Academy of Sciences (2013112).

Abstract
In this paper we analyze the evolution of China’s growing importance in international scientific collaboration over the past decade. Using data from nearly 12 million articles indexed in Clarivate Analytics's Web of Science Core Collection we develop novel weighted and unweighted centrality measures to quantify China’s emerging role in the global network of scientific collaboration. We analyze the networks formed by international co-authorship in two five-year periods: 2006-2010, and 2011-2015. This analysis highlights China’s sharp increase in prominence in international scientific collaborations. Our findings help to enumerate China’s position as the fastest growing international collaborator among the 40 countries studied. We further contextualize our work in a discussion of international scientific collaboration as both a key driver of China’s economy and its emerging perception as a first-world innovator and intellectual power. Finally, we suggest directions for further research including more granular analysis by county and academic discipline.

Conference Topic
International scientific collaboration; Country-level studies;

Introduction
China’s impressive economic development over the past several decades (resulting from the "reform and opening-up" polices begun in the late 1970's) has been widely lauded by a range of observers (Engardio, 2005; Zhou, 2015). The growing prominence of China in global science and innovation is also becoming a subject of broad fascination and is studied ever more frequently (Engardio, 2005; Klochikhin, 2013; Zhou, 2015). Research often drives innovation and China has heavily invested in research in recent years, particularly in the past decade, with substantial results. We see a symbiotic connection between China’s emerging scientific and economic significance and one that can be validated by quantifying the growth in international scientific collaborations, as measured through co-authored scientific papers, between China and other leading countries with mature, knowledge-based economies. Based on papers indexed in Clarivate Analytics’s Web of Science Core Collection, China’s research output surpassed the UK in 2008 and is now second only to the United States. Certainly from the perspective of publication volume, China is playing a more and more important role in global scientific research. This inevitably also has positive economic impact, as many of the breakthroughs
presented in scientific publications will evolve into commercial technologies and products driving investment and employment growth for China.

Collaborative research can inspire participants by exchanging and synthesizing diverse ideas and viewpoints resulting in high impact science. Researchers from different countries are varied in culture and educational background, and often have distinct views on the same research problem. Furthermore, international collaboration can integrate and leverage both physical and intellectual resources from participating countries; this is a clear advantage for research in the era of big science (Niu & Qiu, 2014). This is also important in explaining why the citation impact of publications with international co-authorship is statistically higher than domestic-only publications (Frenken, Hardeman, & Hoekman, 2009; Glänzel & Schubert, 2001; Narin, Stevens, & Whitlow, 1991; Nomaler, Frenken, & Heimeriks, 2013). These generally mutually beneficial results explain why most countries show interest in collaborating with other countries in scientific research.

When considering the role of countries in the scientific collaboration network, the distinctions are remarkable. Some leading nations like the US, the UK, Germany, and France have researchers who co-authored a significant number of papers with many other countries scattered around the world; conversely, there are also examples of countries that only have intensive collaborations with their local geographic neighbors. From this perspective the US, the UK, Germany, and France are the key nodes of the global collaboration network. Over the past several years the collaboration among countries in scientific research has intensified considerably (Zhou & Glänzel, 2010). With China’s rapidly increasing volume of publications, it is emerging as an important collaborator with other countries in scientific research. Academics studying scientometrics and research policy, the Chinese government, research administrators, and even the general public are all interested in China’s emerging position in the international scientific collaboration network. This paper endeavors to quantify the prominence of countries in the collaboration network and investigate the evolution of China’s role over the past decade.

To measure the role and importance of nodes in a network, the most commonly used methods are from Social Network Analysis (SNA). Degree centrality, closeness centrality, and betweenness centrality are three commonly used measures in SNA (Freeman, 1978; Hanneman & Riddle, 2005). However, these measures cannot be reliably applied to the analysis of the international collaboration network of countries since such a network is usually a complete graph. A network is seen as a complete graph if any two nodes have a direct connection, or there is an edge between any two nodes (Wilson, 2012). In a collaboration network formed by countries whose publication output is beyond very minimal, any two countries would have a collaboration relationship, and such a network is a complete graph. In a complete graph, the values of centrality measures for all the nodes will not be significantly different. It is therefore inappropriate to gauge the roles of different nodes using traditional centrality measures as they would not be distinguishable.
International scientific collaboration is a complex and heterogeneous phenomenon, and bibliometric methods can offer deep insight into national characteristics in international co-authorship relations (Glänzel, 2001). In particular, International co-authorship has emerged as a standard proxy of international collaboration (Hennemann, Wang, & Liefner, 2011; Katz & Martin, 1997).

Methods and Data
We use two indicators to measure the role and importance of countries in the global collaboration network. We look at countries as aggregate proxies for all of the papers co-authored with at least one international author. The core idea underlying the indicators is based on the fact that for two countries \( i \) and \( j \), if the collaborated publications between \( i \) and \( j \) take up a high proportion of all collaborated publications of \( j \), then \( i \) is an important collaborator of \( j \). Let \( C_{ij} \) denotes the number of collaborated publications between countries \( i \) and \( j \), and \( C_j \) denotes the total number of publications with international co-authorship of \( j \). The ratio \( C_{ij}/C_j \) measures the importance of \( i \) as a collaborator of \( j \) among all \( j \)'s collaborators (Zhou & Glänzel, 2010; Zitt, Bassecoulard, & Okubo, 2000). The ratio is the numerator of co-authorship preference index proposed by Glänzel and Schubert (Archambault, Beauchesne, Côté, & Roberge, 2011; Schubert & Glänzel, 2006). Formula (1) accumulates \( i \)'s importance among all its collaborators and represents \( i \)'s overall importance as a collaborator within the network.

\[
\sum_{j \neq i} \frac{C_{ij}}{C_j}
\]

Formula (1)

In formula (1) we do not take the volume of \( j \)'s publications into account when we accumulate \( i \)'s importance over \( j \). For a large country \( j \) with a high volume of publications and a small country \( k \) with small number of publications, \( C_{ij}/C_j \) may be much lower than \( C_{ik}/C_k \). But \( j \) is usually more influential than \( k \) since \( j \) typically publishes many more papers and attracts many more citations. In this sense formula (1) does not consider the impact of country \( j \) when we evaluate \( i \)'s importance. To overcome the limitations of formula (1) we can weight the ratio \( C_{ij}/C_j \) by the global share of \( j \)'s publications \( P_j \). \( P_j \) is calculated as the number of \( j \)'s publications divided by the number of world’s total publications.

\[
\sum_{j \neq i} \frac{C_{ij}}{C_j} P_j
\]

Formula (2)

In this paper both indicators will be used to measure the roles of countries in the collaboration network.

The data used in our analysis comprises papers indexed in Clarivate Analytics’s Web of Science Core Collection and published between 2006 and 2015. Only papers of document type Article and Review are considered.
To construct and analyze the international scientific collaboration network in a realistic way, only the 40 largest countries (measured by overall publication output between 2006 and 2015) are considered. Researchers from the 40 countries published 11,947,664 papers in all. Note that if a paper is co-authored by scientists from multiple countries, this paper is only counted once. The total volume of papers published by the 40 countries accounts for 95.4% of the world’s output. So, at least for the purposes of our present research, the collaboration network formed by these 40 countries can reasonably represent the entire international collaboration network well. Plus, it is more convenient for us to calculate the countries’ performance from formula (1) and (2) in this tailored network, especially given the space restraints for this paper. The measures from formula (1) and (2) are called unweighted and weighted centrality respectively.

**Results**

Table 1 shows the unweighted centralities of the 40 countries with the highest publication output between 2006 and 2015. The rank is based on the total number of publications (both internationally co-authored and domestic-only collaborations are taken into account.) Perhaps not unexpectedly, the centrality of the US is much higher than that of all other countries studied. This suggests that most of the world’s countries have substantial collaborations with the US and demonstrates the core role of the US in the global collaboration network. The UK, Germany, and France also attract substantial collaborations and are important nodes of the network. Clearly, a commonality of the US, the UK, Germany, and France is that they are all well-established countries with a large volume of scientific publication output. China and Japan also produce many publications but their centralities are not as high as their positions in publication output. Although China’s overall publication volume is second only to the US, China’s centrality is just slightly higher than that of the Netherlands, a small country, but one widely known for innovation in science and technology.

For the 20 countries with the highest centralities in Table 1, Table 2 shows the increase of centralities between the two five-year periods 2006-2010 and 2011-2015. Table 2 clearly displays that China has the largest increase of centrality, over the periods studied, with its centrality ranking rising from 10th position in 2006-2010 to 7th place in 2011-2015. This unmistakably indicates that along with a rapid increase in publication volume, China is also emerging as an important collaborator with researchers in other countries around the world.

Table 3 lists China’s top 10 collaborators between 2011 and 2015. The fourth column $C_{ij}/C_j$ calculates the proportion of China’s international co-authored publications with each country in each country’s total collaborations. Focusing on the values of $C_{ij}/C_j$, China is the least prominent collaborator for France and the Netherlands, and the most important collaborator for Singapore. Papers co-authored by researchers from China and Singapore account for more than 30% of Singapore’s total international collaborations.

</table>

China’s unweighted centrality ranks 7th and weighted centrality ranks 5th. China’s position in the collaboration network rises under the weighted centrality measure because China’s main collaborators are major countries (shown in Table 3) and our formula (2) gives more weight to the collaboration between China and those countries.

Like the unweighted case, Table 5 shows the increases of weighted centralities for the 20 countries in Table 2 between 2006-2010 and 2011-2015. As in Table 2, China has the largest centrality increase further demonstrating the rapid growth of China’s role and importance in the international collaboration network. In Table 2 the US’s centrality increase is nominal; however, based on weighted centrality, the US’s increase is significant and second only to China. This suggests that despite its already dominant position, in the past several years the US has continued to focus on increasing collaboration with other major countries. Curiously, Japan is the only country with flat or negative (weighted and unweighted) centrality growth. One reasonable interpretation of this is that China is eclipsing Japan as the leading Asian country in the international scientific collaboration network in recent years. We speculate that this may be a result of
China’s purposeful focus on growing its international influence and impact in science and innovation in hopes of driving further economic development, however further research is needed to validate this assertion.

</tbody>
</table>

To better visualize the collaboration network, we choose to plot countries with large volumes of publications with international co-authorship. In figures 1 and 2, only countries with more than 30,000 such collaborations and connections with at least 20,000 collaborations in each of the five-year periods are plotted. In other words, the edges (collaboration) between two nodes (countries) are plotted only if the two countries have at least 20,000 collaborations. In Figures 1 and 2, the size of each node is proportional to the total number of co-authored publications and the width of the connection is proportional to the number of co-authored publications between the pair of countries.
In Figure 1, the US is clearly at the center of the network and the first primary collaborator of all countries except Switzerland in the five-year period 2006-2010. The top 3 collaborators of the US, measured by volume of publications, are the UK, Germany, and Canada. China’s total number of international collaborations is significantly lower than that of the US, the UK, Germany, and France between 2006 and 2010.

![Collaboration network between 2006 and 2010](image)

**Figure 1. Collaboration network between 2006 and 2010**

A very different view emerges when we compare Figure 2 with Figure 1. While the US is still the center of the network, the UK, Germany, France, Italy, Spain, and China all grow into sub-centers. China’s international collaboration volume increases so that it is close to that of the UK and Germany. The US and China are the only two countries with more than 20,000 co-authored papers with the UK, Japan, and Australia. This view clearly shows China’s emerging importance as a significant collaborator with other leading countries.
Conclusion and Discussion
Along with its bustling economy, China has rapidly increased its productivity of academic publication output over the past decade to the point where its annual volume of papers is second only to the United States; and the gap is quickly narrowing. At the same time, global collaboration (as measured through papers with international co-authorship) in scientific research has intensified. Researchers in scientometrics and research policy, the Chinese government, and the public are all interested in China’s growing prominence in the international scientific collaboration network accompanied by the broader economic implications of this emergence. This paper endeavored to quantify this phenomenon using novel bibliometric measures.

Commonly used measures of a node’s role and importance in a network, such as degree centrality, closeness centrality, and betweenness centrality are based in general social network analysis. However, different from a general social network, the scientific collaboration network of countries is a complete graph where any two countries have connections (collaboration relationships.) Thus, traditional measures of nodes cannot be realizably applied to analyze the scientific collaboration network of countries.

We proposed two novel indicators to measure the role of countries in the global collaboration network. In formulating these two indicators, we presumed that if the collaborations between countries $i$ and $j$ account for a large proportion of $j$’s total collaborations, then $i$ plays an important role among all $j$’s collaborators. Although these measure help to quantify China’s emergence in importance in the network, they still do not show China’s collaborative role in line with its position as second (only behind the
US) in overall publication output. China’s increase in importance in the past decade is the most significant among the 20 countries with the highest overall publication output. China is clearly emerging as a sub-center for substantial international scientific collaboration.

It is well established in the existing literature that international scientific collaboration is complex and affected by geographic, linguistic, cultural, sociological, and economic factors. While we revealed the roles of several leading countries in an aggregate quantitative way, we did not analyze any of the myriad underlying factors that very likely impact the actual collaborations. There is certainly opportunity for further deep study in these areas for interested researchers. In addition, we analyzed international collaborations based on publications across a broad range of academic disciplines. It is also probably worth studying collaborations in individual fields for a more nuanced understanding of the distinctions within discipline-specific sub-networks; we imagine that these can differ greatly and such study could reveal further interesting and instructive insights.

In this paper we only consider and measure the collaboration relationship from the perspective of bilateral relations. For the collaborations between A and B, although many other countries also participated in their coauthored papers, we disregard such multilateral collaboration information when we consider the collaborations between A and B. To describe the complete collaboration relationships by taking the full coauthorship information in the papers into account, we need more complex methods, indicators, and multilateral collaboration visualization. This is an important topic and it’s worth deep exploring in the future.

Interdisciplinarity and collaboration: On the relationship between disciplinary diversity in the references and in the departmental affiliations

Abstract: We proposed a novel conceptual framework to investigate two different aspects of interdisciplinarity in the process of knowledge integration: the subject categories referenced and the specialist disciplines of the authors’ listed affiliations. Diversity was used to capture the disciplinary heterogeneity of our data sample in both respects. We presented an explorative methodology for retrieving feature words to classify the affiliates disciplines. Some interesting observations were drawn from this pilot study. 1) In general, there are positive relationships between interdisciplinarity and collaboration, but the specific nature of those relationships varies among different journals and according to different indicators. 2) Based on a schematic model of the discipline diversity in references versus the discipline diversity in affiliations, the combinations of ‘low-low’ and ‘high-high’ occur much more frequently than ‘low-high’ or ‘high-low’ in each of the journals under study.

Conference topic
Methods and techniques; Indicators; Interdisciplinarity

Introduction

Interdisciplinary research (IDR) is generally seen as a source of creativity and innovation (Dogan & Pahre, 1990). And, there is a general consensus that what differentiates IDR from multidisciplinary research is the degree of knowledge integration (Porter et al. 2008). As such, appropriately identifying interdisciplinary activity is an important step in understanding where it occurs and that it is properly assessed (Rousseau et al. 2017). According to the National Academy of Science in the US (2004), IDR is:

“a mode of research by teams or individuals that integrates information, data, techniques, tools, perspectives, concepts and/or theories from two or more disciplines or bodies of specialized knowledge to advance fundamental understanding or to solve problems whose solutions are beyond the scope of a single discipline or area of research practice”.

The above definition emphasizes knowledge integration on the part of individuals, teams, departments, institutions, regions, and even countries. The more an article, or any other investigative piece, integrates different sources, the more interdisciplinary it becomes. According to Grant et al. (2015), two of several ingredients that generate excellent outcomes in IDR are:

- Diversity in research fields: a broad range of disciplines supports exceptional levels of research excellence.
- Diversity of research organizations: where mission-led units complement large and small universities with regional as well as international engagement.

Various bibliometrics indicators have focused on measuring interdisciplinarity in terms of the knowledge that originates from different research fields. Categorical analysis has predominantly relied upon lists of cited references (e.g., Rafols & Meyer, 2010; Wang et al., 2015, Zhang et al., 2016). However, measuring the diversity of research organizations has not been widely explored.
In a recent study, Adams et al. (2016) noted that the same project may be indexed as interdisciplinary according to one parameter, say the diversity of its references, but not for another, such as its authors’ affiliations or the universities the study originated from. It is not surprising that different indicators can deliver inconsistent, or even contradictory, results. For this reason, Adams et al. (2016) points out that it is essential to consider a framework for analysis that draws on multiple indicators, rather than expecting any simplistic index to produce an informative outcome on its own.

The research questions in this study arise from Grant et al.’s (2015) IDR progenitors – diversity in research fields and diversity in research organizations. We not only measure the interdisciplinarity of research studies through their cited references, but we also try to identify diversity in the listed affiliations of the studies’ co-authors at a departmental level. Our two main research questions are:

1. Can IDR be achieved by single authors or one research organisation, or does IDR normally require collaboration between different entities?

2. What is the relationship between disciplinary diversity in the references of a study and the affiliations of the study’s co-authors?

Data and Methods

Data

For the purposes of this study, all the article-style publications in three journals – Scientometrics, Bioinformatics and the Journal of the American Geriatrics Society – were downloaded from Clarivate Analytics’ Web of Science (2006-2015). These three journals were chosen following the strategy in our previous study (Zhang et al., 2016). In total, our sample dataset contained 11,883 records. The reference for each paper were retrieved using a simple search from Web of Science. The authors’ affiliations were obtained by first identifying feature words in the affiliates’ names from full attributions of the authors. The feature words were: Dept, Sch, Ctr, Coll, Inst, Lab, Assoc, Fac, Div, etc. Then, the thesaurus function in Thomson Data Analyzer’s (TDA) text mining tool was used to clean the information. Because our research question focuses on affiliations at the departmental level, but some of the feature words are also common to university and institution names, e.g., the Harbin Institute of Technology, a thorough manual check was conducted to reduce the effect of noise. After discarding the records that did not include affiliations or lacked relevant feature words, 9572 affiliations were confirmed from the bylines of 11,318 articles.

Methods

Setting the Discipline classification systems

It is clear that using the term IDR, first requires a definition of the term discipline. Here, we use the term discipline as a synonym for a research specialty or field of study. There are already several pre-defined ‘intellectual’ classification schemes in wide use in bibliometrics, such as the 22 broad field classifications used in the Essential Science Indicators database or the 250+ subject categories used by Web of Science (WoS). Glänzel and Schubert (2003) proposed, and subsequently developed, a hierarchical scheme: the Leuven–Budapest (ECOOM) subject classification. We chose to adopt both the WoS and ECOOM classifications as our pre-defined benchmarking systems. ECOOM’s hierarchical structure makes it meaningful for building a matching and comparison system, while the 250+ categories in WoS can all be assigned to one of 68 subfields or 16 major fields in ECOOM.
The WoS category corresponding to the references in the articles was obtained directly from the WoS database, and no further classification or reclassification processes were applied, beyond reducing the WoS categories to a set of 245 relevant subject areas, as explained in the affiliate classification process.

The most challenging task was to match the affiliations with the discipline most relevant to their work. After retrieving all the subject-related feature words from the 9572 affiliate names through several rounds of manual and machine-based processing, we firstly tried to match each affiliate to one of ECOOM’s 16 major fields. ECOOM was chosen over the WoS classifications because the subject-related feature words in the affiliate names were not specific enough to allow proper matches in many cases. However, some adjustments to ECOOM’s system were required to completely match all the records, as shown in Table 1.

Table 1. The relationships between ECOOM’s major disciplines and our corresponding major disciplines used to classify the affiliations

As a result, ECOOM’s 16 major fields were reduced to a total of 13 major disciplines: 1) Computer Science & Information Technology, 2) Agriculture & Environment, 3) Biology, 4) Medicine, 5) Chemistry, 6) Engineering, 7) Geosciences & Space Sciences, 8) Mathematics, 9) Psychology, 10) Physics, 11) Arts & Humanities, 12) Social Sciences, General, 13) Social Sciences (Economics & Management).

Some brief notes about the adjustments made to ECOOM’s 16 major disciplines follow:

1) Multidisciplinary Sciences was excluded. Given our main research question is to study interdisciplinarity in research, each departmental affiliation needed to be classified into a
specific discipline. Therefore, the field of ‘Multidisciplinary Sciences’ is not applicable to this study.

2) The two medicine fields were merged into a single discipline, Medicine. The two fields of biology and bioscience were merged into a single discipline, Biology. This change was made because many departmental affiliations contain broad subject-related feature words, such as ‘Dept Med’ and ‘Dept Bio’. Hence, Biology and Medicine were treated as two independent disciplines in our classification scheme.

3) Some interdisciplinary fields in ECOOM were divided into specific disciplines. Biomedical Research was divided into Biology and Medicine; Neuroscience & Behaviour was divided into Medicine and Psychology. Note that in cases where an affiliate’s name contained a word related to biomedical, it was assigned to both Biology and Medicine in the new system. In other words, multi-assignment was allowed.

4) Psychology was added as an independent discipline. In recent years, there has been a great deal of development in psychological research, and the trends within this field are commonly found in the names of affiliates all over the world.

5) Computer Science & Information Technology was added as a new major discipline. Our data sample included many studies on computer science and information technology, and related feature words were frequently found in the affiliate names. To adapt the data distribution in our sample to maintain a relative balance between each discipline, we separated Computer Science & Information Technology from Engineering and Social Sciences I (General, Regional & Community Issues).

6) Social Science I & II were divided into two specific disciplines: Economy & Management and General Social Sciences. This adjustment was also made to even out the data distribution of the affiliate feature words within our sample.

As previously mentioned, every major field and sub-field in ECOOM has a strong match to the categories in WoS. WoS tags 252 categories to 12,000+ journals in its 2016 edition. The six newest categories, ‘Audiology & Speech-language Pathology,’ ‘Cell & Tissue Engineering,’ ‘Ergonomics,’ ‘Green & Sustainable Science & Technology,’ ‘Logic,’ and ‘Nanoscience & Nanotechnology’, were only added in 2016 and are not included in ECOOM’s classification scheme. These categories were removed, along with multidisciplinary sciences as mentioned above, to arrive at a final list of 245 WoS categories. These were synchronized with the 16 major ECOOM fields to further help classify the affiliates into our 13 disciplines.

Assigning departmental affiliations to their corresponding discipline(s)

Discipline-specific lexicons for the 245 WoS categories were used to correlate the discipline feature words retrieved from the affiliate names with a field of research. All feature words were carefully checked using a combination of manual and machine-based work to build a vocabulary of feature words for each major discipline, and this list was used to assign the affiliates to one or more of the 13 disciplines in our classification system.

Throughout the entire process, we focused on a balance between data precision and the recall rate, and this trade-off between accuracy and efficiency was the primary motivator for the decision to use feature words as our vocabulary. After several rounds of manual and machine-based screening, 379 discipline feature words were collected from the affiliates’ names and 8444 departmental affiliations were identified and classified into the 13 different disciplines. Records without listed
affiliations were excluded, resulting in 10,899 articles for further analysis, i.e., 91.64% of the original data sampled.

We attempted to obey some rules in our processing procedure:

1) Unknown words in affiliate names were classified using official sources. Generally, the abbreviations of academic terms in affiliation names, such as Med, Bio, Stat, made it easy to identify their discipline(s). However, some words, e.g., ‘Fis’ and ‘Quim’, were harder to classify. In these cases, a manual trace of the author’s full affiliations in the original document to the affiliate’s official website was conducted to confirm their field of research manually. In the example above, ‘Fis’ and ‘Quim’ were identified as the Spanish abbreviations for ‘Física’ and ‘Química’, and the corresponding English words are Physics and Chemistry.

2) ‘Full matching’ technology was applied whenever needed. For instance, the abbreviation term ‘Dis’ is an abbreviation for the medical feature word ‘Disease’. However, ‘Dis’ may also appear in ‘ADIS’ or ‘Discovery’, etc. The same applies to other abbreviations, such as ‘eye’, ‘soc’, ‘eth’, ‘art’, ‘gene’. In these cases, ‘full match’ was set for these particular words to avoid possible noise.

3) Where an abbreviation may have two meanings, the full affiliate name was used. For example, when the feature word ‘Vet’ appears alone in an affiliate name, it usually means Veterinary and should be classified into Biology. However, when it appears within the phrase ‘Vet Affairs’ or ‘Vet Admin’, it represents ‘Veterans’, and the related affiliate was generally found to be a veterans rehabilitation center, which was classified into Medicine. A manual check of the full affiliate name resolved each case.

4) Affiliates with more than one discipline feature word in their name, like ‘Dept Biochem’ and ‘Div Biomed Stat & Informat’, were regarded as interdisciplinary affiliations and were given multiple assignments into each corresponding discipline. For example, ‘Dept Biochem’ was assigned to both ‘Biology’ and ‘Chemistry’.

**Applying interdisciplinarity measure indicators**

Among the various interdisciplinarity measures available, we focused on measuring diversity through its three components: variety, balance, and disparity (Stirling 2007). These three decompositions make it possible to explore different components of diversity in the cited references of a corpus of publications and the affiliations of the authors. We selected the true diversity measure (TD) proposed in Zhang et al. (2016) as the representative indicator of integrated diversity, and the number of different subject categories as the decomposed measurement representing variety in the concept of diversity.

**TD** is defined as

$$TD = \frac{1}{\sum_i p_i p_j (1-d_{ij})}$$  \hspace{1cm} \text{(1)}

where $i$ is the index, $x_i$ is the number of references/affiliations to the $i$-th subject category, and the subject categories are sorted by $x_i$ in non-decreasing order. $p_i = x_i / \sum x_i$. $d_{ij}$ is the dissimilarity between the subject categories $i$ and $j$. $d_{ij} = 1 - s_{ij}$, where $s_{ij}$ is the Salton’s cosine similarity between the subject categories $i$ and $j$ based on the WoS subject cross-citation similarity matrix (1991-2015). When the 13 disciplines in the departmental affiliations are used, the WoS subject cross-citation matrix is aggregated into the ‘DA_ fields’ (see in Table 1) similarity matrix. $d_{ii} = 0$ for all $i$. Detailed information and supplementary materials can be found at http://suo.im/1o7Ff9 or
Figure 1 presents an outline of the data processing methods used in this study.

The following abbreviations are used for the four diversity measures applied in this study:

- $N_{SF\_A}$ denotes the “number of different discipline fields in the affiliations”;
- $N_{SC\_R}$ denotes the “number of different subject categories in the cited references”;
- $TD_{A}$ represents the “true diversity measure of the affiliations”;
- $TD_{R}$ represents the “true diversity measure of the references”;

Affiliate(s) always refers to the departmental affiliation(s) listed by an author.

Also, note that WoS’s 245 categories were used to classify the references, whereas the affiliates were classified into the 13 major disciplines derived and adjusted from ECOOM’s classifications.

**Results**

**Descriptive statistics**

Through a count of the co-authors, listed affiliations, and countries in the attributions for each paper in the three selected journals, and based on the data processing and the classification systems presented in the Methods section, we assigned all the affiliations and references into their corresponding disciplines and calculated the $N_{SF\_A}, N_{SC\_R}, TD_{A}, TD_{R}$ for each individual
paper. The descriptive statistics for each of the measures in the three journals is shown in Table 2. It’s interesting to see that the Journal of the American Geriatrics Society (JAGS) had the largest collaboration scale in terms of both the number of authors and the average affiliations, while Bioinformatics had the largest average values across all the diversity measures (N_SF_A, N_SC_R, TD_A, TD_R). This difference was due to the fact that Bioinformatics has high interdisciplinarity in both affiliations and cited references, and as a contrast, the large collaboration in JAGS are more based on same or similar disciplines. Scientometrics had a lower level of both author and affiliate collaborations.

The number of affiliations and countries is highly skewed, so we adopted a dummy variable. If the attributions in a paper included more than one affiliation or country, the variable was set to 1, and 0 otherwise. The same applied if a paper was written by multiple authors or only one author. Table 3 presents the collaboration ratios for each journal. The author collaboration ratio represents the percentage of multi-authored papers. The cross-affiliate collaboration ratio reflects the percentage of papers written by co-authors with different affiliations. The international collaboration ratio shows the percentage of papers written by co-authors from different countries. And, the cross-discipline affiliation ratio shows the percentage of papers written by co-authors with affiliations across different disciplines.

It is interesting to note that the JAGS had both the highest author collaboration ratio (98.11%) and cross-affiliation collaboration ratio (80.29%), but the lowest international collaboration ratio (16.01%). This suggests that papers in the JAGS are highly collaborative, but these collaborations are mostly on a national level. Bioinformatics had the highest international collaboration ratio (27.62%), and cross-discipline affiliations ratio (79.10%), which indicates that the articles in Bioinformatics have a higher international and interdisciplinary orientation in terms of collaboration. The co-authorship, cross-affiliation, and cross-discipline ratios for Scientometrics were the lowest of the three journals.

Figure 2 demonstrates the distribution of individual articles versus the number of affiliations, the number of different disciplines among the affiliates, and the number of different subject categories in the cited references. In *Bioinformatics* and *Scientometrics*, articles with a single affiliation dominate. By contrast, the *JAGS* shows a rather different distribution, where cross-affiliate collaboration is common. However, it is interesting to note that most collaborations are within a single discipline. The level of cross-discipline affiliations in *Bioinformatics* is also remarkable, given their low proportion of cross-affiliations. Single-discipline affiliations are dominant in both the *JAGS* and *Scientometrics*. In terms of the variety of disciplines in the cited references, *Scientometrics* appears to have the lowest interdisciplinarity compared to the other two journals. However, the distribution of $N_{SC\text{-}R}$ in *Scientometrics* has a rather long tail to the right, and the article with most reference subjects – a total of 64 categories – was found in this journal.

Fig.2 The distribution of individual papers according to the number of affiliations, $N_{SF\text{-}A}$ and $N_{SC\text{-}R}$ in the three journals under study
Is IDR more achieved by collaboration among different entities?
To answer this research question, we divided all the articles in each journal into groups according
to the number of authors, affiliations, countries, and affiliate disciplines, then calculated
the average number of reference subjects for each group. Figure 3 shows the results of the comparison
between the three different journals. Both Bioinformatics and the JAGS show a general increase in
interdisciplinarity in line with an increasing number of authors, affiliations, affiliate disciplines,
and the number of referenced subjects. In Bioinformatics’ case, these rising trends are rather
striking. Against expectations, no specific relationship was found between reference diversity and
the collaboration ratios for Scientometrics. Since the number of countries is highly skewed, we
separated the articles published within a single country from those with international collaborations.
In general, the papers in Bioinformatics and the JAGS with international collaborations contained
a more diverse set of reference subjects but Scientometrics, again, presented an exceptional case.

We further calculated the average TD_R for each group according to the number of authors and
affiliate disciplines. Figure 4 presents the results. Similar to our observations in Figure 3, the JAGS
and Bioinformatics both showed a rising trend in TD_R, along with an increase in the number of
co-authors, affiliate disciplines – and, again, exceptionally so for Bioinformatics. Yet, once more,
Scientometrics presents a different profile. Combined with the previous analysis, Scientometrics
generally shows a lower level of collaboration than the other two journals, and the relationships
between collaborations and interdisciplinarity are rather inexplicit.

Fig. 3 The relationships between
the number of referenced subjects and the different collaboration measures
Fig. 4 The relationship between TD_R and the different collaboration measures in the three journals

Disciplinary diversity in references vs. disciplinary diversity in affiliations

In this section, we explore knowledge integration from two different perspectives – disciplinary diversity in references versus disciplinary diversity in affiliations. Fig. 5 provides a schematic representation of this twofold perspective, following Porter et al. (2007) and Rafols and Meyer’s (2010) proposals. Since this study examines individual publications and knowledge integration through the disciplines associated with author affiliations and references, the central node in each graph represents the focal literature. The affiliate discipline sets are on the left, and the reference discipline sets are on the right. Each of the colored icons in the network represents a discipline. There are four possible combinations:

(i) low affiliate discipline diversity – low reference discipline diversity in the references (LDA-LDR) represents cases of specialized disciplinary research, where all references are from same or similar disciplines, accomplished by authors from the same or similar affiliation disciplines.

(ii) low affiliate discipline diversity – high reference discipline diversity (LDA-HDR) indicates cases where the references cite a variety of subjects, but the authors are affiliated with the same or similar disciplines.

(iii) high affiliate discipline diversity – low reference discipline diversity (HDA-LDR) represents cases of specialized research, where all references cite the same or similar disciplines, but the authors are affiliated with a variety of disciplines.

(iv) high affiliate discipline diversity – high reference discipline diversity (HDA-HDR) denotes cases where the references cover a variety of subjects, accomplished by authors with a variety of affiliation disciplines.

Tables 4 and 5 show that the ‘low-low’ and ‘high-high’ combinations occur much more frequently than ‘low-high’ or ‘high-low’ in each of the journals under study. It is interesting that Scientometrics follows a similar pattern to the other two journals across all quadrants, even though the relationship between the interdisciplinarity and collaboration measures of their papers was obscure in our previous analyses. Bioinformatics presents the only somewhat exceptional case. When using the integrated diversity measure (TD), the distribution among the four combinations is relatively even. This observation deserves deeper exploration in the future.

To illustrate the schematic model using our empirical data, we ranked all the individual publications in each journal according to the two measures of variety (N_SF_A, N_SC_R) and the two measures of integrated diversity (TD_A, TD_R) in descending order. The top third of all publications for each measure were regarded as “high,” and the bottom third were regarded as
“low”. After a cross-matching process between the high and low groups based on each measure, we derived the representative paper samples for each combination as shown in Fig. 5. The proportion of articles for each of the four combinations are shown in Tables 4 and 5.

Conclusions

In this article, we proposed a novel conceptual framework to investigate two different aspects of interdisciplinarity in the process of knowledge integration: the subject categories referenced and the specialist disciplines of the authors’ listed affiliations. Diversity was used to capture the disciplinary heterogeneity of our data sample in both respects. We presented an explorative methodology for retrieving feature words to classify the affiliates disciplines, based on a
Some interesting observations were drawn from this pilot study. 1) In general, there are positive relationships between interdisciplinarity and collaboration, but the specific nature of those relationships varies among different journals and according to different indicators. For example, interdisciplinarity in the articles in the Journal of the American Geriatrics Society and Bioinformatics is increasing, in line with an increase in the number of authors, affiliations, and affiliate disciplines, but Bioinformatics is showing exceptional interdisciplinary growth. Whereas, the relationship between collaboration and interdisciplinarity for Scientometrics is not at all explicit.

2) Based on a schematic model of the discipline diversity in references versus the discipline diversity in affiliations, the combinations of ‘low-low’ and ‘high-high’ occur much more frequently than ‘low-high’ or ‘high-low’ in each of the journals under study.

We feel this research is beneficial to the study of interdisciplinarity. Our future research will adapt the proposed approaches for use with larger bibliometric sets.

Abstract

At early 2016 the new index was launched on Web of Science platform — Russian Science Citation Index (RSCI). The database is free for all Web of Science subscribers except those from the former Soviet Union countries. This database includes publications from 652 best Russian journals and is based on the data from Russian national citation index — Russian Index of Science Citation (RISC). RISC was launched in 2005 but there is very limited information about it available in English-language scholarly literature by now. The aim of this paper is to describe the history, actual structure and user possibilities of RISC. We focus on the novel features of RISC which are crucial to bibliometrics and unavailable in international citation indices.

Introduction. History and main objectives of RISC

RISC was launched in 2005 as a government-funded project primarily aimed at creating a comprehensive bibliographic/citation database of Russian scholarly publishing for evaluation purposes based on Scientific Electronic Library (further eLIBRARY.RU) which started as a full-text database of scholarly literature for grant holders of Russian Basic Research Foundation. The main purpose of eLIBRARY.RU was to provide Russian scientists with papers from leading academic journals (Eremenko, 2003).

The evaluation of research implies the bibliometric analysis of research output of scientists, organizations, etc. At the same time only less than 10% of publications of Russian scientists are included into international citation indexes, i.e. Web of Science and Scopus (Tretyakova, 2015). Almost all publications in social sciences and humanities are in Russian — and they are absent from international databases. The primary aim of the federal target scientific-technical program was to collect and index information from all available publications in Russian scholarly journals and their reference lists to make possible the further evaluation of journals’ quality and research output of Russian scientists, universities and research organizations.

In general, motives for creating national citation indexes are explained by Pislyakov (2007). There are plenty of examples and stories of implementation of such databases for different countries. For example, in China even several national indexes were created (Jin & Wang, 1999; Su, Deng & Shen, 2014; Wu et al., 2004; Ye, 2014). There are also cases in India (Yadav & Yadav, 2014), Japan (Negishi, Sun & Shigi, 2004) etc. Other stories were not so successful, the Serbian case was presented at previous ISSI conferences (Šipka, 2005; Pajić, 2015).
Unlike Web of Science and Scopus there are no strict criteria for journals to be indexed in RISC. At the very beginning of the project it was decided to index any scholarly journal. Nevertheless, the principle of indexing can not be called purely declarative: eLIBRARY.RU refuse indexing the propaganda journals or magazines that were deemed to be just popular or commercial media designed for a wide non-scientific audience.

It is important to differ the journals at the eLIBRARY.RU platform from journals indexed in RISC. Journal catalogue of eLIBRARY.RU now includes 12975 Russian periodicals, only 4847 of them being indexed in RISC. RISC indexes also 541 foreign journals which are published mainly in former Soviet countries.

The research output can not be evaluated only by journal publications — the scientific activity is also reflected in different book publications, conference materials, dissertations, etc. In 2013 the book project was launched in RISC and now eLIBRARY.RU platform hosts non-periodical publications: monographs, reference books and dictionaries, textbooks and manuals, collections of articles, conference proceedings, theses and dissertation abstracts.

The problem of author identification is crucial for all citation databases and there are different ways to solve it. RISC involves authors to resolve this problem with the service Science Index for authors since 2011 and for organizations since 2012 (Arefiev, Eremenko & Glukhov, 2012).

In 2015, the collection of the best journals of all journals indexed in the RISC was created for launching on the Web of Science platform in a separate database Russian Science Citation Index by agreement with the company Thomson Reuters IP (now — Clarivate Analytics). It has greatly expanded the presence of Russian scientific journals in the international information space, especially for periodicals in the field of social and humanitarian, technical and medical sciences, which were underrepresented in the Web of Science and Scopus. At the same time the RISC core has been selected. It includes the best publications that may be used to evaluate the effectiveness of scientific research based only on the highest quality segment of the scientific works of Russian scientists.

- Preprint
Content and coverage. Information sources

There are 25 million documents at eLIBRARY.RU platform with almost 260 million references. The distribution of publication types is shown in Fig. 1.

eLIBRARY.RU contains almost 60,000 titles, 14,500 of them are Russian. Full texts are indexed for 4391 journals, this enables extracting the citation context (in the form of snippets), the unique feature of RISC unavailable in other citation databases. Each year the number of journals in eLIBRARY.RU is growing approximately 300 journals per year (Fig. 2).

In 2010 an agreement was reached with the leading international publisher of scientific literature Elsevier to import into RISC the information about Russian authors and to attribute to them their works from the international citation database Scopus. This makes possible a comprehensive evaluation of publication output and citation analysis of Russian scientists and scientific organizations. Since then RISC takes into account not only papers in Russian journals indexed in the database, but also Russian papers in international journals.

Books come to eLIBRARY.RU from several sources. The main are publishers’ or authors’ agreements with eLIBRARY.RU. There are 1,750 contracts with 1,500 Russian and foreign publishers to deposit books to eLIBRARY.RU platform and more than 5,000 contracts with the authors to include their monographs.

The main source for patent information is Federal Institute for Industrial Property, the research reports are mainly imported from database of Russian Foundation for Basic Research. The whole number of documents in eLIBRARY.RU and their distribution by document types is shown in Fig. 3.
Figure 3. Annual number of documents in eLIBRARY.RU since RISC launching

Structure

Publication metadata

Every publication in RISC is attributed to specific publication type: research article, review, short communication, conference paper, letter, research report, book review, annotation, letter, editorial, biographical item; monograph, article collection, textbook, dictionary or reference book, brochure, guidelines; conference proceedings; dissertations; patents; grant report; preprint.

Publication metadata may include different identifiers — DOI, UDC, PMID, etc. As usual, the abstract and keywords in Russian and English are provided by publishers together with the references.

The preview of each publication is supplied with its bibliometrics and altmetrics indicators. The registered users may also see the links for citations in Google scholar. The links for the full text at the external sites are also available if publisher provides this information.

The bibliometric indicators include number of citations in RISC, Web of Science and Scopus, the citedness normalized by journal and subject area, other essential information. Altmetrics show the number of previews, downloads at eLIBRARY.RU and the number of article sets created by users to which this paper was added.

Lists of references have links to the publications included into database and citation snippets (if their full text is available at eLIBRARY.RU). It is possible thanks to the important difference of RISC from Web of Science and Scopus: RISC is not only fully integrated with eLIBRARY.RU platform, but is a part of it. Bibliographic and bibliometric information are combined with the service of online electronic library, providing access to the full texts which are stored in the system together with metadata. Today almost 4,500 journals use eLIBRARY.RU as a full-text
hosting platform. Citation snippets is a unique feature of RISC comparing with Web of Science, Scopus or Google Scholar.

Author profiles
At the moment of registration the scientist inputs his/her personal data, affiliations, name variants, research interests, list of journals, where he has publications, ResearcherID, Scopus, ORCID identifiers. This helps to identify the authors in papers. Each registered author receives a SPIN-code — Scientist Personal Identification Number. The number of registered authors now exceeds 430 thousand.

For each author, we may find all documents at eLIBRARY.RU where the scientist is identified as an author, editor or reviewer, the list of citing publications and analysis of author’s publication output. The metrics are available: the number of papers and the citations received by them, h-index, bibliometric indicators for the last 5 years and distribution of publications by types, journals, coauthors, etc. Also there are the links to scientist profiles in external systems (Scopus, ResearcherID, ORCID, etc).

The publications extracted from reference lists in the full author publication list is the second unique feature of RISC in comparison with Web of Science and Scopus, where such publications can be found only by special option of reference search as secondary documents. This option is also realized in Google Scholar.

Organization profile
Organization profile includes the general official information about organization and its publication output.

Publication data include lists of documents with organizational affiliation, all publications of authors during the period of their work in organization and all publications of current staff regardless of affiliation mentioned. These options help to evaluate research output in organization and potential opportunities.

Analysis of publication activity of organization overviews the whole number of publications in RISC and citations received, number of authors affiliated with organization and other characteristics. Also, one can find there the value of h-index, g-index and i-index of organization.

Publications of the last 5 years are analyzed in detail, including the data on publications in different journal groups (Russian journals, foreign journals, RSCI journals, etc.), their citedness in RISC, number of publications that were cited at least once, distribution of publications by OECD fields of science.
Yearly bibliometric and altmetric indicators for the last 10 years are also available together with statistics for paper distribution by science disciplines, types of documents, organizations, authors, citations, number of coauthors.

**Journal profile**

Full journal information includes fields that make possible journal search by multiple parameters: journal title, publisher, ISSN, country, subject area, language, indexed/not in Web of Science or Scopus, availability of full texts and others.

Page with analysis of journal demonstrates a set of journal metrics. The essential indicators are the number of documents and citations received during the last 8 years and various statistical reports: distribution of indexed documents and references to them by subject areas, keywords, authors, organizations, type of citing publications, et al.
Access

The access to RISC is free to all users after registration. RISC and eLIBRARY.RU are widely used not only in Russian Federation. The number of registered users and top-25 countries by registered users are demonstrated in Figures 6 and 7 respectively.

Users have free access to the full texts of open access journals and to the services like creation the sets of articles, journals and authors. Almost 50% of full-text journals in RISC are in open access. The access to the full text in the journals under subscription is available to the researchers and students from institutional network if the institution is subscribed to these journals, or for individual researchers by payment for a certain article. The registered users can make their own remarks to a document, discuss it with other users and even evaluate the publication. These remarks and evaluations are available to other users and can be seen in altmetric section in publication description.
The usage of the database is shown in Figure 8. Remarkably, the ratio of views/downloads is rather stable over time.

**Analytics services**

RISC provides several standard forms of analytical reports mentioned above — the analysis of publication output of an author, organization and journal.

The registered user may create his own publication sets. The analysis of user-created publication sets presents a summary of the total number of publications, the number of papers in academic journals, the number of articles in journals included into the Web of Science or Scopus, the number of articles in journals included in the RISC core, the number of articles in journals included in the RSCI, the average impact factor of the journals in which the articles were published, the number of authors, the average number of publications per author, the total number of citations of publications, the average number of citations per article, the number of articles cited at least once, the number of self-citations (articles from the same set), h-index of the publication set.

**Journal metrics**

Like all citation databases, RISC allows to evaluate the quality of academic journals by citation metrics. There is a whole range of different indicators calculated for this purpose.

At first, there is a set of ‘impact factor-like’ indicators that show the average number of citations per document in a certain journal. Two-year and five-year impact factors with or without journal self-citations are calculated for each journal in RISC. Additionally, the two-year impact factor is calculated which includes citations from all document types from RISC, so the share of non-journal publications in the total number of citations to journal’s papers may be assessed.

It should also be noted that the high value of the impact factor does not guarantee the high quality of an academic journal. This index can be artificially inflated by self-citations or citations from the ‘friendly’ journals. Therefore, it should be considered in conjunction with other indicators calculated in the RISC. One must pay attention to the share of journal self-citations and its Herfindahl index for citing journals. High values of these parameters (greater than 40% for the self-citation index and more than 1,500 for the Herfindahl index) indicate that a significant proportion of cites to the journal come either from its own papers or from a very limited number of other periodicals.

In eLIBRARY.RU this index is also used for organizations mentioned as an affiliation of a citing author in journal articles. It helps to assess if the scientist is cited widely, not from its own institution.
The number of journal citations and self-citations, the average number of items in the reference list, citing and cited half-life is also calculated for RISC journals.

**Science Index journal indicator**

The special complex journal indicator is calculated in RISC — Science Index journal indicator. Its methodology includes normalization by OECD subject categories, by average size of reference lists in the science field, by chronological distribution of citations and the share of them leading to papers included to eLIBRARY.RU database. It resembles the SNIP indicator (Moed, 2010), but differs by citation window (Science Index uses 5 years instead of 3 in SNIP). Additional detail is that Herfindahl-Hirschman index is added to the methodology which weights how diverse are citations the journal receives.

This methodology helps to make cross-disciplinary comparisons and rank journals more accurately.

**Journal selection for RSCI**

The aim of the joint project of the company Thomson Reuters (its scientific department which is now ‘Clarivate Analytics’) and eLIBRARY.RU is to select the best Russian academic journals and make a separate database Russian Science Citation Index (RSCI) which is available at the Web of Science platform.

![Figure 12. Journals recommended by experts and included in RSCI](image)

Selection of the best journals from RISC for RSCI database at the Web of Science platform was made by bibliometric evaluation and peer expertise. The expert council was established. The council consists of the scientists and science administrators from leading institutions (Russian
Academy of Sciences and top Universities). For the expertise top-10% of scientists with high bibliometric indicators for every discipline were selected, it means that about 30,000 experts were invited. The final choice of journals was made by a working group when both the expertise and bibliometric analysis were combined. The results are shown in Fig. 12.

Finally, 652 journals were selected for RSCI. Distribution of RSCI journals by subject compared with RISC is shown in Figure 13.

**Conclusion**

Russian journals are aggregated now at the eLIBRARY.RU platform. The first and probably the most important point is that Russian journals have now become visible. All regional journals from distant regions now are available for researchers, at minimum at the level of titles/abstracts.

One of the main functions of science is communication (Merton, 1968). As sociologists of science think, if a brilliant research is not communicated to others, this is not a scientific achievement. So the creation of eLIBRARY.RU makes Russian science much better. We may even say that from classic sociological point of view the launch of such a database often turns non-science to science in Russia. Now a researcher from Moscow has a chance to communicate with a researcher from Vladivostok (more than 6,000 km distance), this is to say be alerted about his papers and be informed of his current research published in a local Vladivostok journal. This is very important for a science in a big country. And many of these papers can be read in full text at eLIBRARY.RU.
Moreover, the platform also helps to assess citedness of journals and their scientific level. One may make reliable evaluation of the quality of indexed journals, publication activity of authors and organizations. RISC includes much more Russian journals from social sciences and humanities than can be found in international citation databases, Web of Science and Scopus.

Today RISC is widely used for the analysis of Russian institutes and universities. For example, one case is given by Zibareva and Parmon (2012). Most probably, this trend will become more pronounced in the future.

Abstract
We present a large-scale analysis of the accuracy of citation data in the Web of Science and Scopus databases. The analysis is based on citations given in publications in Elsevier journals. We reveal significant data quality problems for both databases. Missing and incorrect references are important problems in Web of Science. Duplicate publications are a serious problem in Scopus.

Conference topic
Data accuracy and disambiguation

Introduction
Citation relations between publications are the cornerstone of many bibliometric analyses. For this reason, the availability of accurate citation data is essential for high-quality bibliometric studies. In this paper, we present a large-scale analysis of the accuracy of citation data in Web of Science (WoS) and Scopus, the two most important multidisciplinary bibliometric databases. Our work continues earlier research on this topic (e.g., Buchanan, 2006; Franceschini, Maisano, & Mastrogiacomo, 2013, 2015; García-Pérez, 2010; Olensky, Schmidt, & Van Eck, 2016). The analysis that we present focuses on citations given in publications that appeared in journals published by Elsevier.

The accuracy of citation data can be studied from two perspectives. On the one hand, we can study the extent to which the reference lists of publications are properly represented in the reference data in a bibliometric database. On the other hand, we can study the degree to which a bibliometric database, based on the reference data it contains, manages to correctly identify citation relations between publications indexed in the database. The first problem is about the accuracy of reference data, while the second problem is about the accuracy of citation matching. Our primary focus in this paper is on studying the accuracy of reference data, although we will also provide some insight into the accuracy of citation matching.

Data
We used the Elsevier ScienceDirect Article Retrieval API to obtain the reference lists of all Elsevier publications that appeared in the period 1987–2016 (except for a small share of publications not included in the subscription of our university). The reference lists were obtained in XML format. We refer to the data set that we obtained in this way as the Elsevier data set. Publications without references were excluded from this data set.

For each publication in the Elsevier data set, we tried to find corresponding publications in WoS and Scopus. In the case of WoS, we focused on publications of the document types article and review published in the period 1987–2016 and indexed in the Science Citation Index Expanded, the Social Sciences Citation Index, or the Arts & Humanities Citation Index. In the case of Scopus, we considered publications of the document types article, review, and conference paper published in the period 1996–2015. Publications from 2016 were not taken into account, because most of these publications are still missing in the most recent version of the Scopus database that we have available internally at our center. Publications from before 1996 were not taken into account because of the limited coverage of these publications in Scopus.
To link publications in the Elsevier data set to publications in WoS and Scopus, we first attempted to match publications based on DOI. If no DOI-based match could be obtained, we tried to match publications based on the combination of the name of the first author, the publication year, the volume number, and the first page number. A match was required for all four fields. In the case of matching based on the name of the first author, only the last name and the first initial of the author were taken into account.

Publications in the Elsevier data set that have been linked to publications in WoS and Scopus are referred to as linked publications. The analyses presented in this paper are restricted to these linked publications. Figure 1 shows both for WoS and for Scopus the number of linked publications per year.

![Figure 1. Time trend in the number of linked publications.](image)

The next step was to match the references in the linked publications in the Elsevier data set with publications in WoS and Scopus. References in the Elsevier data set do not include a DOI. Matching was therefore done based on the combination of the name of the first author, the publication year, the volume number, and the first page number. References for which a match could be made are referred to as linked references.

Table 1 reports some statistics summarizing the results of linking the Elsevier data set with WoS and Scopus.

**Results**

*Analysis based on the number of references in a publication*

We start by making a comparison for the linked publications of the number of references in the Elsevier data set and the number of references in WoS and Scopus. In this comparison, we
do not make use of the linking of references discussed above. We consider only the number of references in a publication. We distinguish between linked publications for which the number of references in WoS or Scopus is equal to, larger than, or smaller than the number of references in the Elsevier data set. A fourth class are linked publications that have no references at all in WoS or Scopus. Table 2 reports the share of the linked publications in WoS and Scopus belonging to the different classes. Time trends are presented in Figure 2.

Figure 2. Time trend in the classification of linked publications based on their number of references.

Figure 2 shows that in recent years there are no or almost no linked publications without references in WoS and Scopus. In the case of Scopus, for almost all linked publications the number of references in Scopus is the same as in the Elsevier data set. The situation is quite different in the case of WoS. A relatively small share of the linked publications have more references in WoS than in the Elsevier data set. Moreover, a large share of the linked publications have fewer references in WoS than in the Elsevier data set. To better understand why some linked publications have more references in WoS than in the Elsevier data set, we manually examined ten randomly selected cases. It turns out that a single reference in the Elsevier data set sometimes refers to multiple cited works. It seems that WoS aims to split up such a reference into multiple references, each of them referring to a single cited work. Based on the ten cases that we examined, we have the impression that the approach taken by WoS to split up references does not always give good results. In some cases, however, it works very well. We for instance found a publication (DOI: 10.1016/j.jorganchem.2015.04.038) that includes the following reference:

This is seen as a single reference in the Elsevier data set. In WoS, this reference has been correctly split up into the following three references:

GAUSS J, 1992, CHEM PHYS LETT, V191, P614
GAUSS J, 1993, J CHEM PHYS, V99, P3629
SCHAFER A, 1992, J CHEM PHYS, V97, P2571

In Scopus, the reference has not been split up. Instead, the reference has been truncated. In Scopus, it refers only to a single cited work. The other two cited works have simply been left out.

Of course, we also need to better understand why there are so many linked publications that have fewer references in WoS than in the Elsevier data set. The analysis reported below provides more insight into this issue.

Analysis based on linked references

We now present a second analysis. This analysis is based on the linked references identified using the approach described in the Data section. For each linked reference, we searched for the corresponding citation relation in WoS or Scopus. In the case of WoS, we used the citation relations identified by a citation matching algorithm developed at our center. We did not have access to the ‘official’ citation relations identified by the database producer, but our own citation relations have been shown to compare favorably with these ‘official’ citation relations (Olensky et al., 2016). In the case of Scopus, on the other hand, we did use the ‘official’ citation relations identified by the database producer.

Of the 136 million linked references in the WoS case (see Table 1), 0.9% did not have a corresponding citation relation. In the Scopus case, 1.2% of the 84 million linked references did not have a corresponding citation relation. Figure 3 shows the time trend in the percentage of linked references for which there is no corresponding citation relation in WoS or Scopus.

![Figure 3. Time trend in the percentage of linked references for which no corresponding citation relation was found in WoS or Scopus.](image)

As can be seen in Figure 3, for both databases the percentage of linked references without a corresponding citation relation has decreased significantly over time. In recent years, in the case of Scopus, about 1% of the linked references do not have a corresponding citation relation. This percentage is somewhat lower for WoS. The difference may at least partly be explained by the use of an advanced citation matching algorithm in the case of WoS.

Why do some linked references have no corresponding citation relation in WoS or Scopus? To answer this question, we manually examined a number of randomly selected linked
references for which there is no corresponding citation relation. We focused on linked references in publications that appeared in 2015. In the case of WoS, 0.7% of the linked references in publications from 2015 do not have a corresponding citation relation. Of the 125,583 linked references without a corresponding citation relation, we examined a random sample of 60 cases. It turns out that the 60 cases can be classified into the following four categories:

- **Missing reference (33 cases, 55.0%)**: The reference is missing in WoS (see also Buchanan, 2006; García-Pérez, 2010). Our examination revealed that in some cases multiple references are missing in the same publication. We found one case (DOI: 10.1016/j.virol.2015.02.016) in which the first part of the reference list of a publication is entirely missing. Interestingly, this turned out to coincide exactly with the references listed on one specific page in the PDF file of the publication, suggesting that even in 2015 indexing of Elsevier publications in WoS was still partly based on PDF files.

The problem of missing references explains why in the analysis based on linked publications discussed above we found that a significant share of the linked publications have fewer references in WoS than in the Elsevier data set.

- **Error in reference (16 cases, 26.7%)**: There is an error in the reference in WoS, such as an incorrect publication year or volume number.

- **Incorrect reference (10 cases, 16.7%)**: The reference has been replaced by a completely different reference (sometimes referred to as a ‘phantom reference’; García-Pérez, 2010). The latter reference has some similarity with the former one (e.g., name of the first author, publication year, and perhaps volume number or first page number), but apart from this it is completely different. Some examples of incorrect references are presented in Table 3. We consider incorrect references to be highly problematic, since they result in serious distortions in citation records.

- **No problem (1 case, 1.5%)**: There is no problem. A closer examination showed that for this linked reference there actually does exist a corresponding citation relation, but this citation relation had been overlooked by our algorithms.

In the case of Scopus, 1.2% of the linked references in publications from 2015 do not have a corresponding citation relation. Of the 73,598 linked references without a corresponding citation relation, we examined a random sample of 30 cases. The 30 cases can be classified into the following three categories:

### Table 3. Examples of incorrect references in WoS. Elements that the original reference and the incorrect reference in WoS have in common are shown in bold.

<table>
<thead>
<tr>
<th>Reference in WoS</th>
<th>Reference in original publication</th>
</tr>
</thead>
</table>

In the case of Scopus, 1.2% of the linked references in publications from 2015 do not have a corresponding citation relation. Of the 73,598 linked references without a corresponding citation relation, we examined a random sample of 30 cases. The 30 cases can be classified into the following three categories:
Missing reference (6 cases, 20.0%): The reference is missing in Scopus. In each of the six cases that we examined, we found that in fact the entire reference list of the citing publication is missing.

Duplicate publications (9 cases, 30.0%): The reference is available in Scopus, but there is a problem related to duplicate publications (Valderrama-Zurián, Aguilar-Moya, Melero-Fuentes, & Aleixandre-Benavent, 2015). There exist multiple records in Scopus for the publication cited in the reference. When creating citation relations, it is therefore not clear which record should be used for the cited publication. In the nine cases that we examined, we found that the Scopus citation matching algorithm had created a citation relation using an inferior record for the cited publication. The record is incomplete, while another more complete record could have been used as well.

Citation matching problem (15 cases, 50.0%): The reference is available in Scopus and a citation relation can be created, but for some reason the Scopus citation matching algorithm has failed to do so.

As mentioned above, the version of the Scopus database that we used in our analysis is not entirely up to date. We therefore also examined the 30 cases discussed above in the online version of Scopus. Interestingly, we found that 13 of the 30 cases have been corrected in the online version of Scopus, which seems to suggest that Scopus data quality has improved significantly during the past year.

Conclusions

Citation data suffers from inaccuracies both in WoS and in Scopus. However, the inaccuracies are of a quite different nature. Missing references are a quite significant problem in WoS. The problem of incorrect references is even more serious. This problem needs to be fixed urgently. In Scopus, the citation matching algorithm seems to need improvement. Moreover, duplicate publications (Valderrama-Zurián et al., 2015) represent an important data quality problem in Scopus that requires serious attention.

Our analysis has focused on citations given in publications in Elsevier journals. These publications represent a significant share of all publications indexed in WoS and Scopus. However, it is not clear to what extent our findings generalize to publications from other publishers.

Introduction
The state of under-representation of the humanities and social sciences in the global databases such as Web of Science and Scopus has become permanent and detrimental. But for scientometric research on mezzo (institutional) level local databases can successfully complement world indexes. The authors present case study of using unstructured data, deriving from University Website and then visually analysing. Cleaning and processing allows to identify metadata which describe academic activities in organizing different events at University. Another data source is University bibliographic database Expertus, the most complementary information resource concerning the publications of employees. This way, two different activities: publishing and organisational one can be compared for each faculty or equivalent division and thus evaluate collective impact in academic environment.

Data and metadata

Data collecting
Application form accessible at University Website https://www.umk.pl/badania/konferencje/ allows to collect such metadata about conferences as: Date, Title, Faculty, Organiser(s), Place, Leader, Secretary, Description. Downloaded data due to HTML format required semiautomatic cleaning. The relatively small records quantity \( N = 1344 \) allowed for quick estimation of similarities and relationships. Due to field about organizers units asymmetric matrix has been created for the quantitative representation of the intensity of cooperation in conference organizing. Asymmetry is connected with unequal roles of the organizer and co-organizer.

Data aggregation
All identified University units (over 300) were grouped into the main categories corresponding to 17 Faculties and one additional, General. Thus, for publishing and organisational activity, cumulative data according 18 categories was obtained.

In order to compare the received visualisations with the generated image according to the Web of Science data, the next level of grouping: faculties into scientific areas was performed. Ultimately, into study we involved domains, such as:
- humanities,
- natural science,
- life sciences,
- medicine/clinical sciences,
- engineering and technical science,
- social sciences.

Analysis
Graphs, maps and diagrams were used in the visualisations. To illustrate the dynamics of publishing activity for each Faculty area chart is used as the most effective in the trend study (Fig.1).

![Figure 1. Dynamics of faculties publishing per year.](image)
The band width exposes publication quantity a year for each faculty. It allows to observe all changes and parallel to capture information which is the most effective unit for analyzed period.

For comparison local and global databases, ring charts were used. Figure 2 presents domain structure for three data sources. As mentioned before, standardized categorization was applied. All domains colored by scheme, which is available at InCites reports: https://incites.thomsonreuters.com/. Outer ring at Fig. 2 shows the best representation of publications for humanity and social sciences according local database –Expertus.
Figure 2. Domain structure of publications of University employees according three databases.

The visualisation of social activities working on joint ventures (conferences, symposia, seminars) can be accomplished by using graphs (Garfield, 1994). We used the legible kind of graph – circular network layout (Fig. 3). Band width indicates the intensity of cooperation in organizing conferences. This way we discovered the close relations in such kind of activity between faculties (for example history and politology).

In order to prove this observation NLP techniques were used. Texts of conferences description were processed by Ward’s clusters analysis (1963) and visualised - the result we can see on Figure 4. Dendrogram presents faculties similarity based on texts clustering. Visualisation results confirmed previous assumptions according relationships between organizational units.

The set of metadata predisposes for extending mapping and broadening the perspective of study.

We can also carry out geomapping and provide analysis of foreign cooperation of University. We can compare publishing versus mobility for each year, but all maps exceed the scope of current work.

Figure 3. Co-organizing local events by different faculties.

Figure 4. Co-organizing local events by different faculties.

Summary

The authors present analytical possibilities of local database in confrontation with global scientometric indexes. Humanity and social sciences became visible on science map based on local data. Visualisation techniques were chosen according data type and analysis purposes (Osiniska & Malak, 2016). Thus, circular graph shows cooperation between units, area chart – dynamics, ring diagram – comparison and structure and dendrogram – close and far similarity. Authors proposed publishing activity of scientists to complement by alternative one - organisational and this way to broaden evaluation framework.

Evaluating efficiency of digital databases used for scientific production in Chinese universities

Jianpin Wang 1,2  Rongying Zhao 1,2 *

1 Research Center for Chinese Science Evaluation, Wuhan University, Wuhan, China
2 School of Information Management, Wuhan University, Wuhan, China

Abstract: It is essential for universities to make optimum use of the resources available for scientific research. The evaluation of efficiency can provide information for making evidence-based decisions. Online databases are currently the avenues by which researchers have access to the scientific-technological information required to carry out their activities. In this work, we, using Data Envelopment Analysis (DEA) and bibliometric method, evaluate the efficiency of the online databases used for scientific production in China in 2015. We choose "Project 985" universities as the sample. The DEA inputs include the number of Databases (DBs) and the number of full-time professors (FTPs), and the output concludes the number of documents indexed in Scopus. The results reveal that the use of inputs to produce scientific publications is inefficient at most of the analyzed universities. The policy recommendations are: improving the libraries’ research support service, promoting the use of open access resources, adjusting policies of incentives for research.

Introduction

In the Information and Knowledge Society, the most important contribution by universities is the generation of Intellectual Capital (Ramezan, 2011). At the level of universities, the production of Intellectual Capital is concretized in the consolidation of networks with other stakeholders and in the production of documents (articles, books, book chapters, patents, Conferences, publishers, among other scientific productions). In order to leverage the generation of Intellectual Capital, the availability of financial capital in universities is imperative (Huggins, 2008). Since the availability of financial capital is restricted in higher education systems (HES) in developing countries and sometimes in developed countries, efficient management of economic resources is a strategic step (Abbott & Doucouliagos, 2003; Kao & Hung, 2008). Therefore, the efficiency analysis of HES has received a growing attention for the formulation of policies related to the optimized use of resources to improve quality and impact of teaching and research.

As to Chinese HES, the greatest challenge is how to build world-class universities, as well as its projection towards the dynamics of globalization driven by Information Communications and Technology (ICT). This is not only the important missions of Chinese HES in the 21st century, but also the important measure to realize the great rejuvenation of the Chinese nation. Then there are multiple constraints that constitute this problem. Two are mentioned by way of illustration. The first restriction is related to the quality of teaching and research. During the past thirty years, Chinese HES developed so fast that it has become the world’s largest higher education system. Regarding the quality of 2560 higher education institutions (technical, technological and university institutions) however, only 38 of them are “Project 985” (1.5%) and 116 are “211-project” (4.5%). At an international comparative level, according to QS University Rankings, there are only 4 Chinese universities within the list of the first 100: Tsinghua University (25), Peking University (41), Fudan University (51), Shanghai Jiaotong University (70). The second restriction is related to funding. Chinese expenditure on higher education for every student as a percentage of GDP has been declining since China began expanding university enrolment in 1999.

To summarize, In Chinese HES the weaknesses persist, new problems emerge, and the economic resources to deal with this are increasingly scarce. For these reasons, it is necessary to ascertain whether the universities are getting an optimal research output with the financial and human resources that they use. So, expanding and deepening the spectrum of efficiency studies in Chinese HES is a relevant task in different scenarios.

Studies on efficiency in HES have crossed four paths: (1) Public policy (Geva-May, 2001); (2) Universities, at the aggregate or individual level (ARCELUS & Coleman, 1997; Chen & Chen, 2011; Johnes, 2006; Klimova Kozyrev & Babkin, 2016; Shen, Wu, Business, & University, 2016); (3) Academic departments and research units (institutes, centers, groups, among others) (Agasisti, Catalano, Landoni, & Verganti, 2012; Wang & Guan, 2005); And (4) university libraries (Simon Simon & Arias, 2011; Sommersguterreichmann, 2010). As can be seen, the literature on the efficiency of HES is large, however, in the context of the Chinese HES, the studies on efficiency of digital database (DB) have not been found. Based on these studies, this work seeks to contribute to the evaluation of DB efficiency in Chinese universities in a new way.

Universities produce knowledge through research, they disseminate it by training graduates and postgraduates and by publishing the results of the research (Pastor & Serrano, 2016). The review of literature in the university efficiency studies finds two ubiquitous variables: (1) The number of teachers or researchers; And (2) Research results or documents.

On the other hand, we identify the absence of an extremely important variable for the current context of scientific research: ICT (Wang, Carley, Zeng, & Mao, 2007; Wuchty Jones & Uzzi, 2007). According to the World Bank, ICT is the hardware set, Software, networks and media.
used for the collection, storage, processing, transmission, and presentation of data, information, knowledge, services, and applications. ICT is restructuring the institutional fabric of higher education and influencing the academic work done by university teachers. Higher education institutions are not only producing and supporting technological innovations but are at the same time intensive users and subject to the limitations of ICT (Välimaa & Hoffman, 2008). Therefore, this study will focus on DB, which are currently the avenues by which researchers have access to the scientific-technological information required to carry out their activities.

With the above, this study has the objective of evaluating the efficiency in the use of the DBs consulted for the scientific production by the "Project 985" universities. Building on the advances identified in the literature, this work contributes on three fronts: (1) An overview of the inventory of the DBs of "Project 985" universities is presented; In the search of literature, a similar contribution was not found, therefore, this study advances significantly in this sense; (2) It presents a relative evaluation of efficiency in the use of these DBs by full-time teachers using DEA method. On one hand, to our knowledge, there is no article devoted to the efficiency evaluation of universities’ DB in China. On the other, the DEA technique has long been utilized as an invaluable tool for conducting efficiency evaluation, but its combination with bibliometric method has been relatively slow; And (3) An updated description of the scientific production of documents indexed in Scopus by "Project 985" universities during the period of 1996-2015 is presented.

In short, this study has the potential to help management determine proper policies and be used as a tool to optimize the investment of Chinese universities for research, since the relative decision-making entities do not currently have the tools to make such evaluation.

The study is organized as follows. After this introduction, Section 2 describes the methodology, the sample of universities studied, and the additional sources consulted. Section 3 very briefly presents the results analysis. The last section (Section 4) discusses the study's conclusions, makes some recommendations, and offers suggestions for future research.

Methodology

Data Envelopment Analysis

The traditional economist definition of efficiency is: The optimal use of inputs to achieve the greatest output (Cook & Seiford, 2009). In this study, the efficiency is measured empirically using Data Envelopment Analysis (DEA), a mathematical optimization model introduced by Charnes et al. (CharnesCooper & Rhodes, 1978) that generalized Farrell’s single input/output measure into a multiple input/multiple-output technique. DEA model estimates the convex hull of the production function by a linear programming optimization, and the inefficiency is defined by a convex envelope of the data.

In our analysis, the extension CCR will be applied. This extension has two orientations: (1) Products (CCR-Outputs); Or (2) Inputs (CCR-Inputs). The first orientation seeks to maximize results with the same inputs. The second orientation seeks to reduce inputs to maintain results. This study follows the first orientation.

Charnes et al. (1978) proposed that the efficiency measure of every DMU is obtained by obtaining the maximum of a ratio between results and weighted inputs subject to the condition that the similar proportions of each DMU should be less than or equal to unity. In this way, the definition of the classical ratio of engineering is generalized: single-output / single-input to a form of multiple-outputs / multiple-inputs, without requiring a priori weight assignment. In this sense, the model is formulated formally:

$$\max h_0 = \frac{\sum_{k=1}^5 u_k y_{k0}}{\sum_{i=1}^m v_i x_{i0}}$$

1097
\[
\text{S.T. } \frac{\sum_{k=1}^{s} u_k y_{kj}}{\sum_{i=1}^{m} v_i x_{ij}} \leq 1; j = 1, \ldots, n. \\
v_k, v_i \geq 0; k = 1, \ldots, s; i = 1, \ldots, m.
\]

Where \( y_{kj}, x_{ij} \) (all positive) are the outputs and inputs of the DMUs analyzed \((j)\); And that \( u_k, v_i \geq 0 \) are the weighted variables to be determined when solving the problem. The efficiency of each of the members of the DMU \((j = 1, \ldots, n)\) is evaluated relatively to the others. Thus, the efficiency index extracted for each DMU is 0 to 1, and the DMU with index 1 are those that delimit the border of efficiency.

**Sample and data**

The DMU sample defined for this study are the 38 Chinese "Project 985" universities (Minzu University of China is not concluded because no documents generated by this universities indexed in Scopus)( shown in Table 1). These universities were selected for four reasons. The first, because these universities generate about 44.4% of the national scientific production. The second, because most teachers with doctorates in the country are linked to these institutions. The third, because these universities are most likely to become the world-class university. The fourth, because most of national investment in Research and Development (R&D) is concentrated in these universities.

The inputs defined for the DEA are two: (1) the number of DBs (digital databases of the library system of each university); And (2) the number of full-time professors (FTPs) (See Table 1). To know the number of DBs and FTPs, we go to the web site of each university of the sample. This investigation took place in the middle of 2016. The number of DBs and FTPs all correspond to 2015. These two inputs were defined because at present the DBs are the most consulted sources by the FTPs, being these the ones in charge of carrying out activities of investigation, teaching, and extension.

The output defined for the DEA are the documents generated by the "Project 985" universities and indexed in Scopus in 2015 (See Table 1). Scopus was chosen because it is the most complete indexed documents database in the market. They took into account the documents of all disciplines (Health Sciences, Life Sciences, Physical Sciences and Social Sciences). All types of documents (articles, reviews, articles in the press, books, book chapters, conference articles, conference reports, letters, editorials, notes, short articles, business articles or articles and errata) were also taken into account.

Results

In the first instance, a regional picture is presented on the performance of China in terms of scientific production indexed in Scopus during the period 1996-2015 (Table 2). Subsequently, a description of the national affiliation of the authors of the documents for 2015 (Figure 1) is presented. Then, an overview of the documents is presented according to its discipline and category for 2015 (Figure 2 and Figure 3). Finally, the results of the DEA are presented (Table 3 and Figure 4). In this vein, Table 2 presents the top ten countries in the scientific production ladder in the world.

</table>

As shown in Table 2, the total number of the Chinese scientific documents indexed in SCOPUS was 4,076,414 during the year of 1996-2015, ranking in the second place while the United States was 9,36,233, more than two-fold as China, ranking in the first place. On the other hand, during the year of 1996-2015, the number of the Chinese citations was 24,175,067, ranking in the seventh place in the world, and the number of Citations per document was 5.93 times, far below the world average level which was 14.16; Another aspect to highlight is the Chinese H-index (563), which is only higher than India in these ten countries. All this suggests that China has become a large country of scientific production, while there is still wide gap in quality compared with the advanced countries.

Source: Scopus, 2015.

**Figure 1. National affiliation of the authors of the documents in 2015**

Another aspect to highlight is the international collaboration and exchange in science and technology have been expanded. As shown in Figure 1, in 2015 there are 444,804 documents indexed in Scopus where at least one of the authors has affiliation to a Chinese entity, followed by the United States with 41,109 and the United Kingdom with 9,314. From this it can be inferred that Chinese partners in scientific production are United States and United Kingdom. There is also substantial collaboration with Australia (3th place) and Hong Kong (4th place).

Source: Scopus, 2015.

**Figure 2. Production of documents by discipline**

As shown in Figure 2, the discipline with the greatest number of documents was engineering with 143,667 (32.3%), followed by medicine with 91,645 (20.6%), and material science with 1,046 (14.8%). On the other hand, the production in social sciences, being in the categories of
others, was not displayed separately. Thus, it is possible to infer that more than 65.9% of Chinese scientific production in 2015 was generated in natural science disciplines such as engineering, medicine, material science, physics and astronomy, chemistry, computer science.

Source: Scopus, 2015.

Figure 3. Production by type of documents

As can be seen in Figure 3, the largest number of documents corresponds to the category of articles with 365,593 (82.2%), followed by conference articles with 58,802 (13.2%), and reviews with 9,681 (2.2%).

Table 3 presents the efficiency index. It is important to emphasize that the efficiency index extracted from the DEA for each DMU is from 0 to 1, with DMUs with index 1 that delimit the efficiency frontier. As shown in Table 3, the University with the most DB is Peking University with 247. The University with the least DB is Renmin University of China with 70. The average is 140 DB, then 39.47% of the sample universities are above this average. The University with the most FTP is Peking University with 2,221. The University with the least FTP is National University of Defense Technology with 320. The average is 945, then 36.84% of the universities in the sample are above this average. The University with the largest production of documents is Tsinghua University with 12,630. The University with the lowest production is Renmin University of China with 894. The average number of documents is 5,197, and 50% of the sample are above this average. In summary, the universities of the sample present an asymmetry between the availability of inputs (DB and FTP) and outputs (documents). This is evident from the wide standard deviations.

On the other hand, the mean of the efficiency index (0.575) is higher than the median (0.545). This means that the distribution of the data is not symmetric and positively biased. Thus, universities with a higher efficiency rate than the average are less frequent in the sample. The two universities that bordered the efficiency frontier were Shanghai Jiaotong University and Beihang University (5.3% of the sample). Two universities obtained an efficiency index higher than 0.90, Harbin Institute of Technology and Tsinghua University (5.3% of the sample). 11 universities (28.9% of the sample) obtained an efficiency index in the range of 0.6 to 0.8. Most universities, equivalent to twenty-three (60.5% of the sample), are less than or equal to 0.6. (See Figure 4).

In summary, a polarization in the efficient use of DB by FTP for the production of documents is evidenced. While 2 (5.3%) of the universities in the country make efficient use of resources for the advance of scientific production, the efficiencies in most of the universities are quite low. In other words, the relationship between human resources and scientific-technological
information resources, and the production of documents, is weak. In addition, there is no efficient use of these resources in general.

Conclusions

The generation of knowledge on the part of the universities is a pillar strategy for the progress of the Information and knowledge Society. In the case of China several restrictions are identified that impede the progress of the higher education system in this regard, including restrictions on quality, and budget. In this sense, it is essential to make optimum use of the resources available for scientific research. However, the availability of inputs that provide information for making evidence-based decisions is restricted. This study seeks to contribute to this gap through an evaluation of efficiency in the use of DB for scientific production by the "Project 985" universities, using DEA and bibliometric method.

China has performed relatively well for it is the second largest country in the quantity of scientific production in the world, while there is still wide gap in quality compared with the advanced countries.

With regard to the co-authors of documents generated by researchers, the majority is in the United States and United Kingdom, above the collaboration with Australia.

As for the areas of knowledge, one of the greatest production is engineering, followed by medicine, and material sciences. Faced with document types, most focus on scientific articles, followed by conference articles, and reviews.

Regarding to the evaluation of efficiency in the use of database for scientific production, its horizon is asymmetric. In addition, the average of FTP of the 38 universities is 945, of which, only 36.84% are above this level. This exhibits an obvious concentration. Faced with ownership in the number of BD, only 39.47% of the sampled universities are above average (140). With regard to document production, only 50% of the sampled universities are above average (5197). Regarding the efficiency index, only 44.7% of the universities in the sample were above average (0.575).

As a point of reference, two of the 38 universities in the sample efficiently use both databases and their research staff for document generation. Finally, it was observed that more than 60% of the 38 universities are below 0.6 of efficiency, where universities with sufficient resources have the performance that do not agreed the efficiency frontier. In other words, the relationship between human resources and scientific-technological information resources, and the production of documents, is weak. Moreover, there is no efficient use of these resources in general.
From this perspective, this paper suggests three recommendations. The policy recommendations are: improving the libraries’ research support service, promoting the use of open access resources, and adjusting policies of incentives for research.

The first recommendation aims to deploy alternative strategies to help the researchers in university achieve eResearch, which refers to the use of information technology to support existing and new forms of research. Some Australian universities have already made some headway there. In order to create a good environment, the information management policy and development trend need to be understood and analyzed; respects of personnel, the Libraries should explore their tasks, the change of their role and the researchers’ demand, so as to become partners of academic community; at the technical level, the libraries should, based on the system platform, concentrate on appropriately describing and effectively uncovering the data, which can promote the research collaboration and innovation (Wilkinson & Treloar, 2008).

The second recommendation suggests that it is necessary to consider the trend and the impact of open access scientific literature. Open access scientific literature allows free, online and peer-reviewed scientific production online. According to the Joint Information Systems Committee (JISC, 2008), open access literature is an alternative for institutions that can not acquire high-priced databases. For its part, the United Nations Educational, Scientific and Cultural Organization (UNESCO) at the World Open Educational Resources Congress recommended that all Member States implement freely available resources at both levels of formal and informal education (Hoosen, 2012).

The third line of recommendations expresses the need to formulate alternative policies for research incentives. According to Franzoni et al. (Franzoni & Stephan, 2011), publication incentive policies involving money bonuses increase the number of articles submitted for review but not the acceptance rate for publication. In fact, the acceptance rate has a negative correlation with the incentive policies based on money bonuses. Additionally, it is proposed that the incentives associated with the academic career possibilities are those that actually have a correlation with the quantity and quality of published research. These policies implemented in countries such as Spain or Germany make access to higher educational levels, promotion, and salary dependent on the performance of researchers, rather than the publication bonus.

In summary, the perspectives on the growth of the scientific production in China are not conclusive. While there was a notable performance in the past which has made the country a visible place in the world, it is necessary to strengthen research capacities in universities as a whole, not only the “Project 985” universities. Faced with the current scenario on the use of DB by FTPs for document production, most universities have to reevaluate their relative performance and propose alternative strategies, such as the improvement of libraries’ research support service, the use of free resources, and adjustment of research incentive policies. Future research in this area could increase the sample of higher education institutions as a whole, not just the "Project 985" universities. They could also take into account the impact of the documents, not only on research documents but also on patents, in order to trace the impact of research on the productive sector.

Acknowledgments
This paper is supported by National Social Science Foundation in China (Grant No.16BTQ055). The authors would like to thank Prof. Junping Qiu who is in Research Center for Chinese Science Evaluation for his valuable comments and suggestions to improve the quality of the manuscript.

Abstract
Research funding based on scientific metrics is strongly required; however, navigating the funding landscape is challenging. Conventional techniques that use intercitation and co-citation cannot be utilized for ongoing projects. Therefore, to grasp research projects on grants and visualize their relationship, this paper proposes to locate projects in a multi-dimensional space using a paragraph vector technique with an entropy-based clustering method. After describing our novel method, we provide details of the experiments we conducted to show that the proposed method successfully formed meaningful project clusters from 25,607 project descriptions from the 7th Framework Programme. Finally, we identify significant relationships from the project map, e.g., projects with similarities in different subject categories and projects bridging different categories.

Conference Topic
Knowledge discovery and data mining, Mapping and visualization

Introduction
Information about research projects is important to investigators, policy analysts, advocacy organizations, and funding agencies. Thus, there is a need to globally analyze research projects funded by grants and visualize their relationships. However, current quantitative approaches to understanding research activities focus on what authors tell us about past accomplishments through analysis of published research papers, and thus most maps of science from literature characterize what was accomplished after the fact. Therefore, this paper focuses on what researchers want to work on and creating a map characterizing what is currently being attempted on research projects in order to provide new insights.

Most funding agencies have their own categories or taxonomy to classify projects. However, even if two projects are assigned the same category, relationships, such as any distance and semantics, may not be found, and projects may be multifaceted and thus have several overlapping categories. Funding agencies also use different categories, and there is no comprehensive scheme to characterize projects; thus, projects cannot be compared between different agencies.

Automatic topic extraction from research projects using lexical approaches, such as Probabilistic Latent Semantic Analysis (pLSA) (Steyvers & Griffiths, 2007) and Latent Dirichlet Allocation (LDA) (Blei, Ng & Jordan, 2003), has been investigated. However, the relationships between projects cannot be measured directly. Moreover, research project descriptions are limited and do not include attributes, such as citations and references. Thus, techniques using intercitation and co-citation cannot be utilized, although projects will eventually include articles in their research results.

Recently, natural language processing (NLP) techniques, e.g., word/paragraph embedding, have been proposed to find relationships between unstructured documents. Such embedding techniques represent words and paragraphs as real-valued vectors of several hundred dimensions. Then, the types and degrees of the semantic relations among the vectors are calculated by the similarities between vectors. This paper proposes a method to extract relationships between research projects using word/paragraph vectors. In addition, to address
an unclustered problem associated with paragraph vectors, we introduce an entropy-based clustering method for word vectors to create concept vectors.

The remainder of this paper is organized as follows. Section 2 discusses related work, and after the introduction of the dataset Section 3 describes a baseline method and the proposed method for extracting relationships between research projects. Experiments and evaluations are described in Section 4, and conclusions and suggestions for future work are given in Section 5.

**Related Work**

As described previously, funding agencies and publishers generally have their own classification systems. In the 7th Framework Programme for European Research and Technological Development (FP7), most projects have three-digit subject index classification (SIC) codes that represent academic subjects, and some projects have more than one code. Thus, interdisciplinary projects can be found by searching multi-labelled projects; however, it is difficult to find similar projects in a simple manner. Moreover, comparison of articles with Association for Computing Machinery (ACM) classification (https://www.acm.org/publications/class-2012) or Springer Nature classification requires taxonomy exchanges.

Previous studies have examined automatic topic classification based on content, such as documents and articles. One uses LDA (Griffiths & Steyvers, 2004) to find the five most probable words in the topics, and each document is viewed as a mixture of topics. Thus, this approach can classify documents across different agencies and publishers. However, the relationship between any pair of projects/articles, such as similarity and correlation, cannot be computed directly.

In this regard, the NIH Visual Browser (Talley et al., 2011; Herr et al., 2009) (http://nihmaps.org/index.php) computed the similarity between projects as the mixture of classification probability to each topic based on pLSA, using the average symmetric Kullback-Leibler divergence function (Kullback & Leibler, 1951). However, this similarity is a combination of probabilities, i.e., it is not derived from actual content semantics.

In another study, a hierarchically structured set of topics with Springer Nature Classification tags was created from Springer Nature Proceeding papers based on an ontology (Osborne et al., 2016). However, the sources were limited to computer science and the similarity or distance between pairwise articles could not be computed.

In a broader sense, mapping projects funded under the FP7 has been visualized based on articles by project members in the Web of Science bibliographic database by examining co-authorship and co-citation patterns (Salah et al., 2013). In addition, Maps of Science (http://mapofscience.com/) is a website that provides the Sci2Tool visualization tools (Borner, 2013) and maps of journals and documents (Boyack, Klavans & Borner, 2005). Here the similarity between journals is calculated using some metrics, such as cosine and Jaccard similarity, based on the attributes of journals (including intercitation and co-citation). Note that these maps promote interdisciplinary research collaboration but do not directly represent project relations.

In contrast, a word/paragraph vector, which is a distributed representation of words and paragraphs, is attracting attention in NLP. Assuming that context determines the meaning of a word (Firth, 1957), words appearing in similar contexts are considered to have similar meaning. In the basic form, a word vector is represented as a matrix whose elements are the co-occurrence frequencies between a word $w$ with a certain usage frequency in the corpus and words within a fixed window size $c$ from $w$. A popular representation of word vectors is word2vec proposed by Google (Mikolov et al., 2013a; Mikolov et al., 2013b). Word2vec creates word vectors using
a two-layered neural network obtained by a skip-gram model with negative sampling. Specifically, word vector is obtained by calculating the maximum likelihood of objective function $L$ in Eq. 1, where $T$ is the number of words with a certain usage frequency in the corpus. Word2vec clusters words with similar concepts in a vector space.

$$L = \frac{1}{T} \sum_{t=1}^{T} \sum_{-c \leq j \leq c, j \neq 0} \log p(w_{t+j}|w_t)$$ (1)

Additionally, Le and Mikolov (2014) proposed a paragraph vector that learns fixed-length feature representations using a two-layered neural network from variable-length pieces of texts, such as sentences, paragraphs, and documents. A paragraph vector is considered another word in a paragraph and is shared across all contexts generated from the same paragraph but not across paragraphs. The contexts are fixed-length and sampled from a sliding window over the paragraph. The paragraph vectors are computed by fixing the word vectors and training the new paragraph vector until convergence, as shown in Eq.2.

$$L = \sum_{t=1}^{T} \log p(w_t|w_{t-c}, ..., w_{t+c}, d_i)$$ (2)

, where $d_i$ is a vector for a paragraph $i$ that includes $w_t$. While word vectors are shared across paragraphs, paragraph vectors are unique among paragraphs and represent the topics of the paragraphs. Thus, by considering word order, paragraph vectors can also address the weakness of bag-of-words models in LDA and pLSA. Therefore, paragraph vectors are considered more accurate representations of the semantics of the content. As a result, we can input vectors directly into analysis using machine learning and clustering techniques to find similar projects/articles in different academic subjects and the relationships between projects/articles from different agencies and publishers.

**Extraction of Project Relationships**

This section introduces our experimental dataset and then describes a baseline method and the proposed method to extract relationships between research projects.

**Funding description dataset**

In this paper, we analyzed project information from FP7 obtained from the Community Research and Development Information Service (CORDIS) website (http://cordis.europa.eu/fp7/) for the following reasons.

- FP7 includes several research areas, from bioscience to computer science.
- Most projects have been completed; thus, the entire structure is included.
- Projects are classified by more than 70 subject terms, i.e., SIC codes.

Precisely, our experimental dataset consists of the titles and descriptions of 25,607 FP7 projects from 2007 to 2013, including 305,819 sentences in total. All words in the sentences were tokenized and lemmatized before creating the following vector space.

**Paragraph Vectors as Baseline**

Before introducing the proposed method, this section presents a problem in applying the paragraph vectors for research project descriptions.
We implemented the paragraph embedding technique using the Deep Learning Library for Java (https://deeplearning4j.org). Then, we constructed paragraph vectors for 25,607 FP7 projects. The hyperparameters were set empirically through experiments as follows; 500 dimensions for 66,830 words that appeared more than five times, the window size \( c \) is 10, and the learning rate and the minimum learning rate are 0.025 and 0.0001 with an adaptive gradient algorithm (AdaGrad), respectively. The learning model is a Distributed Memory model (PV-DM) with hierarchical softmax.

In Fig. 1, each dot represents a project, and the distance between projects is the cosine similarity of the paragraph vectors. As a result, we found that projects are scattered and not clustered by any subject or discipline in the vector space. Most projects are connected to a small number of projects. Thus, it is difficult to grasp trends and compare an ordinary classification system, such as SIC codes. Looking closely at the vector space, some reasons for this unclustered problem are that each word with nearly the same meaning has slightly different word vectors, and shared but unimportant words are also considered the commonality of paragraphs. In fact, Le and Mikolov (2014) stated that classification accuracy with multiple categories was less than 50%. Thus, to address this problem, we introduce an entropy-based clustering method for the word vectors before constructing the paragraph vectors.

**Paragraph Vectors with Entropy-based Clustering of Word Vectors**

This section proposes a method for constructing concept clusters of word vectors, aiming to make paragraph vectors meaningful groups from the scientific and technological point of view. The fact that synonyms tend to gather in a word vector space indicates that the semantics of a word spatially spread to a certain distance. This observation is also suggested in related literature (Vilnis & McCallum, 2015). Thus, to unify word vectors of the same concept, excluding trivial common words, we generated concept vectors of the word vectors based on the significance of each concept. The proposed flow is as follows. We first extracted 19,685...
concepts (broader terms) with more than one hyponyms (narrower terms) from the JST science and technology thesaurus. The JST thesaurus primarily consists of keywords that have been frequently indexed in 36 million papers accumulated by the JST since 1975. Currently, this thesaurus includes approximately 276,179 terms with English and Japanese notations in 14 categories from bioscience and computer science to civil engineering. The JST thesaurus is publicly accessible from Web APIs in the J-GLOBAL website (http://jglobal.jst.go.jp/en/), along with the visualization tool Thesaurus Map (http://thesaurus-map.jst.go.jp/jisho/fullIF/index.html (in Japanese)). We then calculated the information entropy (Shannon, 1948) of each concept in the FP7 projects. Next, after creating concept clusters according to the degree of entropy, we unified all word vectors in the same concept cluster to a concept vector and constructed paragraph vectors based on the concept vectors. The overall flow is shown in Fig. 2.

Figure 2. Construction of paragraph vectors based on concept vectors.

Shannon's entropy in information theory is an estimate of event informativeness. Thus, we used this entropy to measure the semantic diversity of a concept that is an idea borrowed from Santus et al., (2014).

Figure 3. Concepts in the JST thesaurus.
As shown in Fig. 3 and Eq. 3, we calculated the entropy of a concept \( C \) considering the appearance frequencies of a hypernym \( T_0 \) corresponding to the concept and its hyponyms \( T_1 \ldots T_n \) as an event probability. The frequencies of synonyms \( S_{i0} \ldots S_{im} \) of term \( T_i \) were summarized to a corresponding concept. Here, \( p(S_{ij}|C) \) is the probability of word \( S_{ij} \) given concept \( C \) and term \( T_i \). For each concept in the JST thesaurus, we calculated the entropy \( H(C) \) in the FP7 dataset. As the probabilities of events become equal, \( H(C) \) increases. If only particular events occur, \( H(C) \) is reduced due to low informativeness. Thus, the proposed entropy of a concept increases when a hypernym and hyponyms that construct a concept appear with a certain frequency in the dataset, respectively. Therefore, the degree of entropy indicates the semantic diversity of a concept. Then, assuming that the degree of entropy and the spatial size of a concept in a word vector space are proportional to a certain extent, we split the word vector space into concept clusters. In fact, our preliminary experiment indicated that the entropy of a concept has high correlation \( R = 0.602 \) with the maximum Euclidean distance of hyponyms in the concept in a vector space, at least while the entropy is rather high. Specifically, we modified a clustering method called \( x \)-means (Pelleg & Moore, 2000) to refine clusters by repeatedly subdividing them until the defined criterion was satisfied. In our method, we set the determination condition as shown in Eq. 4. This condition represents that the vector space \( w_0 \ldots w_n \) is subdivided according to the ratio of two words \( w_i, w_j \) with the highest entropies \( E(i), E(j) \) in a cluster. Each cluster is subdivided until entropy becomes under 0.25 (threshold of the top 1.5%) or the number of elements in a cluster is less than 10. These parameters were also determined empirically through experiments.

\[
C(w) = \begin{cases} 
C(w_i) & (E(i) > \frac{||w_m - w_i||}{||w_m - w_j||}) \\
C(w_j) & \text{(otherwise)}
\end{cases}
\]

(4)

, where \( C(w) \) is a concept vector of \( w \). After generating 1,260 concept clusters from 66,830 word vectors, we considered the centroid of all vectors in a cluster as a concept vector. Then, we constructed paragraph vectors based on the concept vectors rather than from each word vector, as shown in Eq. 5.

\[
L = \sum_{t=1}^{T} \log p(C(w_t)|C(w_{t-c}), ..., C(w_{t+c}), d_t)
\]

(5)

The above process is expected to have the following effects. Using concepts with high entropy included in the JST thesaurus, which are significant in scientific and technological contexts, as common points with each paragraph vector (excluding trivial words), paragraph vectors can comprise meaningful groups in the vector space. Simultaneously, unknown synonyms and closely related words not defined in the thesaurus can be included in the concept vector if they are in the same cluster. Taking the centroid vector as a representative vector in a cluster is to separate each concept vector as much as possible to form a clear difference in the vector space.

**Experiments and Evaluation**

The Distributed Recursive Graph Layout (DrL) algorithm, which produces edge-weighted force directed graphs, was used to visualize the relationships between projects. The inputs to the DrL
algorithm are pairwise similarities, where the weight of each edge in the network represents the similarity between two adjunct projects. The DrL algorithm produces a layout wherein similar nodes are placed close to one another and shows the local clustering of related nodes and the global structure of related clusters. As shown in Fig. 4, we computed 328 million cosine similarities for all pairs of the 25,607 projects; however, we only kept those that were above a given threshold as edges.

Figures 1 and 4 show results obtained with the same hyperparameters for the baseline and proposed methods, respectively. We confirm that the proposed method (Fig. 4) has several clusters in the paragraph vectors compared to the baseline method (Fig. 1). For more quantitative comparison, Figure 5 shows the relationships between the cosine similarities and the number of edges, and the relationship between degree centrality and the number of nodes (i.e., projects) in the case of the cosine similarities of >0.35. As a result, we confirmed that
edges with higher cosine similarity and nodes with higher degrees increase. Therefore, note that the numbers of projects appeared in Figs. 1 and 4 are different when the figures have the same edge threshold.

Figure 5. Comparison between paragraph vectors and ones with entropy clustering.

For qualitative evaluation, we compared the map with the categories of the FP7 projects, i.e., SIC codes. Then, we focused on the middles of clusters, which are centers of research projects, the edges of clusters, which are novel projects because of the longest distance from the center, and also bridges in a gradient between clusters. These bridge projects provide information about the relationships and interdisciplinary approaches between different subjects and also suggest potential areas for future projects for funding agencies, since new clusters may be created on the bridges in future.
Here, we describe four example findings from the obtained funding map. In Fig. 6 corresponding to area A1 in Fig. 4, the middle cluster is the biggest cluster including more than 5,000 projects, which correspond approximately 20% in the map. Although we need an in-depth analysis for the inside of the cluster, we confirmed that there are three obvious bridges to the clusters for Biotechnology (BIO) and Medical Biotechnology (MED), Social Aspect (SOC), and Information and Media (INF) and Information Processing and Information Systems (IPS).

In Fig. 7 corresponding to area A2 in Fig. 4, in terms of fusion of humans and machines, projects about robots and human sensors in the INF and related studies in the BIO and the MED, e.g., inserting chips into the human brain, are located in the left and right clusters. Then, sociological and ethical research in the SOC runs across the two clusters as a bridge. This may suggest the possibility of future collaboration of such studies. In addition, although we need a consensus of the novelty, there seem to be novel projects on the bridge, such as ‘seeing’ with the ears and several biomimetic studies. We will further investigate the extraction of such novel projects. Moreover, by comparing 2008 and 2014 industrial projects, such as Industrial Biotech (IBI) and Industrial Manufacture (IND) such projects increased six-fold in the second half of the FP7, and we confirmed that the subjects were initially limited but finally spanned a wide range across the map.

In contrast, some projects with the Life Science (LIF) code that were obviously about Aerospace Technology (AER), were in fact clustered as AER projects in the map. This case supports the certainty of the map.

Finally, we are evaluating the accuracy of the map with a statistical sampling method. In our preliminary experiment, we randomly extracted 100 pairs of the projects with the cosine similarity of >0.5 so as to make the distribution similar to the one of all pairs. Each pair has two project titles and descriptions, and a cosine value that is divided into three levels: weak (0.5 <= cos. < 0.67), middle (0.67 <= cos. < 0.84) and strong (0.84 <= cos.). Then, three members of our organization, a funding agency in Japan confirmed the similarity of each pair. The members were provided the prior explanations for the intended use of the graph and some examples of evaluation. As a result, we confirmed that 78% of the project similarities (i.e., the distances in the graph) matched majority votes of the members’ opinions. By contrast, the accuracy of the
distances in Fig. 1 was 21%. The evaluation results were determined to be in “fair” agreement (Fleiss’ Kappa = 0.29).

Conclusion and Future Work

Navigating the funding landscape is challenging. However, the research projects do not have references; thus, analyzing the projects using journal citation linkages has difficulty. Therefore, we assessed project relationships using recent semantic similarity measures. After improving the existing paragraph vector technique with an entropy-based clustering method, we successfully formed lattice-like clusters, which are linked by strings of aligned projects whose subjects are relevant to each other. Finally, we confirmed the good face validity and retrieved some relations of particular interest from the map.

As the next step, we need to extract new insights from the proposed map of research projects. Especially, we will compare our map to previous science maps based on published research papers, since they could be applied to assess whether projects are novel by extracting conventional topic words from clusters in the citation-based maps and/or journal disciplines and calculating the similarity between the topic words and project descriptions. In future, we could use the paragraph vectors for several statistical applications, such as multi-dimensional scaling and clustering, rather than drawing cosine similarity networks. In particular, we could consider extracting more semantic relations of projects, such as the most common topics between two projects, from the offset vectors of the projects. We plan to perform additional comparisons with other project datasets, such as FP7 and JST funding projects. Since concept vectors can be shared across different languages, English documents and Japanese documents can be compared through the JST thesaurus with English and Japanese notations. Furthermore, visualizing overlaid heterogeneous datasets, such as funding projects and conference papers, will be of interest, as well as the visualization of their temporal changes to detect emerging research areas. The current FP7 funding maps is publicly accessible in our website (http://togodb.jst.go.jp/sample-apps/map_FP7/).

Abstract
The present study proposes \textit{LitStoryTeller}, an interactive system for visually exploring the semantic structure of a scientific article. We demonstrate how \textit{LitStoryTeller} could be used to answer some of the most fundamental research questions, such as how a new method was built on top of existing methods, based on what theoretical proof and experimental evidences. More importantly, \textit{LitStoryTeller} can assist users to understand the full and interesting story a scientific paper, with a concise outline and important details. The proposed system borrows a metaphor from screen play, and visualizes the storyline of a scientific paper by arranging its characters (scientific concepts or terminologies) and scenes (paragraphs/sentences) into a progressive and interactive storyline. Such storylines help to preserve the semantic structure and logical thinking process of a scientific paper. Semantic structures, such as scientific concepts and comparative sentences, are extracted using existing named entity recognition APIs and supervised classifiers, from a scientific paper automatically. Two supplementary views, ranked entity frequency view and entity co-occurrence network view, are provided to help users identify the “main plot” of such scientific storylines. When collective documents are ready, \textit{LitStoryTeller} also provides a temporal entity evolution view and entity community view for collection digestion.

Conference Topic
Mapping and visualization; Knowledge discovery and data mining; Methods and techniques.

Introduction
With the sheer volume of scientific publications every year, it becomes a double-challenge for researchers to not only comprehend a collection of research articles as a whole, but also to grasp effectively important pieces of information scattered everywhere in each single article. As a solution to this double-challenge, researchers from multiple areas have contributed insights. In the domain of scientific mapping, some existing work have proposed applications to digest a collection of research papers on collection-level, such as CiteSpace (Chen, 2006), Action Science Explorer (Dunne, Shneiderman, Gove, Klavans, & Dorr, 2012), VOSViewer (Van Eck & Waltman, 2010). In broader scope of digital humanity, several applications have been developed to digest a text corpus on topic-level, such as VarifocalReader (Koch, John, Wörner, Müller, & Ertl, 2014), Serendip (Alexander, Kohlmann, Valenza, Witmore, & Gleicher, 2014), on sentence-level, such as PICTOR (Schneider et al., 2010), and on word-level, such as POSvis (Vuilleumot, Clement, Plaisant, & Kumar, 2009) and Wordle (Viegas, Wattenberg, & Feinberg, 2009).

Existing work mentioned above are insufficient to solve the double-challenge for scientific paper digestion. First, scientific mapping applications focus on extracting collection-level patterns as a whole, and are not suitable for individual document analysis. Second, applications in digital humanity, though on multiple-levels, are not tailored for scientific paper digestion. Most existing work in this area are designed for special text corpus, such as poem, play, news, Bible, and so on, but very few if not none are tailored for scientific papers. Third,
even for those applications that are not confined to one type of text, the toolkit developed for
detailed investigation is still simplified. To bridge this gap, we present LitStoryTeller for better support of scientific paper digestion. On document-level, LitStoryTeller automatically extracts scientific concepts (or entities exchangeably in this paper) from full-text and visualizes entities and their co-occurrence and comparative relations in storylines. Here we use the visual metaphor of “storyline” in a play, where entities are considered as “characters”, and paragraph/sentence are seen as “scenes” where “characters” get on stage. With this visual metaphor, we are able to preserve the logical plot of a scientific paper. Moreover, this storyline is synchronized with a text viewer, so that user could navigate through the full-text using the “characters” and “scenes” in the storyline as anchors. Supplementary views are also provided to help users to get focused on the main plot of the storylines. On collection-level, LitStoryTeller visualizes all entities in a collection with two different views, i.e. entity community view and temporal entity evolution view. To our best knowledge, this paper is among the first work that is designed to support document-level exploration using a storyline visual metaphor and leveraging a variety of techniques such as entity extraction and comparative sentence classification methods. The main contributions of the present work are as follows:
1. We develop a framework for document-level exploration of scientific papers, using a “storyline” visual metaphor that preserves the logical thinking plot of a scientific paper;
2. We develop modules for named entity recognition and comparative sentence classification that could run in real-time to support semantic-level exploration of a scientific paper;
3. We also support collection-level exploration of scientific papers, using techniques for community detection algorithm and temporal network visualization.

The rest of the paper is organized as follows. Related work discusses existing work; System design presents the design of the proposed system; Case study demonstrates the utility of the system through a case study; Conclusion draws conclusion of the present study.

Related Work

Single-document visualization
In digital humanity, previous work has been done to facilitate users’ exploration of a single document. Depending on the granularity of the visualization, applications can be divided into the following categories.

Topic-level document visualization
To facilitate exploration of a document, some applications focus on finding the latent topics of a document first, and use topics as an intermediary between words and full document for visualization. Varifocal-Reader (Koch et al., 2014) uses text segmentation method to segment full text into topical segments, and annotates entities such as person and location. Serendip (Alexander et al., 2014) uses statistical topic models as a bridge between words, topics and documents, and visualize the three elements in matrices. The advantage of this approach is that it helps to capture the topical structure of a document for easier digestion. However, it might also suffer from loss of finer-level details, such as detailed information in sentences and entities.

Sentence-level document visualization
Other applications focus on organizing and visualizing a document on sentence-level. One application chooses not to display all sentences plainly, but rather to display sentences using a fish-eye view so that salient passages will be highlighted as focal, and the rest will be put as receded (Correll, Witmore, & Gleicher, 2011). Another application extracts quote sentences from news narratives and could support searching of quotes by speakers (Schneider et al., 2010). The strength of this approach is that finer-level details (sentences) could be organized
and shown to users. On the other hand, the weakness is that sentences alone cannot bear semantic meanings, unlike a topic or an entity.

**Word-level document visualization**

There are multiple applications on word-level document visualization. One application finds frequent word usage patterns and highlights them in full-texts (Don et al., 2007). Another application supports to visualize all neighbouring words of a given word query in a word cloud view (Vuillemot et al., 2009). One work visualizes the word frequency distributions over the narrative scope (Clement, Plaisant, & Vuillemot, 2009). Another work proposes to visualize words in a document as word cloud, known as “Wordle” (Viegas et al., 2009). One work, specially tailored for play script, visualize characters-scenes as a matrix, with character-on-stage-scene as highlights (Wilhelm, Burghardt, & Wolff, 2013). There are also some works on phonetic-levels, often tailored for poem analysis (Abdul-Rahman et al., 2013; McCurdy, Lein, Coles, & Meyer, 2016).

The advantage of visualization on word-level is that it reserves the finest-level of details. However, most of these works do not reserve the relationships between words, or entities. Besides individual weaknesses, work mentioned above are not tailored scientific paper exploration. First, most of the work above are confined in specific corpus such as poem, play, news, Bible, and so on. Second, few of the existing work on word-level focus on word-word relationships. Third, existing work lacks support for semantic information extraction, such as comparative sentence classification.

**Scientific fields evolution visualization**

Our present work is also analogous to the research of visualization of scientific field evolution on an abstract level. Research in this direction usually constructs a network of concepts or keyphrases by various proximity metrics based on co-word analysis, and then clusters the concepts into scientific fields. Then temporal patterns are investigated, such as the emergence and recombination of each scientific field in the network over time (Chavalarias & Cointet, 2013), and interactions between academic push and technological pull for theories (Callon, Courtial, & Laville, 1991). Here each scientific field is considered a “unit” in the storyline of scientific evolution, whereas in our present study, the basic “unit” of the storyline is a concept within a single scientific paper. Also, a link in scientific evolution represents the high-level connection between two scientific fields, whereas in our study, a link represents the sentence/paragraph-level co-occurrence of two concepts.

**Argumentation visualization**

Our work may also be overlapped with research in argumentation visualization. Research in this area attempts to visualize the structures of argumentations, usually in an interactive collaborative learning environment, to support decision making (Kirschner, Buckingham-Shum, & Carr, 2012). Our work instead attempts to visualize the structures of concepts in a scientific paper via automatic natural language processing of the full text and interactive visualizations.

**Storyline visualization**

There are two classical works in storyline visualization. One work proposes to visualize the storyline of a screen play by arranging characters and scenes over time (Tanahashi & Ma, 2012). More specifically, each character is represented by a curved line, and each scene is emphasized by bundling all character lines of this scene closer. Another work improves on the previous one by optimizing several objective functions to make the storyline more compact and visually-pleasing (Liu, Wu, Wei, Liu, & Liu, 2013). The present study utilizes a similar design of storyline as the bare-bone template (Elvery, 2017), which use curved line to represent a character, and a rectangle with lines passing through it to represent scenes. Character lines are arranged by first grouping characters using community detection algorithm, and then place each group as far apart as appropriate.
**Named entity recognition**

Majority of existing work on named entity recognition are supervised methods. Models used include Hidden Markov Models (HMM) (Bikel, Miller, Schwartz, & Weischedel, 1997), Maximum Entropy Models (ME) (Borthwick, 1999) and Conditional Random Fields (CRF) (McCallum & Li, 2003). Supervised named entity recognition usually have superior performances. However, these methods usually require a large amount of human-labeled data in a specific domain. In the present paper, we take advantage of the Microsoft Entity Linking API (https://www.microsoft.com/cognitive-services/en-us/entity-linking-intelligence-service), which not only recognizes named entities under a wide range of topics based on Wikipedia coverage, but also links entities of variant forms together.

**Comparative sentence classification**

Bing Liu has worked on the topic of comparative sentence extraction in a series of papers. In one paper, he proposes to use manual keyword list and frequent sequence mining, together with supervised classifier to classify sentences (Jindal & Liu, 2006a). In another work, he further proposes to not only classify sentences into comparatives/non-comparatives, but also extract the subjects as well as comparative relations from comparative sentences (Jindal & Liu, 2006b). In the present paper, we implemented the full pipeline for comparative sentence classification as in (Jindal & Liu, 2006a).

**System design**

In this section, we first provide an overview of the workflow of the proposed system, and then describe each module in detail.

**Overview of system workflow**

The overview of system workflow is depicted as in Figure 1. The workflow starts with a paper-uploading page. The uploaded full-text is tokenized, POS tagged, stemmed and converted to a feature vector. Then sentence feature vectors are sent to the comparative-sentence-classifier (1 in Figure 1) to generate comparative/non-comparative labels. In the meanwhile, POS tagged and stemmed sentences are sent to the named-entity-recognition module (2 in Figure 1). The recognized entities are sent to the single-document-storytelling module (3 in Figure 1). This module utilizes the labels generated in (1) and entity-sentence-paragraph alignments generated in (2) to create a storyline visualization, together with two supplementary views. Finally, when multiple papers have been uploaded into the system, the collective-documents exploration module (4 in Figure 1) can retrieve all entity co-occurrences stored in the local repository and visualize the entire document collection with two views. We will discuss each module below in detail.

**Comparative-sentence-classification module**

A comparative sentence expresses an ordering relation between two sets of entities with respect to some common features (Jindal & Liu, 2006b). Existing packages such as nltk.corpus.reader.comparative_sents (Pantone, 2017) cannot be used in the present study because it can only work on specific corpus with labeled comparative/non-comparative classes, entity names and relations. Instead, in the current system, we built a comparative-sentence-classification pipeline by implementing and modifying algorithms proposed in paper (Jindal & Liu, 2006a).
Full-text pre-processing
The objective of pre-processing is to convert the raw full-texts into POS tagged and stemmed sentences with corresponding indexing in paragraphs. After removing irregular characters and segmenting full-text into paragraphs by line breaks, we segment each paragraph to sentences with the NLTK PunktSentenceTokenizer. In the meanwhile, we record sentence offsets, namely starting and ending positions in paragraphs.

Feature extraction. The feature extraction step aims to pre-mine all frequent sequence patterns emerging from the training corpus. A frequent sequence pattern is a sequence pattern with sufficient confidence and support in the corpus, where $t_i$ is POS tag of a surrounding word to a keyword. For example, assume the sentence "X outperforms Y" is prevalent in a corpus, then the corresponding frequent sequence pattern will be $<\{NN\}, \{VBZ, outperform\}, \{NN\}>$, where outperform is the keyword. More specifically, we perform the following steps to extract frequent sequence patterns:

(1) Construction of keyword-list. In the original work by (Jindal & Liu, 2006a), to identify comparative sentences, three categories of keywords are proposed, namely adjectival/adverbial comparatives, single-verb keywords, and phrase-keywords, 83 keywords in total. In our study, we added four keywords: "fail", "gain", "over" and "contrast".

(2) Extraction of candidate sequences. For each keyword matched in a sentence, we extract a sequence with certain window size for it as a candidate sequence. For example, for the following sentence, where outperform is in our keyword-list:

"The concatenated features A outperform the original feature set of B."

The corresponding candidate sequence will be (window size = 3):

$[(\{JJ\}), (\{VBZ\}), (\{DT\}), (\{outperform\}, \{NN\}), (\{DT\}), (\{JJ\}), (\{NN\})]$  

(3) Frequent sequence pattern mining. We adopt the PrefixSpan algorithm to mine frequent sequence patterns from all candidate sequences generated in the last step. The PrefixSpan algorithm utilizes projection of search space into prefix sequences to reduce the number of candidate subsequence generations (Han et al., 2001). In our study, we implemented the PrefixSpan algorithm, with the minimum support $\tau$ for frequent sequence set to be 0.1, and the minimum confidence set to be 0.6.
**Classifier training.** After getting all the frequent sequence patterns, we consider them as features of a sentence, and train a Bayes Classifier based on given labels (Jindal & Liu, 2006a). If a sentence satisfies one frequent sequence pattern, the corresponding feature will have value 1, otherwise 0. We manually labelled 286 sentences from research papers, and feed the training corpus into a classifier. Here we report the results of Bayes classifier, with higher precision than those of SVM and Logistic Regression classifier. The accuracy of 5-fold cross-validation is $(0.84 \pm 0.02)$ for the Bayes classifier.

**New sentence prediction.** In the prediction-phase, each sentence is first POS tagged and stemmed. Then the sentence is converted to a feature vector indicating what frequent sequence patterns this sentence satisfies. Last, the feature vector is fed into the trained Bayes classifier to generate a prediction, namely comparative or non-comparative.

**Named-entity-recognition module**
We refer entities as important scientific concepts or terminologies discussed in a research paper. To recognize such entities in a researcher paper on-the-fly with high recall is a challenging task. In the current system, we take advantage of the Microsoft Entity-Linking API. This API not only recognizes a wide range of scientific concepts recorded in Wikipedia, but also automatically performs entity disambiguation.

One down-side of using the Microsoft Entity Linking API is that there is a limit for the service per day. Therefore, we propose a batch mechanism to minimize the number of calls as few as possible for each paper. We batch sentences into blocks before sending them using API. The block size is set to be 10000 characters. Then we use the returned results from the API to map the entity offsets in the block back into its offsets in sentences and paragraphs.

**Single-Document Story Telling**
This part of the system focuses on supporting users to grasp the important pieces of detail information in a research paper through storyline visualization. First, to help users started in the storyline, we provide two ways to determine which entities to read first (Figure 1(a) and (b)). Following these leads, user could read the storylines of these entities through the “Text-storyline cross-reference” view (Figure 1(c)) iteratively and spot important scientific conclusions with the help of “comparative sentence indicators”.

**Ranked entity frequency view**
This view provides an intuitive way is to determine which entities to explore first: to look at how many times an entity has been mentioned in a document as in (Figure 1(a)). Users could start their exploration focusing on these top-ranked entities.

**Local entity co-occurrence network view**
We could also consider the importance and interestingness of an entity to be its authority over other entities as in view (Figure 1(b)). We use the force-layout(Bostock, 2017) to draw the co-occurrence network of entities. The size of the entity indicates its frequency in a document; while the width of link indicates how frequently two entities co-occur in one sentence.

**Text-storyline cross-reference” view**
After determining which entities are of high priority to explore first, users could use the “text-storyline cross-reference” view for “close-reading”. More specifically, we design two views within the “text-storyline cross-reference” view, namely, the “Storyline view” and “Text view” (Figure 1(c)). The collaboration between the two views will help users to navigate through the full text following accumulative clues in the storyline viewer.
We borrow the “storyline” metaphor from theatre play for our visualization of a research paper. As in traditional “storyline” of a novel or a play, there are characters and scenes, and there are beginning, development, turning point, climax and conclusion in the plot.

A research paper shares similarity with the formality of a play. Essentially, a research idea is demonstrated through developments of concepts throughout its abstract, introduction, related work, methodology, experiment, discussion, conclusion and references. These sections can be regarded as grand scenes at a coarse-level. Further, each paragraph and each sentence can be considered as major scenes at fine-level. In our study, the scientific concepts are referred as entities, which can be extracted automatically from each sentences, paragraphs, and sections.

As in Figure 2(a), the storyline of a research paper comprises of entities (characters) and sections/paragraphs/sentences (scenes). The storyline should be read from left to right, as its development in the research paper. More specifically, the glyphs in the storyline represents different elements as follows:

1. **Entities.** Each entity, in a unique colour, is a scientific concept, represented by a curved line called lifeline, from left to right, indicating the period that the entity is first/last mentioned. The width of the curve line is in proportion to the frequency of an entity.

2. **Grande scenes.** Sections, such as abstract, introduction, or conclusion, are considered as grand scenes. These grand scenes are visualized with vertical lines separating the storyline into sections.

3. **Major scenes.** Each major scene is a paragraph or sentence with at least one recognized entity in it. It is represented by a transparent rectangle with soft corners. Each entity lifeline

---

**Figure 2. Storyline of a research paper**

(a) Initial storyline of a research paper

(b) Re-drawn storyline with focus-on-demand Cartesian fisheye view after mouse move
may pass through one or more major scenes, indicating occurrences in these major scenes. Multiple entity lifelines passing through the same major scene indicate their co-occurrences.

4. **Comparative sentence indicators/each scene.** At the bottom of the storyline, we visualize every scene with a rectangle at equal steps. The shade of the rectangle represents our confidence whether this scene contains “comparative statements”.

As in Figure 2(b), the storyline visualization is the main vehicle for users to perform various operations and navigate through the full-text document. We have enabled the following interactive operations on the storyline viewer:

1. **Focus-on-demand fisheye view.** To avoid too long and sparse a storyline, a focus-on-demand zoom-in/zoom-out mechanism is desirable. We support this goal by implementing a fish-eye effect on the storyline (Figure 2(b)-(1)). This enables users to expand any part of a storyline to see details at focus, and shrink the rest of the storyline as background.

2. **Select one or more entities.** The label as the starting point of each entity is selectable (Figure 2(b)-(2)). When clicked, the corresponding life-line of entity will be highlighted.

3. **Select a major scene.** Each major scene, represented with rectangle, is selectable (Figure 2(b)-(3)). When clicking the major scene, the “Text view” will synchronically jump into and highlight the corresponding section of the scene (Figure 1-(1)).

4. **Select a comparative statement.** Each scene is displayed at the bottom with equal steps (Figure 2(b)-(4)), whose shade indicates how likely the scene contains a comparative statement. These glyphs are also selectable and synchronized with the text viewer.

5. **Switch scene granularity.** The granularity of the scene can be switched from “paragraph” to “sentence” by clicking on the “visualize sentences” button (Figure 2(b)-(5)).

**Text view**

We enable the text view to have synchronized responsive behaviour in accord with operations in the storyline view. That is, when corresponding operations be performed in the storyline viewer, such as selecting an entity, selecting a scene (paragraph/sentence), the corresponding content within the text view will be highlighted and brought to the focus area.

**Overview of a collection**

We provide two types of visualizations: temporal entity evolution view and entity community view.

**Temporal entity evolution view**

The temporal entity evolution view is designed to visualize how entities in an entire document collection evolve over time. Some entities appear very early in the collection, marked by the publication date of its corresponding paper, while others emerge at much later stage, with strong connections to the earlier ones. These connections can also be seen as mapping between research fronts (novel entities) and intellectual base (old entities) (Chen, 2006). We take co-occurrences between old and novel entities on sentence-level as the connections, and visualize these connections chronologically to show entity evolution.

As in Figure 1-(4), we use an arc-diagram layout to visualize entity evolution over time. In our arc diagram, each circle represents an entity with label below it. Its colour indicates the corresponding paper where this entity first appeared in. Each arc connecting two circles represents co-occurrences of two entities in one or more sentences, whose thickness indicates the frequency of the co-occurrences. The entities are arranged from older to new horizontally based on their corresponding papers’ publication time where they first appeared in.
**Entity community view**

The entity community view is designed to visualize the communities within the co-occurrence network of entities across the collection. In entity communities, some entities appear as outliers, while others connect multiple other entities to form a cohesive community, or occupied important “positions” in the network such as connecting two major communities as pivotal points (Chen, 2004). These entities are worth further analysis.

As in Figure 1-③, we implement a force-layout graph (Bostock, 2017) to visualize the entire entity co-occurrence network. The force-layout attempts to minimize the number of crossings of edges in a network by optimizing energy functions(Kobourov, 2012). In our visualization, each circle represents an entity, and its size indicates its frequency in entire document collection. Each link represents co-occurrences between two entities, whose width indicates how often the two entities co-occurred together. We use the Louvain method for community detection which optimizes global modularity through updating local communities(Blondel, Guillaume, Lambiotte, & Lefebvre, 2008). Entities belonging to one community are coloured with a unique colour.

**Case study**

We report a case study to demonstrate the purpose and functions of the current system design.

**Use Scenario**

We present the use case of a typical user named Alice. Alice is a graduate student, who has previous experience in research, and has some exposure to interactive visual analytic systems. Alice is surveying on research papers related to the topic of “Latent Dirichlet Allocation” (LDA), a probabilistic graphical model (Blei, Ng, & Jordan, 2003). Alice has already obtained a collection of full-text research papers on this topic (13 papers). Alice realizes that there are multiple models before and after the proposal of LDA, such as LSI, pLSI, hLDA and HDP. Alice is especially interested in how each model was built on top of one or more previous models, by improving the weakness of the previous ones on various metrics. Alice is also curious about what accompanying algorithms are frequently used together with these topic models, such as inference methods. These research questions are summarized as follows:

1. How is each novel model built or different from old models? Taking the example of LSI and pLSI, how does the new model (pLSI) is superior to the old model (LSI)?
2. What mathematical formula and inference algorithms are usually used together with each topic model?
3. Overall, what concepts (topic models, mathematical formula, and inference algorithms) are discussed the most in this document collection? How do these concepts evolve over time?

**Single-Document Storytelling**

To answer research question (1) and (2), Alice selects the paper of probabilistic Latent Semantic Indexing (pLSI) to see how pLSI is built on top of Latent Semantic Indexing (LSI). Alice uses the single-document storytelling view for this task.

Due to space limitation, we skip the step of finding important entities with our supplementary views, and assume Alice already identifies the most important entities. Recall that question (1) is “How is each novel model built or different from old models?” To answer this question, Alice decides to read the storylines of the two main characters: pLSI and LSI at paragraph-level. Alice observes that the two highlighted lifelines have several crossings (co-occurrences in a paragraph), as in Figure 3. Alice believes that these crossings are crucial to answer question (1). Interestingly, all crossings yield important information about the relationships between pLSA and LSI, as can be read from the tooltip of the crossings in the figure. These
tooltips clearly stated how pLSA is built on top of LSI theoretically and mathematically.

Figure 3. Storyline of "Probabilistic Latent Semantic Indexing" at paragraph-level.

Now Alice wants to go deeper into details, so she switches to read the storyline at sentence-level, as in Figure 4. This time, Alice notices multiple crossings at the “6. Experimental Results” section. Alice decides to read the sentences in these crossings. Interestingly, all crossings yield “conclusive” information about the relationships between pLSI and LSI, as can be read from the tooltips. Also, most of the crossings belong to the scenes with darker shade at bottom, indicating that pLSI and LSI are frequently compared in the section of “Experimental Results”. At this point, Alice is very confident about knowing how pLSA is different and most likely an improvement from LSI, with both theoretical foundations and experimental results.

Figure 4. Storyline of "Probabilistic Latent Semantic Indexing" at sentence-level.

To answer research question (2), Alice examines crossings in Figure 4 again. Alice finds out that LSI is mostly associated with “Singular Value Decomposition”, and pLSI with “Expectation-Maximization Algorithm”. Indeed, to solve LSI, the most common used method is “Singular Value Decomposition”, while for pLSI, the algorithm for inference is “Expectation-Maximization Algorithm”.

Collective-document exploration view

To answer research question (3), Alice uses the entity community view and temporal entity evolution view to understand relations among all the entities discussed in this collection.
Identifying communities
Under the Entity Community View as in Figure 5(a), Alice identifies major communities of sub-topics around LDA topic model in this document collection: LDA models (green), LSI-related models (blue), HDP models (light-brown). Some small communities, such as those in yellow and red are discussed only a few times, thus are more marginalized in the network.

Tracing entity evolutions
Under the Entity Evolution View, as in Figure 5(b), Alice can see how entities evolve over time. Alice pays special interests to entities with thicker arcs across papers. These entities have been frequently discussed both in its original papers and in newer papers, and this has led to a sequence of topic model names. From this sequence, Alice has a general idea of what are some older models (LSI, pLSI), what are newer models (LDA, HDP), and which new model is evolved around which old model. This provides a concise answer to question (3). At this point, Alice successfully answers the three research questions by using the current system.

Conclusion
The present study proposes LitStoryTeller, an interactive system for visually exploring the semantic structures of scientific papers. With a screen play metaphor, the proposed system provides interactive storyline of a research article, taking advantages of a variety of techniques such as named entity recognition and comparative sentence classification. Visualizations at collection-level are also provided to aid overall reading digestion. A comprehensive case study demonstrated the usefulness of the proposed system, by answering realistic research questions from research papers. There are two limitations in the current study. First, the Microsoft API may not be able to identify very recent scientific concepts not yet included in Wikipedia. Although we have provided the function of entity customization for users, we plan to develop our own scientific entity recognizer in the future. Second, the metrics of entity importance used in present study are relatively simple, namely entity frequencies and graph centrality. In the future, we plan to propose more robust metrics such as tf*idf, to eliminate entities that are very common yet not rich in meanings in their contexts.

University rankings in computer science: a study and visualization of ‘geo-based’ impact and conference proceeding (CORE) scores

Philip Ehret¹, Alesia Zuccala², and Bela Gipp³

¹philip.ehret@uni-konstanz.de, ³bela.gipp@uni-konstanz.de
University of Konstanz, Konstanz (Germany)
²a.zuccala@hum.ku.dk
University of Copenhagen, Copenhagen (Denmark)

Abstract
This is a research-in-progress paper concerning two types of institutional rankings, the Leiden and QS World ranking, and their relationship to a list of universities’ ‘geo-based’ impact scores, and Computing Research and Education Conference (CORE) participation scores in the field of computer science. A ‘geo-based’ impact measure examines the geographical distribution of incoming citations to a particular university’s journal articles for a specific period of time. It takes into account both the number of citations and the geographical variability in these citations. The CORE participation score is calculated on the basis of the number of weighted proceedings papers that a university has contributed to either an A*, A, B, or C conference as ranked by the Computing Research and Education Association of Australasia. In addition to calculating the correlations between the distinct university rankings and the separate ‘geo-based’ versus CORE scores, we are in the process of developing a geographical visualization tool that presents the metrics so that they may be examined in an explorative way.

Conference Topic
University policy and institutional rankings; Science communication; Mapping and visualization

Introduction
University rankings have rapidly become an influential tool in government and educational policymaking (The Guardian, 2013), and after the first Academic Ranking of World Universities (ARWU) was introduced in 2003 (also known as the ‘Shanghai Ranking’), alternative rankings began to appear. These include, though in no specific order, the QS World Ranking of Universities, the Times Higher Education (THE) Ranking, SCImago ranking, and the Leiden Ranking. In past years, each ranking has been touted, examined for their disadvantages and advantages, and assessed on the bases of their similarities (e.g., Aguillo et al., 2010; Waltman et al., 2012; Bornmann et al., 2013). Certain methodological approaches have also been more heavily criticized than others (Liu & Cheng, 2005; Liu et al., 2005; VanRaan, 2005). Some critics, for example, are sceptical about approaches that rely on the amalgamation and use of weighted variables (Billaut, 2010), and others are concerned with reproducibility (Docampo, 2012). Most researchers tend to agree; however, that normalization is key to producing rankings, especially when using publication and citation data with variable field differences (López-Illescas et al., 2011).

University rankings are here to stay, and since can often be influential, there are always ample reasons to examine them further. One approach is to focus on statistical shortcomings within the ranking itself, but another is to identify and examine new variables of interest and test them to see if they show some form of positive, negative, or neutral relationship to that ranking. In this sense, correlation measures are useful, if they provide further information and
insight into the communication practices of a research field, where a ranking might not present the full picture. The field that we have chosen to investigate is information and computer science, and the type of university rankings that we use in this study implement either a field-normalized approach – i.e., the Leiden Ranking – or a field-specific approach, such as the QS World University Ranking.

Currently, our research is ‘in-progress’ and it is based on two components. The first component is metric in nature, and the second involves developing a visualization tool that will allow users to explore our results geographically.

With data pertaining to: a) the Leiden University Ranking (2016), b) the QS World University Ranking in Computer Science (2016), c) university-to-university directed citation counts collected from Web of Science (WoS) journal articles (2012-2016), the first part of our study will focus on the following:

1) What is a particular university’s ‘geo-based’ impact (i.e., geographical reach) in the field of computer science as measured by the citations it receives from a variety of international universities?

2) Do high-ranking universities in the field of computer science tend to receive a broader geographical reach of citations than those that achieve a lower rank?

Our third research question relies also on Leiden and QS World University Ranking data, but includes: a) only conference proceeding publications matched to ranked universities, and b) data from the Computing Research and Education Conference (CORE) Ranking (2014).

3) Do computer scientists working at top ranked universities tend to participate more often in the top ranked CORE conferences than those from lower ranking universities?

Methods

Rankings, articles and proceedings data collection:

The Leiden Ranking data, the QS World University Rankings in the field of computer science, and the CORE Computing Research and Education Conference data are publicly available on the Web. By using a standard web scraping method, we will collect data from the following sites:

1) Leiden Ranking: http://www.leidenranking.com/ranking/2016/list

With the Leiden ranked list we will limit the universities to those associated with the field of ‘mathematics and computer science’ and use the basic P indicator (i.e., total number of publications), and percentile-based indicators: \( P_{top-10\%} \) and \( PP_{top-10\%} \). A percentile-based indicator is that which values publications based on their position within the citation
distribution of their field (Waltman & Schreiber, 2012). The $P_{\text{top-10\%}}$ is more precisely defined as: “the number of publications which belong to the top 10\% most frequently cited publications; a publication belongs to the top 10\% most frequently cited if it is cited more than 90\% if the publications published in the same subject area and in the same year” (Bornmann & Williams, 2013)

The indicator we use from the QS 2016 World University Rankings in Computer Science & Information Systems is computed as an “overall score” (a score of 0 to 100) for each university, and it is comprised of four components: 1) academic reputation (i.e., a global survey of academics), 2) employer reputation (i.e., a global employer survey), 3) research citations per paper, and 4) the h-index (see https://www.topuniversities.com/subject-rankings/methodology)

The Web of Science data for a set of computer science journal articles (doctype = Article,) for the period of 2007 to 2011 (publication years) has been provided to us from Clarivate Analytics (i.e. formerly Thomson Reuters). Our indicator for ‘geo-based’ impact is calculated in terms of citation variability, that is, the variability in the origin of citations received by the universities from other universities in countries worldwide (i.e., this is specifically for the articles published in 2007 to 2011, which have been cited during the period of 2012 to 2016). This approach, shown in the formula below, is adapted from what has been done earlier by Gao et al. (2013):

$$g_i(l) = \left| \bigcup_{i=1}^{P(l)} \bigcup_{j=1}^{C(l)} O(j) \right|$$

$I$: A certain institution

$P(l)$: Number of papers published by researchers affiliated with institution $I$

$C(i)$: Number of incoming citations for paper $i$

$O(j)$: Country of origin for citation $j$

And finally, a set of conference proceedings articles recorded in WoS for the year 2016 (doctype = Article,Proceedings Paper), will be matched to both their university of origin as well as the rank of the actual conference, as listed at the (CORE) Conference website. According to the CORE webpage: “conference rankings are determined by a mix of indicators, including citation rates, paper submission and acceptance rates, and the visibility and research track record of the key people hosting the conference and managing its technical program.” This includes a more detailed statement concerning the categorization ranks, which are labelled as A*, A, B, and C (see CORE, 2016).

For each university we will determine an overall CORE score based on the weighted proportion of its proceedings articles that match with one of the CORE rankings: A*, A, B, and C. Thus for each Core rank we will give an ‘A*’ a weight of 3, an ‘A’ a weight of 2, a ‘B’ a weight of 1 and a ‘C’ a weight of 0.5. If, for example, a university produces 5 articles each associated with the following CORE ranks (3=A*, 1=A, 1=B) we would obtain a CORE score = $[3(3/5) + 2(1/5) + 1(1/5)] / 5 = (1.8 + 0.4 + 0.2) / 5 = 0.48$. 

1133
Visualization:

The visualization component of this study is currently under development at the Department of Computer Science, University of Konstanz (see Figure 1, below). The aim is to provide users with an interactive tool that can support immediate geographical comparisons for a set of ranked universities from the field of computer science. A drop-down menu (left of screen) presents the university’s most recent rank, as per the Leiden ranking method for ‘mathematics and computer science’, the QS World Academic ranking in computer science, and associated Computing Research and Education Conference CORE score and geo-based impact.

The circular nodes on the map identify each university within its specific country. Red lines, or trajectories connect the university to other universities worldwide and illustrate the degree to which it is receiving citations. For instance, a user can click on a specific university node (University of Konstanz) in our geographical visualization tool, then hover over the trajectory and find a pop-up text at the right of the screen, which indicates total citations received for a specific time period. For example, (s)he might see a count of 30 incoming citations to University of Konstanz (Germany) from University of Toronto (Canada) for the period 2011-2016.

The countries in which the universities are situated will also be coloured as per their average geo-based impact. Again, the user can hover over a country, and at the right side of the screen a pop-up text will appear with the country name, its flag, and average geo-based impact, as calculated from the geo-based impacts of all of its regional universities’. A country with an above average geo-based impact will be coloured a darker shade of blue, and a country with a below average geo-based impact will be coloured a lighter shade of blue.

![Figure 1. Prototype of the geographical visualization tool for university rankings, CORE scores, and geo-based impacts in computer science.](image-url)

**Expected Results**

The results of this study will give scholars the opportunity to monitor their university’s current rank within a specific research field and to identify additional field-related measures
associated with these rankings. With the metric part of our study we expect to find that high-ranking universities in the field of computer science tend to receive a broader geographical reach of citations than those that achieve a lower rank. We further expect to find that computer scientists working at top ranked universities tend to participate more often in the top ranked CORE conferences, than those working at lower ranked universities. This will be shown on our geographical visualization tool in terms of multiple trajectories (red lines) corresponding to received international citations. It will also be shown on the basis of a high ‘geo-based’ impact measure and a high CORE score for each university in a pop-up menu beneath their corresponding Leiden and QS rankings.

Abstract
A term map offers a visualization of a network of terms that co-occur in scientific publications. Term maps are usually created based on the titles and abstracts of publications. In this paper, we explore the use of full-text data for creating term maps. We create and compare a series of term maps based on the full text of publications in Journal of Informetrics. We use our results to discuss the advantages and disadvantages of different approaches for creating term maps.

Conference topic
Co-occurrence analysis; mapping and visualization

Introduction
Bibliometric analyses have traditionally been based on meta data of scientific publications. Increasingly, however, the full text of publications is becoming easily accessible for large-scale analyses. Some journals (e.g., journals published by Frontiers, PLOS, and Ubiquity Press and journals such as F1000Research and PeerJ) have websites from which the full text of a publication can be downloaded in XML format. This simplifies the large-scale processing of full-text data. For other journals (e.g., journals published by Elsevier, Springer, and Wiley), bulk downloaded of full-text data, in XML or some similar format, is possible through an API, provided that one has the required license.

The increasing availability of full-text data in convenient file formats offers lots of interesting possibilities for improving bibliometric analyses. In this paper, we explore one such possibility. We study the use of the full text of scientific publications for creating so-called term maps, and we compare the use of full-text data with a more traditional approach based on titles and abstracts. The term maps studied in this paper are created using VOSviewer (www.vosviewer.com; Van Eck & Waltman, 2010, 2014), a popular software tool for bibliometric visualization that is often used for creating term maps.

Term maps
A term map offers a visual representation of a term co-occurrence network. A term co-occurrence network is a network of terms in which the relatedness of terms is determined by their number of co-occurrences. Terms are often extracted from scientific publications, usually from titles and abstracts, and the number of co-occurrences of two terms typically equals the number of publications in which the terms occur together. A term co-occurrence network may for instance be constructed based on the publications that have appeared in a particular field of science.

To obtain an easy to interpret overview of the research that is done in a certain scientific field, it can be helpful to create a visualization of a term co-occurrence network constructed based on publications from that field. Such a visualization is referred to as a term co-occurrence map, or simply a term map. The VOSviewer software tool facilitates creating term maps. Example of term maps created using VOSviewer can be found in Figures 1, 2, and 3.
Interpreting a term map

A VOSviewer term map can be interpreted as follows:

- The size of a term reflects the number of occurrences of the term, for instance the number of publications in which the term occurs.
- The distance between two terms approximately reflects the relatedness of the terms, with strongly related terms typically being located close to each other. The relatedness of terms is determined based on their number of co-occurrences.
- The horizontal and vertical axes have no special meaning. A term map can be freely rotated and flipped. Since the distances between the terms remain the same, this does not affect the interpretation of the map.
- Colors are typically used to indicate clusters of strongly related terms. Terms that have the same color tend to be relatively strongly related to each other.
- There often is a considerable overlap of terms in a term map. When terms are overlapping, a label is shown only for the most frequently occurring term. For other less frequently occurring terms, only a circle is shown, not a label. When a term map is explored interactively using VOSviewer, it is possible to zoom in on a specific area in the map. This will reduce the overlap of terms, resulting in more labels being visible.

In the interpretation of a term map, it is recommended to focus on the general patterns emerging from the map. Focusing too much on individual terms is often less useful. A group of terms located close to each other, and typically having the same color, tends to represent a topic (or a research area) in a scientific field. The terms offer an indication of what the topic is about. By looking at the different groups of terms in a term map, one gets an impression of the main topics in a field. In addition, the distances between different groups of terms provide insight into the relatedness of the different topics in a field. Neighboring groups of terms tend to represent closely related topics.

Creating a term map

More information about the way in which term maps are created by VOSviewer is provided by Van Eck and Waltman (2011). For the purpose of this paper, the following points are of particular importance:

- Terms may consist of multiple words. Any sequence of nouns and adjectives, with the last word in the sequence being a noun, can be a term. Terms are extracted from publications, typically from titles and abstracts, using natural language processing algorithms. Plural terms are converted into singular ones.
- The terms included in a term map are selected using a term selection algorithm. The idea of this algorithm is to select terms that seem to relate specifically to one or a few topics in a field. More general terms are filtered out. This can be terms such as ‘conclusion’, ‘method’, and ‘result’, but also terms that, within a certain field, can be considered very general. For instance, in the field of oncology, the term ‘oncology’ is very general and is therefore likely to be filtered out. In addition to general terms, terms that occur in only a very limited number of publications are also usually excluded.
- Occurrences and co-occurrences of terms can be counted in two ways, either using a binary counting approach or using a full counting approach. In the binary counting approach, only the presence or absence of a term in a publication matters. The number of occurrences of a term in a publication does not matter. The full counting approach, on the other hand, does take into account the number of occurrences of a term in a publication.
To illustrate the distinction between binary and full counting, consider a publication in which terms A and B occur, respectively, two and three times. In the binary counting approach, this is counted as one occurrence of term A, one occurrence of term B, and one co-occurrence of the two terms. The full counting approach counts this as two occurrences of term A, three occurrences of term B, and six (i.e., two times three) co-occurrences of the two terms.

**Term maps based on full-text data**

When term maps are created based on the full text of scientific publications rather than based on titles and abstracts, a number of new possibilities emerge. The most straightforward way to count co-occurrences of terms is to count a co-occurrence for any pair of terms occurring in the full text of a publication. In this approach, if terms A and B both occur only once in the full text of a publication, term A in the first sentence and term B in the last sentence, this is counted as a co-occurrence. One could argue that in this situation terms A and B can hardly be considered to be related, and one may therefore prefer to count co-occurrences only for pairs of terms that are located sufficiently close to each other in the full text of a publication. This may mean that co-occurrences are counted only for pairs of terms that are located within a certain maximum distance from each other (i.e., co-occurrences are counted only within a certain window), where this maximum distance may for instance be expressed in terms of a certain number of words or characters. Alternatively, co-occurrences may be counted only for pairs of terms that are located within the same organizational unit in the full text of a publication, for instance in the same sentence, the same paragraph, or the same section.

We have explored a number of different approaches for counting co-occurrences in the full text of publications. In the rest of this paper, our focus will be on the approach in which co-occurrences are counted at the level of sentences, paragraphs, sections, or entire publications. We will contrast this approach with the traditional approach in which co-occurrences are counted in titles and abstracts.

**Data**

Our data set includes the full text of publications in *Journal of Informetrics* in the period 2007–2016. All publications of the Elsevier document types correspondence, editorial, erratum, full-length article, review article, and short communication were taken into account. The full text of the publications was downloaded in XML format using the Elsevier ScienceDirect Article Retrieval API. In total, the full text was obtained for 688 publications. Sections and paragraphs within the full text of a publication could be identified in a straightforward way using XML tags. In the case of sections, we focused on the main sections in a publication. If these main sections were subdivided into subsections, this subdivision was ignored. Sentences could not be identified using XML tags. Instead, we developed a sentence splitting algorithm to identify sentences. Table 1 offers some statistics for our data set.

Creating the term maps

In total, we created ten term maps. Two maps were created based on titles and abstracts, one using binary counting and one using full counting. The other maps were created based on full-text data. In these maps, co-occurrences were counted at the level of sentences, paragraphs, sections, or entire publications and either binary counting or full counting was used.

As explained above, when creating a term map, general terms are typically left out. We left out 40% of the terms, which is the default choice in VOSviewer. We also needed to choose the minimum number of occurrences that a term is required to have in order to be included in a map. For each of the maps based on full-text data, we choose the minimum number of occurrences in such a way that the map includes about 2,000 terms. The maps based on titles and abstracts were created based on a smaller amount of data, and therefore we needed to follow a different approach for these maps. In the case of these maps, we used a quite low threshold for the minimum number of occurrences of a term. A term was required to have at least five occurrences.

The so-called attraction and repulsion parameters in VOSviewer, which determine the layout of the terms in a term map, were set to values of 1 and 0, respectively. These values generally yielded maps with a satisfactory layout. The resolution parameter, which determines the granularity of the clustering of terms, was set to its default value of 1. An exception was made for the three maps discussed in more detail in this paper (see below). For each of these maps, the value of the resolution parameter was fine-tuned in order to improve the consistency between the layout and the clustering of the terms.

Comparing the term maps

Due to space limitations, it is not possible in this paper to present a full comparison of all ten term maps. However, the maps have all been made available online. They can be explored interactively at [www.neesjanvaneck.nl/JOI_full_text_term_maps/](http://www.neesjanvaneck.nl/JOI_full_text_term_maps/).

We focus on comparing the following three term maps:

- Binary counting map based on titles and abstracts (Figure 1).
- Full counting map based on full-text data with co-occurrences counted at the level of entire publications (Figure 2).
- Full counting map based on full-text data with co-occurrences counted at the level of paragraphs (Figure 3).

In the case of the map based on titles and abstracts, we use binary counting because this is the default choice in VOSviewer and, consequently, because this is probably how term maps are typically created when VOSviewer is used. In the case of the maps based on full-text data, we use full counting because it turned out that full counting clearly yields more satisfactory results than binary counting, especially when co-occurrences are counted at the level of entire publications (see the maps available online).

Our findings resulting from comparing the three above-mentioned term maps can be summarized as follows:

- In terms of the level of detail that is provided, the maps based on full-text data are much richer than the map based on titles and abstracts. The latter map includes fewer than 400 terms, while the other two maps each include more than 2,000 terms. Especially when one zooms in on a specific area in a map, the full-text maps offer significantly more information than the map based on titles and abstracts.
- The full-text map based on paragraph-level co-occurrences has a more fine-grained structure than the full-text map based on publication-level co-occurrences. The former map for instance has an area in which many statistical terms are located closely...
together. Likewise, it includes areas showing the names of scientific fields and of countries. In the map based on publication-level co-occurrences, the structure is less fine-grained and similar areas are less well visible.

Which of the different term maps offers the most satisfactory representation of research published in *Journal of Informetrics*? In our view, there is no simple answer to this question. When a map is used as a static visualization, the increased level of detail provided by full-text data seems to be of limited value and a map based on titles and abstracts may offer sufficient information. On the other hand, when a map is used interactively, there seems to be a clear added value in the use of full-text data. One then has the possibility to zoom in on specific areas in a map to fully benefit from the detailed information extracted from the full text of publications.

When full-text data is used, the choice between the different levels at which co-occurrences can be counted is not entirely straightforward. Working at the paragraph level yields a more fine-grained structure than working at the publication level. This may be seen as an advantage. On the other hand, it seems that areas in a paragraph-level map do not always represent topics in the literature. For instance, an area showing all kinds of statistical terms does not represent a topic covered by *Journal of Informetrics*. There are not many publications in *Journal of Informetrics* that have statistical methodology as their core topic. Statistical terms are used in quite a lot of publications in the journal, but they usually do not represent the core topic of these publications. However, statistical terms probably tend to occur together in specific paragraphs in a publication, and this explains why a paragraph-level map includes an area in which many statistical terms are located closely together. This is an accurate reflection of the co-occurrence patterns of statistical terms at the level of paragraphs, but it does not represent a topic covered by *Journal of Informetrics*.

**Conclusion and future research**

In this paper, we have presented a first exploration of the possibility to create term maps based on the full text of scientific publications rather than based on titles and abstracts. Using the VOSviewer software tool, we have compared maps created in a number of different ways. Instead of identifying a single optimal approach for creating term maps, we have discussed advantages and disadvantages of different approaches.

There are a number of issues that can be addressed in future work. First of all, the analysis presented in this paper can be redone at a larger scale, for instance involving more than one journal. In addition, alternative approaches for counting co-occurrences of terms in the full text of publications can be explored. In particular, the idea of counting co-occurrences of terms that are located within a certain maximum distance from each other can be tested. Some practical issues also need further attention. For instance, term maps created based on full-text data include quite a lot of author names, and one may want to filter these out. Finally, the use of full-text data for creating other types of maps can be studied. Maps based on co-citation relations are especially likely to benefit from the availability of full-text data.

Gender differences in research diversification behavior

Abstract

This work investigates whether and in what measure there occur gender differences in research diversification behavior by scientists. We analyze the nature of research diversification along three dimensions: extent of diversification, intensity of diversification, and degree of relatedness of topics in which researchers diversify. For this purpose we propose three bibliometric indicators, based on the disciplinary placement of scientific output of individual scientists. By classifying scientists by gender and field of research, we are able to assess gender differences along the above three dimensions in each field.

Conference Topic

Research Fronts and Emerging Issues; Studies on the level of individual scientists
Introduction

Scientific research is becoming increasingly interdisciplinary (Porter & Rafols, 2009). This might well be the effect of a policy started in the mid-1990s by a number of funding agencies and higher education institutions, aimed at promoting the expansion of interdisciplinary research. At the same time, there were initiatives aimed at reducing the underrepresentation of women in science. The development of the interdisciplinary research (IDR) phenomenon has attracted the attention of many scholars and raised challenges on various fronts. Also gender differences in research have been the focus of many investigations, in particular female underrepresentation, performance differences and their determinants. Research has focused on each of these trends independently, but very few studies have considered their interaction, such as investigating whether there occur gender differences in the propensity to diversify one’s own research activity. Leahey (2006) contends that in addition to institutional issues, the extent of research specialization can also help explain the process by which gender affects research productivity. The preference of women for less specialised research, hinders their capacity to get published and cited. Unfortunately, her claim is based only on findings from two disciplines: sociology and linguistics. Rhoten and Pfirman (2007) showed that female scientists are much more likely than male scientists to engage in IDR projects. The authors consider also the expectation that women are well positioned to make major advances in interdisciplinary science. The current work intends to shed additional light on the issue of gendering of interdisciplinary science. It aims at assessing whether and to what extent there occur gender differences in field diversification of research activities. The analysis will be carried out at fine-grained field level, to detect possible differences across fields.

The investigation entails defining and measuring IDR. In the next Section we will review the literature on the subject. In Section 3 we present the methodology applied and the data used to conduct the analysis. In Section 4 we present the results, and in Section 5 the conclusions.

Literature review

A review of the literature on IDR studies shows that the issues receiving most attention are the taxonomic problem, the development of schemes for conceptual and practical definition of IDR, and subsequently its measurement (Huutoniemi, Klein, Bruun, & Hukkinen, 2010). According to a review by Klein (2008), the most commonly accepted scheme for definition of IDR is that involving three concepts: multidisciplinarity, interdisciplinarity and transdisciplinarity. Each of these is characterized by a particular type of “knowledge integration”, meaning the particular type of merging of theories and concepts, techniques and tools, information and data, from various fields of knowledge (Porter, Roessner, Cohen, & Perreault, 2006). According to Wagner et al. (2011) the phenomenon of knowledge integration can occur within a single mind, as well as within teams.

According to Stirling (1994), IDR displays some combination of only three basic properties, named “variety”, “balance” and “disparity”. Stirling (2007) also proposes the indicators suited to measurement of each: the “variety” indicator is defined as the answer to the question: “how many types of thing do we have?”; for “balance” it is instead the answer to “how much of each type of thing do we have?”; finally, “disparity” is “how different from each other are the types of thing that we have?”.

In the bibliometric sphere, these concepts have been widely applied in the investigation of IDR, as demonstrated in a review of the issue by Wagner et al. (2011). Many studies take a bottom-up approach, building from measurement of interdisciplinarity for individual articles.
The proposed measures are based on the disciplinary profile of the cited references, considering that reference to the preceding literature in various disciplines is as a signal of acquisition and integration of the results of these disciplines (Porter, Cohen, Roessner & Perreault, 2007; Rafols & Meyer, 2010; Wang, Thijs & Glänzel, 2015; Mugabushaka, Kyriakou & Papazoglou, 2016). In particular, Porter and Rafols (2009) used the works published in a cluster of selected journals indexed in the WoS over the period 2007-2011, examining their relative lists of references and identifying the disciplinary areas of the works cited, in terms of: i) number of subject categories (SCs) cited; ii) distribution of the citations among the SCs; iii) similarity or disparity among these SCs. In substance, Porter and Rafols (2009) proposed the measurement of Stirling’s (1994) three basic properties of research diversification through mapping the subject categories of cited publications. Zhang, Rousseau and Glänzel (2016) adopt the same approach to study the interdisciplinarity of journals.

Other studies are instead based on a top-down approach: again using typical disciplinary classifications such as WoS subject categories, they study the frequency distributions for scientific portfolios produced by defined units of analysis. For example, van Raan and van Leeuwen (2002) propose an approach for measurement of the IDR of a research organization through the percentage of its publications in each SC, or of citations received from each SC. Bourke and Butler (1998) had previously investigated the IDR conducted within Australian university departments, through the analysis of journals hosting the 1990-1994 publications authored by researchers of each department. Rinia, van Leeuwen, van Vuren and van Raan (2001) applied a similar approach in the Netherlands, analyzing the outcomes from a nationwide evaluation program of all academic groups in physics. As an aside, the intention of the last two works was to understand if IDR should be assessed in the same way as “disciplinary” research.

One of the areas of analysis little visited by scholars concerns IDR at the level of individual researcher. This is a strategic area, if one thinks of the challenges of complex research and the current recourse to policy aimed at fostering interdisciplinary work and thus influencing choices by the protagonists – the researchers themselves. The only contributions in the literature seems to be that from Schummer (2004), who carried out a coauthor analysis of nanotech journals in 2002-2003. By mapping “disciplinary” affiliation of coauthors, he was able to measure the IDR of each scientist in terms of interaction with the disciplines associated to all their coauthors. Using a similar approach, Abramo, D’Angelo and Di Costa (2012) analyzed the degree of collaboration among all Italian academics from different disciplines in order to identify the most frequent “cognitive combinations of knowledge” in research activity, drawing on 2004-2008 WoS publications by all Italian professors in the sciences. Abramo, D’Angelo, and Di Costa, F. (2017) studied diversification in research activities of Italian academics, along three dimensions: extent, intensity and relatedness of field diversification. We now intend to investigate gender issues in IDR. In other words, whether and in what measure female and male scientists tend to diversify their research activity, and if this tendency varies according to their belonging to different research fields.

**Data and methods**

**Methodology**

The results obtained from empirical investigations on research diversification depend on both the breadth of time for observation of scientific production and the schemes applied for sectoral classification of the scientific output and researchers. As for the first factor, the longer the observed time window, the wider the scientific portfolio of the subject under
investigation and, consequently, its alleged variety. As for the second factor, the outcomes of an analysis aiming at measuring diversification depends heavily on the classification scheme for research output and its grain. We take a top-down approach, analyzing the disciplinary placement of scientific output of individual scientists. We resort to Web of Science (WoS) subject category (SC) classification for the following reason.

Wang and Waltman (2016) provide a comparative analysis of the accuracy of WoS and Scopus journal classification systems. The authors firmly conclude that the “Web of Science performs significantly better than Scopus in terms of the accuracy of its journal classification system”. Probing beyond the issue of greater or lesser precision in assigning a journal to a field, the problem certainly originates in the classification schemes of the two repositories. The WoS scheme comprises 252 SCs covering the sciences (178), social sciences (47), and arts & humanities (27).Ⅰ In Scopus, each journal is instead assigned to one of the 334 “All Science Journal Classification” (ASJC) codes.Ⅱ At first glance the greater granularity of the Scopus classification scheme would seem an added value over WoS. However, examining the two schemes closely, we have discovered that:

- in the WoS, in addition to “Multidisciplinary Sciences” there are another nine “undefined” categories (e.g. “Chemistry, Multidisciplinary”), while in Scopus there are 27 categories with even more critical levels of non-definition, of the kind “Medicine (all)” or “General”;
- 32.8% of all the journals indexed in Scopus have at least one undefined code (compared to 8.7% in WoS), 21.7% have an undefined code and no other code (against 8.3% in WoS), and 4.2% of journals have still more than one undefined code;
- journals indexed in Scopus are on average assigned 1.87 codes, compared to 1.58 under WoS.

Although an unambiguously “correct” classification system has yet to be identified, the above findings led us to opt for WoS field classification.

To assess different diversification behavior across fields, we recur to the Italian “scientific disciplinary sector” (SDS) classification scheme for academics. In the Italian academic system all professors are classified in one and only one field (named “scientific disciplinary sector”, or SDS, of which 370 in all), grouped into disciplines (named “university disciplinary areas”, UDAs, 14 in all).Ⅲ In this study we focus on the sciences, for which the WoS coverage of publications by Italian universities is satisfactory. The sciences consist of 192 SDSs grouped into nine UDAs.Ⅳ Unfortunately, apart from the Italian one, the only other large-scale system known to us is the Norwegian Research Personnel RegisterⅤ compiled by the Nordic Institute for Studies in Innovation, Research and Education (NIFU). The NIFU system classifies scientists in 58 scientific fields grouped in five main domains (Rørstad & Aksnes, 2015). If Scopus recognizes 334 ASJC codes and WoS 252 SCs, reason would have it that the field classification of scientists should be numerically comparable. For the above reasons we opted for the Italian SDS classification of academics.

The next step is the construction of the publication portfolio of each individual scientist, from which we can proceed to disciplinary classification of the works (full counting). In the case of Italian academics, we can apply an algorithm for disambiguation of author names, developed by D’Angelo, Giuffrida and Abramo (2011), which allows us to assign the publications indexed in WoS to their relative academic authors.

**Dataset**

The dataset for the analysis is the 2004-2008 scientific production achieved by Italian professors in the sciences. The choice of a publication window quite far in the past is in consideration of a planned follow-up study with the aim of assessing whether output in
diversified fields is more influential in terms of citations than output in the prevalent field of the author: a longer citation window assures more robust and reliable results. Data on academics are extracted from a database maintained at the central level by the Ministry of Education, University and Research, indexing the name, sex, academic rank, affiliation, and the SDS of each professor. Publication data are drawn under license from the WoS Core Collection.

The overall dataset consists of 31,101 productive professors. Table 1 shows their distribution by UDA and gender, as well as the relative scientific production for the five-year period under observation. In the investigated fields, the share of female professors is 29%, varying across UDAs, with a minimum in Industrial and information engineering (13.3%) and a maximum in Biology (48.2%). Female professors co-authored 35.6% of total publications in the dataset, while males 90.6%. Civil engineering and Industrial and information engineering are the two UDAs with the major gender gap in co-authorships. The analysis of single-authored papers reveals that the share of female individual performers is lower than male. The same holds true analyzing papers authored only by professors of the same gender.

Indicators

The disciplines in which research activity is classified often overlap, and generally have quite weak boundaries – the fields within them even more so. The confines are anything but static, since continuous scientific progress contributes to variation in the scope of the fields, as well as the birth of new ones and disappearance of old ones. As already said, the analysis of IDR must in any case involve some predetermined reference classification: in our study we use the WoS classification system. We associate each publication in the database with only one topic. By topic we mean the SC of the hosting journal in the case of a mono-category journal, or the combination of WoS SCs when the publication is issued in a multi-category journal.

The authors can thus be divided into two classes: those who diversify, meaning their publications fall in more than one topic; those who do not diversify, meaning their
publications fall in a single topic. We refer to these classes as “diversified” and “specialized” authors. Obviously the distribution of the scholars between the two classes depends on the breadth of the publication window observed, the intensity of publication, as well as the classification scheme for disciplines. The object of our study is the diversified authors and their gender. For each author, we can first of all identify the dominant topic in which the individual publishes, meaning the most recurrent SC or SC combination in their publication portfolio. Similarly, we can identify the dominant discipline in which the topic falls, meaning the most recurrent discipline or discipline combination. We consider the case of Maria Rossi (Jane Doe in English), professor in the SDS FIS/03 (Physics of matter), who in the period of observation produced eight articles published in four different journals (Physical Review B, Physical Review E, Chemphyschem and Physical Review letters). Given the classification of these journals under the WoS system, we have the distribution illustrated in Table 2. The eight articles fall in four different topics, belonging to two different disciplines/combination of disciplines. The dominant topic is subject category UK (Physics, condensed matter), given that half of Rossi’s publications fall in this topic; while the dominant discipline is Physics. We can also observe cases of more than one dominant topic, which above all is more likely when the subject’s number of publications is low.

We will investigate three dimensions of diversification of research by individual professors. The first is “extent of diversification (ED)” given by the number of topics covered in the person’s scientific portfolio. The second is intensity of diversification, meaning the proportion of the professor’s output falling outside of their sector of specialization – measured by the indicator “diversification ratio (DR)”, given by the ratio of papers falling in topics other than the dominant one to the total number of publications. The higher the value of ED and the closer DR is to one, the more the individual’s research activity is diversified. The opposite situation denotes a highly specialized professor. There can also be antithetical situations: i) a high ED value jointly with a low DR value would indicate that the subject is predominantly specialized but open to exploring new fields; ii) a low ED value with a DR value tending to one is quite unlikely, unless the scientific production is very low. The last dimension investigated is the cognitive relatedness of the topics studied by the academic. Measurement of this requires definition of a threshold of cognitive proximity. For this purpose we associate the individual WoS topics to the disciplines, meaning we can identify the topics as “related” if they fall within the same discipline. The indicator for this dimension is “relatedness ratio (RR)”, equal to the ratio of number of papers in the dominant discipline to total number of papers. An RR of 1 indicates that the professor, although diversifying, does not go beyond their own disciplinary area. It is likely that a statistician (whose sphere of research can range from statistics to economics, medicine, agriculture, etc.) would have a much lower degree of relatedness than a surgeon.

According to the above taxonomy, for Maria Rossi we observe:
- An ED of 4;
- A DR of 0.5, since half of the total publications fall outside his dominant topic
An RR of 7/8, since 7 of the 8 publications are associated with the dominant discipline (Physics).

Analysis

In this section we analyze the three main dimensions characterizing research diversification, by the above indicators ED, DR and RR. Given the different operating definition of the indicators, the three datasets relative to ED, DR, RR analyses are of different sizes:

- **ED**: 31,101 observations in all, i.e. all professors with at least one publication in the period examined;
- **DR**: 26,943 observations in all, i.e. all professors with at least one publication falling in topics other than the dominant one;
- **RR**: 23,007 observations in all, i.e. all professors with at least one publication falling in disciplines other than the dominant one.

**Extent of research diversification**

We start the analysis at field level. As an example we consider the BIO/10 (biochemistry), falling in the UDA Biology. In this SDS 863 professors published at least once (in WoS indexed journals) in the period under observation (Table 3). The gender distribution shows 433 male professors and 430 female. Males’ average ED (6.635) is higher than females’ (4.588), but it is also true that males publish on average (14.02 publications) more than females (8.72). Controlling for publication rates, the average ED per publication presents no gender differences (0.508 vs 0.505).

</tbody>
</table>

The graph of Figure 1 confirms the strong correlation between ED and publication rates (Pearson ρ = 0.872), and shows the very large concentration of males among outliers (13 out of 14 professors with over 50 publications were male).

Aiming at investigating whether and in what measure there occur gender differences in research diversification behavior, we therefore adopt two different models of analysis:

- In the first model (Model 1) we assess the relation between ED and gender, via a direct OLS regression;
- In the second model (Model 2) we add the independent variable: number of publications by each single professor.

Results are presented in Table 4 for each SDSs of UDA Biology. With regard to Model 1, the impact of gender on ED is significant in over two thirds of the SDSs (13 out of 19) and is positive, meaning that being male leads in general to higher ED. As far as Model 2 is concerned instead, $R^2$ notably raises thanks to the introduction of output as independent variable. Alongside gender’s significance wanes: it remains significant in only five SDSs, and in two of them (BIO/02-Systematic Botanics e BIO/06-Comparative Anatomy and Citology)
it is negative, meaning that being female leads to higher ED.

Dependent variable: Extent of diversification (ED). Independent variables: Model 1, “gender” (F=0, M=1); Model 2, “gender” (F=0, M=1) and total output. OLS estimation method. Statistical significance: *p-value <0.10, **p-value <0.05, ***p-value <0.01. "Obs" equals the number of professors with at least one publication in the period examined.

The same analysis has been repeated for all 192 SDSs in the sciences (Table 5). With regard to Model 1, gender has a significant impact on ED in 76 SDSs, being positive in 70 SDSs. At UDA level, it is positive in at least half of the relevant SDSs in Mathematics and
computer science (6 out of 10), Chemistry (7 of 12), Biology (13 of 19), and Medicine (26 of 52).

With regard to Model 2, significance drops to 33 SDSs and in 14 of them impact is negative, i.e. being female leads to higher ED.

Finally, we have aggregated observations at UDA level (Table 6). According to Model 1 the impact of gender on ED results significant in each UDA and at overall level, with the only exceptions of Physics and Earth sciences. The positive regression coefficient indicates that males tend to diversify research activity more than females. Controlling for the different intensity of publication of males (Model 2), significance drops to two UDAs only, Mathematics and computer science and Biology; and in the first one are females that show higher ED.

**Dependent variable:** Extent of diversification (ED). **Independent variables:** Model 1, “gender” (F=0, M=1); Model 2, “gender” (F=0, M=1) and total output. OLS estimation method. Statistical significance: *p-value <0.10, **p-value <0.05, ***p-value <0.01. “Obs” equals the number of professors with at least one publication in the period examined.

**Intensity of research diversification**

The second dimension of diversification analyzed concerns the intensity of diversification, measured by the indicator “diversification ratio (DR)”, i.e. the ratio of the number of
publications falling in topics other than the dominant one to the total number of publications.

With reference to professors in BIO/10-biochemistry, gender differences by DR drop as compared to those by ED (presented in Table 3): males on average show a DR value (63.8%) similar to that of females (65.2%). Also the correlation between DR and publication rates decreases (Pearson ρ 0.298).

As expected ED e DR are correlated (Pearson ρ 0.573): as said before, the higher the value of ED and the closer DR is to one, the more the individual’s research activity is diversified or, viceversa, specialized. Figure 2 shows the dispersion of the two indicators regarding 814 professors in biochemistry (416 males and 398 females) with ED different from zero, subdivided into four quadrants drawn along the medians of the relevant distributions (5 for ED and 66.7% for DR). Occurrence of females in quadrant II (107 out of 179) is higher than males’. This means that the combination of below median ED and above median DR is a more a female trait. The opposite is true in quadrant IV (46 males out of 61). The chi-quadro test confirms the significance of such concentrations.

**Figure 2: Dispersion diagram of extent of research diversification (ED) vs diversification ratio (DR) for Italian academics in BIO/10-biochemistry (2004-2008 production)**

The OLS regression shows that gender impacts in a significant way the intensity of research diversification only in Biology e in Chemistry (Model 1 in Table 7). We observe that R² remains close to 0 even when output is included in the model as an independent variable. In Model 2, the regression coefficient is significant (and negative) in two UDAs only, Industrial and information engineering and Mathematics and computer science. The latter confirms what already observed along the dimension ED: it is females who show a higher propensity to research diversification in this discipline.

Statistical significance: *p-value <0.10, **p-value <0.05, ***p-value <0.01. “Obs” equals the number of professors with at least one publication falling in topics other than the dominant one.

### Degree of relatedness

We have finally analyzed the cognitive relatedness of the topics studied by academics who diversify their research. We have measured it by the indicator named “relatedness ratio (RR)”, given by the ratio of publications falling in disciplines other than the dominant one to the total number of publications. With reference to the SDS BIO/10-biochemistry, the distributions show that on average males (54.5%) present an RR slightly higher than females (53.1%). In this SDS, there occurs no correlation between RR and publication rates (Spearman $\rho$ -0.044).

The regression analysis at UDA level shows that gender impact is significant at overall level (last row of Table 8), as well in two UDAs, Physics and Biology (Model 2). In Model 1 the relation is significant also in Agricultural and veterinary sciences. Regression coefficients are positive in these UDAs, showing that males tend to diversify their research in fields more closely related than females.

Conclusions

Since Cole and Zuckerman (1984) referred to gender differences in research productivity among academic scientists as a “puzzle”, scholars have widely investigated possible determinants of female underrepresentation and lower performance. Very few studies have considered whether there occur gender differences in the propensity to diversify one’s own research activity and if such difference may explain performance gap. In Leahey (2006) opinion the preference of women for less specialised research, hinders their capacity to get published and cited and can help explain the process by which gender affects research productivity. Unfortunately, such conclusions are based only on observations from sociology and linguistics. With a different but related perspective, Rhoten and Pbirman (2007) showed that female scientists are much more likely to engage in IDR projects than males. The current work has tried to shed additional light on this issue.

Based on observation of 2004-2008 scientific production of all Italian professors in the sciences, we demonstrated that gender impact on the extent of research diversification is meaningful both at overall level and at discipline level, with the only exceptions of Physics and Earth sciences. Males tend to diversify research activity more than females. However, this seems mainly due to the higher publication intensity of males: when controlling for individual output, significance drops to two disciplines only, Mathematics and computer science and Biology; and in the first one are females that show higher extent of research diversification, confirming both Leahey (2006) and the Rhoten and Pbirman (2007) views. Conversely, in Biology such view is contradicted.

The greater propensity to research diversification of females in Mathematics and computer science is confirmed along another dimension of diversification, the “intensity of diversification”, which points out higher intensity of diversification of women also in Industrial and information engineering.

The use of a third indicator measuring the relatedness of topics investigated by diversified professors allows us to state that males tend to diversify their research in fields more closely related than females both at overall level, as well in Physics and Biology.

We conclude that the attempt to solve the puzzle of gender differences in research is weak-willed: the different research diversification behavior of females with respect to males tends to vary based on the dimension of diversification analysed and the specificity of each discipline. Our findings suggest caution in identifying research diversification as a co-determinant of the gender productivity gap between males and females.

interdisciplinarity of journals. *Journal of the Association for Information Science and Technology*, 67(5), 1257-1265.

NOTES

iv Mathematics and computer sciences; Physics; Chemistry; Earth sciences; Biology; Medicine; Agricultural and veterinary sciences; Civil engineering; Industrial and information engineering.

vii In view of a future extension of the analysis to other personal determinants of diversification, we have excluded 2,682 productive professors whose age is not available.

viii Article, reviews, letters and conference proceedings

ix We have associated each WoS subject category to one and only one of the following disciplines: Mathematics; Physics; Chemistry; Earth and space sciences; Biology; Biomedical research; Clinical medicine; Psychology; Engineering; Economics; Law, political and social sciences; Multidisciplinary sciences; Art and humanities.

x Because the intensity of publication varies across the SDSs within each UDA (consequently, ED and output distributions are structurally different), we have rescaled each variable by the average of the relevant distributions excluding nil values (Abramo, Cicero, & D’Angelo, 2012)

xi In this case the number of observations drops to 747 (368 females and 379 males), since we observe only authors with at least one publication falling in disciplines other than the dominant one.
Do Google Scholar and Web of Science reflect women’s and men’s scholarly impact differently? A comparison of U.S. researchers in sociology and economics

Jens Peter Andersen1 Mathias Wullum Nielsen2

1 jpa@ps.au.dk

2 mwn@stanford.edu
Department of History, Stanford University. Stanford (United States)

Abstract
Several studies have demonstrated differences in Google Scholars’ and Web of Science's coverage of citing publications. In this paper, we examine whether citation data retrieved from Web of Science and Google Scholar reflect women’s and men’s scholarly impact differently. Our study is based on a sample of 200 randomly selected U.S. authors in economics- and sociology-related research areas. Our results illustrate noteworthy gender disparities in the per-paper citation rates across the two databases. In sociology, we find that women benefit more than men, when impact assessments are based on data from Google Scholar, while the opposite is the case in economics. If our results prove to be robust in a larger data-set, based on a more exhaustive matching of documents, they illustrate how the selection of data-sources can have consequences for how individual scholars are assessed, e.g. in tenure or grant review evaluations.

Conference Topic
Science policy and research assessment; Journals, databases and electronic publications; Data Accuracy and disambiguation; The application of informetrics on evaluation

Introduction
Advances in information technology has spawned a growing use of citation-indices in the assessment of individual researchers’ scholarly impact. Today, citation-counts inform tenure, hiring and funding decisions in many disciplines (Nielsen, n.d.; O’Connor & O’Hagan, 2016; Stephan, Veugelers, & Wang, 2017; Van den Brink, Fruytier, & Thunnissen, 2013; Weingart, 2005), and individual citation-performance has been shown to correlate positively with academic salary levels (Leahey, 2007). Citations are becoming essential building blocks for academic success and status in the academy; and given their increasing importance as sieves for allocating opportunities and rewards, the data sources used in citation analyses deserve careful consideration.

This paper investigates the potential gender consequences related to the use of different databases in the assessment of individual researchers’ scholarly impact. Based on a sample of 200 randomly selected U.S. authors in economics- and sociology-related research areas (100 women and 100 men), we examine whether citation data retrieved from Web of Science and Google Scholar reflect women’s and men’s scholarly impact differently. For authors in economics, we find that men benefit considerably more than women, when citation-scores are based on Google Scholar data as opposed to Web of Science data. In contrast, women are put at a relative advantage when Google Scholar is used as data source in sociology. The paper proceeds as follows: First, we briefly discuss differences between Web of Science and Google Scholar and specify our focus. Second, we describe methodology and data. Third, we present and discuss preliminary results, and conclude.
Framing the problem

During the last decade, Web of Science’s longstanding role as primary data-source in citation-analysis has been challenged by new data-providers such as Google Scholar and Scopus. Studies comparing Google Scholar, Scopus and Web of Science reveal large variations in content coverage dependent on discipline and time period (Falagas, Pitsouni, Malietzis, & Pappas, 2008; Neuhaus, Neuhaus, Asher, & Wrede, 2006). Existing comparisons focusing on the coverage of citing publications, however, typically find that Google Scholar captures more unique citations than Scopus and Web of Science, especially in the newer literature (Bosman, van Mourik, Rasch, Sieverts, & Verhoeff, 2006; Harzing & Alakangas, 2016; Kulkarni, Aziz, Shams, & Busse, 2009; Meho & Yang, 2006). This is not surprising given that Google Scholar includes many publication types not covered by the other databases (e.g. doctoral theses, conference proceedings, anthology articles, books, regional and online journals and publication outlets in other languages than English). In this study, we examine whether a shift from Web of Science’s “restrictive” citation index to Google Scholars’ more “inclusive” citation tracker, Harzing & Mijnhardt (2014) has any implications for the relative citation-performance of women and men. A recent study by Harzing & Alakangas (2016) found that disparities in the coverage of citing publications between Web of Science and Google Scholar were larger for the social sciences than for the natural and health sciences (computer science and engineering are exceptions). Thus, we limit our focus to the social sciences; specifically, authors in economics- and sociology-related research areas.

Methods & data

Data collection

Given our specific interest in analysing the potential gender consequences of database selection, rather than attempting to make general conclusions on women's and men's citation-performance, we harvested articles based on individual Google Scholar profiles. These were subsequently matched to corresponding Web of Science records. To identify Google Scholar profiles for researchers in economics- and sociology-related areas, we created a background population of authors having published in journals categorised under sociology and economics in Web of Science between 2014 and 2016. Author groupings created by Caron & Van Eck (2014) enabled us to obtain additional information, such as email and institutional affiliation for each author. A total of 8,565 economics scholars and 3,126 sociology scholars from the U.S. formed the basis of our selection process. These were classified as men or women based on their first name, using the Gender API1 tool. Gender API draws on social media data to provide statistical probabilities on whether any given first-name belongs to a man or a woman, while accounting for country variations. As certain names yielded inconclusive results, we limited our dataset to names that could be classified with at least 95% certainty. Gender statistics for the dataset are available in Table 1.

1 www.gender-api.com
From this background population, candidates were drawn in alphabetical order (which for this particular case should be as good as any other kind of presumed randomness), and a search for their profile on Google Scholar was performed. The user interface for this procedure presented candidates interchanging between men and women and both fields, to ensure that both genders and fields were represented equally, despite differences in their distributions. We limited our final sample to 200 Google Scholar profiles: 50 for each gender in each field. We used keywords available for each Google-Scholar profile, or departmental affiliation(s) to ensure that the scholars were indeed active within either economics or sociology-related research. Using the R-package ‘scholar’ (Keirstead, 2015; R Core Team, 2015), full publication lists were downloaded, including bibliographic information and citation counts.

A very large proportion of references in Google Scholar were to books, conference proceedings, teaching material, trade journals and other grey literature not captured by Web of Science. To identify publications registered in both Web of Science and Google Scholar, we ran complete reference strings, including authors, title, journal and source information past the CrossRef API2, retrieving DOI information on all publications with a match score above 95. This procedure allowed us to retrieve DOIs from 3,376 out of 21,844 documents. Of these, only 1,743 could be matched to a Web of Science record. The remaining references were run through a series of regex searches to identify journal, volume, issue, publication year and page information. Matching these to Web of Science increased our total sample of matched records to 4,903. Citation data from both sources were collected up until the most recent time3.

**Evaluation methods**

Our analysis is based on a comparison of raw citations up until the present. Given our focus on the relative difference between a given paper's citation score in Google Scholar and Web of Science, and not the general citation-impact of the paper, we do not normalize for field. We also compute citation-ratios such that the ratio, \( R \), of a given paper is the number of citations received in Google Scholar divided by those received in Web of Science. The ratio thus expresses the relative citation advantage of Google Scholar, or the increased ratio of included sources. For raw citation comparisons, we report arithmetic means and confidence intervals computed using one-sample t-test in R. For the ratios, we choose instead to report the harmonic mean, which is better suited for this type of variable. To calculate confidence intervals for the harmonic means in R, we use bootstrapping (Canty & Ripley, 2015) and generate harmonic means of 10,000 resamplings of each group. The confidence intervals are found by selecting the values at the 2.5\textsuperscript{th} and 97.5\textsuperscript{th} percentile.

**Results**

Figure 1 presents the raw distribution of citations per paper in economics, as given by the two databases and grouped by gender. The corresponding distributions for sociology are shown in Figure 2. It is obvious from these illustrations that the citation advantage of Google Scholar is large in all cases, and that men in general receive more citations, but especially in Google Scholar. The overlap of confidence intervals for men and women should, however, be noted, despite the rather large differences in means.

3 retrieved April 28, 2017
Figure 1. Raw citation distributions for Web of Science (WoS) and Google Scholar (GS), grouped by database and gender. Limited to economics.

Figure 2. Raw citation distributions for Web of Science (WoS) and Google Scholar (GS), grouped by database and gender. Limited to sociology.

Figure 3 displays the ratios and bootstrapping percentile confidence intervals between citation scores. First of all, the figure reveals how sensitive the analysis is to outliers, implying that interpretations should be made with extreme care. However, the mean distributions indicate quite large differences for women and men in both economics and sociology, and given our use of harmonic means, which is the most conservative of the mean-calculations, this is a quite clear observation nonetheless.
Discussion
To our knowledge, this paper is the first to examine whether citation data from Web of Science and Google Scholar reflect women’s and men’s scholarly impact differently. Our results illustrate noteworthy gender disparities in the per-paper citation rates across the two databases. In sociology, we find that women benefit slightly more than men, when impact assessments are based on data from Google Scholar, while the opposite is true in economics.
If our results prove to be robust in a larger data-set, based on a more exhaustive matching of documents and a larger sample of Google Scholar profiles, they illustrate how the selection of data-sources in research evaluations can have consequences for how individual scholars are assessed, e.g. in tenure or grant review evaluations. Further, research-based comparisons of women's and men's citation performance (see e.g. Nosek et al., 2010) using Google Scholar data may prove to be incompatible, with equivalent studies (focusing on the same discipline) using Web of Science data.
In the present research, we have regarded all possible papers from each scholar, regarding them as “their” paper, regardless of the number of co-authors or first-authorship. This can potentially skew the results, however, as each paper is linked to a particular profile, we expect the potential effect of this factor to be smaller, than if the body of papers had been randomly selected. It is important to note that the research presented here is in progress, and the process for data collection and cleaning will be enhanced and expanded in future work. This should considerably strengthen the preliminary findings presented in this paper.

Abstract
Human capacity for innovation is not well-utilized in a system that favors one gender over another. Despite decades of policies in gender equity in science, disparities persist along several dimensions. One dimension that has been relatively understudied is the role of funding on gender disparities in science. To address this gap, we provide an historical analysis (1981-2016) of funding, by gender, from the National Science Foundation in the United States. We find that the mean rate of funds received by women is higher than that of men (and has been so since the early 2000s). However, men control the dominant share of funding and fellowships. As a work -in-progress paper, we discuss the extraction and cleaning of the data, provide an initial analysis, and describe the ongoing analysis of these data. The results provide policy makers with a much needed historical lens on progress towards parity, identifying areas of success and areas which require additional efforts in order to fund women at rates equal to their participation in science.

Conference Topic
Science policy and research assessment; Funding; Gender; Science of science

Introduction
Innovation is critical to economic development, yet is hindered by gender disparities in the scientific workforce (Etzkowitz, Kemelgo, & Uzzi, 2000). Despite more than a decade of policies aimed at achieving gender parity (Hagmann, 1999), women produce proportionally and comparatively less than men—in terms of both scientific articles (Lariviere et al., 2015) and patents (Sugimoto et al., 2015)—and their work receives fewer citations (Lariviere et al., 2015). The matriculation of students in undergraduate programs is not the problem: the OECD (2012) reports more female entrants than men in all but four countries (Germany, Turkey, Korea, and Japan). Rather, disparities are seen further downstream (Newsome, 2012)—women drop out of academe at a higher rate than males or fail to advance, creating more opportunities for men to progress through the ranks. As a recent editorial in Nature (2013) noted, in the United States and Europe, “barely one-fifth of full professors are women,” and progress on gender equality in science “seems to have stalled”. The so-called “leaky pipeline” phenomenon has been the focus of a number of studies seeking to understand what contributes to the attrition of women (Morgan, Gelbgiser, & Weeden, 2013), though this metaphor has been under increased scrutiny as an explanatory mechanism (Miller & Wai, 2015).

One possible alternative explanation for gender disparities in science is in the allocation of resources. The largest amount of funding for academic research comes from the federal government (SEI, 2012), and studies have shown that gender serves as a predictor of grant attainment (Jagsi et al., 2011; Jagsi et al., 2009). It has been suggested that bias in grant attainment (such as racial discrimination (Anon., 2011) and other success is due to cumulative advantage (Merton, 1973), with successful advisors unconsciously choosing advisees who
reflect their own social characteristics, thus perpetuating educational elitism in scholarship (RAND, 2005). This is exacerbated by the fact that younger faculty are less likely to receive federal support than their more senior colleagues (RAND, 2005). Women fare poorly in disciplines where research is expensive (Duch et al., 2012), and male authorship is disproportionately associated with contributing resources, whereas female authorship is significantly more likely to be associated with labor roles such as performing the experiment (Macaluso et al., 2016). Studies which have sought to identify gender disparities in federal funding have been hampered by the lack of demographic data collected on applicants, despite Title IX compliance regulations (Mervis, 2015). Additionally, studies have sought to examine the relationship between funding and outcome metrics, with varied results. Few studies have employed advanced statistical methods and large-scale integrated data to examine the relationship between funding and outcome metrics, and fewer still have examined how this relationship is moderated by gender and country of funding.

This study addresses the lack of historical information on rates of funding by gender by means of a diachronic analysis of grants awarded by the National Science Foundation. As a research in progress, this work presents the methods of data extraction and cleaning of the data, initial descriptive results, and plans for future analyses.

Data and Methods

Funding data for this paper was retrieved from the National Science Foundation (NSF) list of awards per year, which can be downloaded in XML format from the NSF website: https://www.nsf.gov/awardsearch/download.jsp. Each project funded by the NSF since the 1950s is available, including the amount received, the title of the project and program through which funding was obtained, as well as the institution funded, among other variables. While data prior to 1981 do not include the name of the principle investigator (PI), data after 1981 includes this information (given name and family name), which allows for the assignment of a gender to the PI of the project. Hence, data presented in this paper cover the 1981-2016 period.

In order to assign gender to given names, we used an algorithm that mines Wikipedia pages of individuals who have a specific given name. More specifically, our gender sorting algorithm uses the Wikipedia API for Python, which retrieves gender information by counting key words in pages of persons with a specific given name. Four steps are used to assign gender to a given name. First, all Wikipedia pages that starts with the given name followed by a space and an uppercase character are isolated. Those pages are normally about a person with the studied given name. Second, the summary text before the first section is analysed for all words between spaces, apostrophes, periods, commas and parentheses. If the sum of the number of occurrences of “he” and “his” in the summary is equal to or more than three times the sum of “she” and “her”, the page is identified as masculine. If the sum of “she” and “her” is equal to or more than three times the sum of “he” and “his”, the page is identified as feminine. If neither cases happen, the page is skipped. Third, once the page list is exhausted or 20 pages have been identified, the query is stopped. Finally, if equal to or more than three quarters of all identified pages are masculine, the given name is set as M. Likewise, if equal to or more than three quarters of all identified pages are feminine, the given name is set as F. The reliability of the algorithm has been tested by comparing it to the Gender.c package—a free name gender database of 36,940 identified. Testing showed gender agreement 99% of the time for these names.

Table 1 presents, for the 1981-2016 data, the number and percentage of awards and of their amounts. It shows that our method allowed for the assignment of close to 93% of awards, and of slightly less than 90% of their amount.

Results

Figure 1 presents, for standard and continuing grants—which account for more than 71% of all funding awarded by the NSF over the 1981-2016 period—the mean amount of award obtained by women and men (left panel), as well as the proportion of total funding (right panel). It shows that, until the end of the 1990s, women’s grants were sizably smaller than those of men, with women obtaining percentages of men’s grants that oscillated between 62% and 94%. However, from 2001 onwards, women obtain mean grants that are slightly above those of men. In terms of proportion of total funding, we observe that, although men still account for a larger share of the funding—which is not surprising given their higher proportion of the workforce—their share is significantly decreasing, from 95% in 1981 to 73% in 2016.

In terms of fellowships awarded—which includes both graduate and postdoctoral—we also observe that, while men still account for the majority of funded projects, women share is increasing (Figure 2). More specifically, while women’s share of fellowships was less than 10% in the early 1980s, they account for more than 40% in 2016.
Limitation
The lack of disambiguation at the individual level makes per capita analyses difficult. This is one of the limitations of the work-in-progress that will be addressed in subsequent research. Furthermore, the name gender algorithm was only tested against a small set of names. A more robust analysis is necessary in order to adequately assess the rigor of this novel method.

Discussion and Future Research
Despite considerable concerns about rates of funding for women in science, there is scant data at the federal level on rates of funding by gender. The main federal provider of academic research funding in the United States is the Department of Health and Human Services (of which the National Institute for Health (NIH) is the primary funding body) (SEI, 2016). Funding provided by the NIH during the period 1997-2003 was studied by Jagsi et al. (2009; 2011). These studies found that women were awarded a third of K08 and 44% of K23 (both early career research awards) funded by the National Institute of Health (NIH) between 1997-2003. Using these data and follow-up data from a sample of 211 women, they found that women were less likely to subsequently receive an R01 (a major research project grant) and published, on average, fewer papers. Studies of funding from the National Science Foundation, which represented (as of 2013) more than 13% of academic research funding—second only to the NIH—has not been analyzed. Our work, therefore, expands both in agency and breadth our understanding of the relationship between gender and funding in science.

The mean amount of grant provided to women is slightly higher than that of men’s and has been since the early 2000s. However, the proportion of total funding remains higher for men than for women, though it has been steadily drawing towards parity since the beginning of the analysis (1981). In 2016, 73% of funding was distributed to men. A similar pattern can be observed for fellowship funding, which has decreased to less than 60% in 2016. However, both of these amounts are disproportionate with many other benchmarks: for example, men comprised 70% of fractionalized authorship on research publications from 2008-2012 (Lariviere et al., 2013) and earned less than half of the doctoral degrees awarded in the US in 2014 (NSF, 2017). This suggests that, despite a trajectory towards parity, funding amounts do not match the gender
composition of the scientific workforce. Of course, there are strong disciplinary differences in both funding and gender composition of the scientific workforce; therefore, further research must take discipline into account. This will require creating a disciplinary taxonomy from the NSF data, given that it is provided according to program.

Grants are intended as inputs in the scientific system. Therefore, it is useful from an indicator perspective to measure the relationship between this input and subsequent output. In future research, we will match the funding data within NSF will other productivity and impact measures (using a disambiguated data set from WoS). This will provide an indicator not only of the rates of funding by gender, but the result of this funding, accounting for differences in discipline and institution. These data will provide a comprehensive and historical understanding of the relationship between funding and gender in the United States for the National Science Foundation. Future research will extend these analyses to other agencies in the United States, such as the National Institute for Health, as well as to other nations.

Science has an indisputable impact on the economy and wellbeing of society. Progress is hindered when a given population is not given adequate representation in science or the resources to perform their activities. The present study provides policy makers with a much needed historical lens on progress towards parity in science funding, demonstrating where parity has been reached (i.e., in mean grant award) and where there is still work to be done.

Abstract
Canada Excellence Research Chairs program—an award worth up to ten million dollars over seven years to attract and support world-renowned researchers and their teams to establish research programs in Government of Canada’s science and technology priority areas at Canadian universities—has been one of the most controversial governmental funding allocations in Canada. One of the main criticisms to this program is the absence of clear selection and recruitment criteria, including promulgation of standards for inclusion and diversity, which have resulted in lack of representation of women among Chairs. The main purpose of this study is to shed light on gender differences in scientific production and impact of publications induced by Canada Excellence Research Chairs program and to examine co-authorship collaboration patterns that are formed as a result of introduction of this program. Findings reveal that when Chairs are listed as main investigators of the scientific work (either last or corresponding authors), female-led papers receive higher rate of citations and are published in journals with higher impact. Although citation impact of papers that include collaborations with women are the highest, more than 78% of researchers of each gender repeat their collaborations, with their male peers on authoring more than one papers. Last but not least, this study concludes that collaborations with women are fragile and are dependent on the presence of central male researchers. Therefore, contributions of women to high impact research is effective as long as they are under the shadow of more central, influential and popular men.

Conference Topic
Science policy and research assessment

Introduction
Occupational gender segregation—a pervasive phenomenon expressing different distribution of women and men across occupations and sectors—has long been of central concern to science and public policy (Bettio, Verashchagina, Mairhuber, & Kanjuo-Mrčela, 2009; Charles, 2003; Fortin & Huberman, 2002). It is commonly differentiated along two dimensions: horizontal and vertical. Horizontal segregation is the differences in concentration of women and men in certain professions or sectors, whereas vertical segregation refers to representation of men and women at different levels or positions of labour hierarchy in terms of income, prestige, and the like. The vertical dimension has dovetailed with well-known notions of “glass ceiling” (Hymowitz & Schellhardt, 1986) and “sticky floor” (Noble, 1992), where visible or invisible barriers prevent women from advancing into top levels of hierarchy, and intrinsic forces tend to keep women at the lowest levels of the hierarchy (Meulders, Plasman, Rigo, & O’Dorchai, 2010).
Academia is no exemption and is not immune to gender segregation. Women in science also hit the glass ceiling—a hindrance to those trying to progress to senior ranks in academia (Caprile, Addis, Castaño, & others, 2012). However, the “leaky pipeline” metaphor (Berryman, 1983) suggests that women tend to leave science long before they face the glass ceiling, bearing witness to the higher attrition of women from science as they advance through the pipeline of science (the educational/professional system training scientists).

In response to the growing concern on women’s progression and retention in academia, science and technology (S&T) policies have typically centered either on getting more women into science and engineering (S&E) fields, or on affirmative action programs to remedy gender disparities along the science pipeline (Buré, 2007). However, increases in quotas as a stand-alone measure is likely to be futile to fix the leaky pipeline and glass ceiling for women in science, unless reinforced by systematic socio-economic strategies that alleviate inequalities in other arenas of society in ways that support productivity, diversity and inclusion (Alexander & Jacobsen, 1999; Cheldelin & Eliatamby, 2011, p. 239; Etzkowitz, Kemelgor, & Uzzi, 2000).

This study tries to articulate these issues into Canadian scientific system, delving into Canada Excellence Research Chairs (CERC) program—an award worth up to ten million dollars over seven years to attract and support world-renowned researchers and their teams to establish research programs in Government of Canada’s S&T priority areas at Canadian universities. These awards are acknowledged to be most generous available globally.

The CERC program was launched in 2008, the successor to government of Canada’s economic plan known as “Advantage Canada”, a plan to improve Canada’s global competitiveness as a knowledge-based society by creating pool of talents and effectively translating research into innovation to provide solutions and address concerns primarily in four fields, namely (1) Environmental Sciences (2) Natural Resources (3) Health Sciences (4) Information and Communications Technologies (Science-Metrix, 2015). Advanced manufacturing, social inclusion and innovative society, and other areas to benefit Canada have been added to the government of Canada’s priority areas after the first competition (Science-Metrix, 2015).

This program has been one of the most controversial governmental funding allocations in Canada over the past decade. The primary criticisms were twofold: (1) the program’s lack of focus on support and retention of local talents, and (2) the absence of clear selection and recruitment criteria, including promulgation of standards for equal opportunities, inclusion and diversity (Ghoussoub, 2013; The Globe and Mail, 2010, 2014). The attention to the latter concern was raised after selection of Chair holders in the first CERC competition in 2010, among which no women were even shortlisted for nomination. This issue provided an immediate impetus to review CERC Gender Issues by the Ad Hoc Panel and the lack of representation of women among CERCs was further dubiously explained by underrepresentation of women in top academic positions, low participation of women in Canada’s top four priority areas, and women’s vulnerability to mobility stress and career change (Science-Metrix, 2015). Canada’s effort to allay this concern was limited to a more transparent recruitment process report from universities, and accommodation of rising stars (rather than established researchers) and number of CERC positions open to all areas of research into the CERC program (de la Giroday, 2013; Science-Metrix, 2015). These initiatives resulted in the selection of only one woman out of nine additional Chairs under the second competition concluded in 2015. As of total, only one of twenty seven appointed CERCs is a woman.

The extreme underrepresentation of women in CERC program reflect one of the consequences of the glass ceiling and leaky pipeline phenomena, upon which attainment of equity and

diversity practices are obviated in Canada’s largest investment in research. This study shares the assumption that appointment of more female CERCs alone does not necessarily lead to promote equitable access to the program for qualified researchers of each gender. For this purpose, this study looks into co-authorship collaborations that are initiated by CERC program and tries to answer one main question: What are the gender differences in research output and scientific contributions that are induced by CERC program? Therefore, this study applies bibliometric and social network analysis (SNA) techniques to provide a cross-gender analysis of scientific production and impact, and collaboration patterns of Canada Excellence Research Chairs.

**Methodology**

Bibliographic publication data is gathered from Web of Science (WoS) database for Canada Excellence Research Chairs, where Chairs are affiliated to the Canadian university awarded in years 2008-2015. Since the focus of CERC programme is on advancement and diversification of Canadian scientific community, collaborators of CERCs are defined as Canadian-affiliated researchers who have authored one or more papers with CERCs. CERC program is launched in 2008 and full given names of authors are available in the WoS from 2008 onwards. Therefore, gender is assigned to the given names of CERCs and their collaborators, using U.S. Census, WikiName, Wikipedia, France and Quebec lists (More details in (Larivière, Ni, Gingras, Cronin, & Sugimoto, 2013)). Among 27 CERCs, 21 CERCs are identified with at least one paper published with their awarded Canadian university. A total of 712 articles were extracted from the Web of Science database, along with their 750 distinct authors.

The quantitative analyses are grounded on bibliometric indicators of scientific output, using the number of scientific publications as an indicator of productivity of a researcher, the normalized citations as research impact, and normalized Impact Factor (IF) as a journal impact indicator. The normalized citation impact of a paper is calculated as the average yearly number of citations received by a paper divided by the average yearly number of citations to all the papers from the same year, in the same subject area and of the same document type (Glänzel & Schubert, 2005; Moed, De Bruin, & Van Leeuwen, 1995). The normalized journal IF is calculated similar to the citation impact where the IF of the journal associated to each paper is considered instead of number of citations.

The proportion of scientific production of each gender is defined as a fractional count of articles, according to which each author account for 1/x count of authorship where x is the number of co-authors of an article affiliated to a Canadian university to which a gender is assigned. In this paper, orders of authors in the byline is considered as a measure of contribution, due to the fact that fields of research of CERCs follow contribution-based authorship ordering as a common practice, based on which first author position is typically given to younger researchers with lower professional rank and last author position is assigned to the principal investigator with high rank (West, Jacquet, King, Correll, & Bergstrom, 2013). Articles with CERCs listed as a corresponding author are also identified to help analyse the contribution of researchers of each gender where CERCs are responsible for the research project as a whole, including acquisition of funding, oversight of a research process and production of the final manuscript (Yank & Rennie, 1999).

The collaboration patterns of CERCs are mapped using the co-authorship network analysis, in which nodes represent authors and two nodes are connected when two authors co-author a paper. Each link (edge) is categorized into whether it connects two female authors (F-F) link, or one female and one male author (F-M), or two male authors (M-M). Weight of each link represents the extent to which two authors who have already collaborated on a paper, repeat
their collaborations by co-authoring another paper together and is referred to as collaboration repetition rate in this research.

In this study, the listed network measures in Table 1 are deployed to characterize the CERC’s co-authorship network, assessing the role of authors of each gender. CERC’s network of co-authorship is further visualized using Gephi’s (Bastian, Heymann, & Jacomy, 2009) Force-Atlas 2 layout, in which the proximity of two nodes is defined by the weight of the edge that links the two nodes.

Findings

21 Chairs are identified with at least one paper affiliated to their awarded university, noting that other 6 Chairs that are not included in our publication data analysis are selected as CERCs from 2015 onward. Therefore, they had no paper published with a Canadian affiliation in years 2008-2015. Among these 21 Chairs identified, one is female (who is involved in authoring 22 papers) and 20 are male researchers (who are responsible for authoring 690 total articles). 214 female and 515 male authors were involved in CERCs’ authorship collaborations, being referred to as CERC collaborators in this research.

Although share of female authorship for CERCs is very limited (4%), women account for 25% of authorship among CERC collaborators (Fig. 1). CERC publications with female collaborators involved, have higher or equal scientific impact as those authored with male collaborators (Fig. 2). When women are lead-authors (first authors), their papers receive lower number of citations although being published in journals with higher impact (Fig. 3). This has been associated to Matilda effect (Rossiter, 1993) in science in several studies (Ghiasi, Larivière, & Sugimoto, 2015; Larivière, 2014), according to which women’s contribution to science is played down and attributed to their male peers (which in this case is in terms of the citation rate expected to be received by publishing papers in journals with higher IF than journals in which male first-authored papers are published). However, when women are last authors their papers receive lower citation rate (Fig. 3).
When Chairs are listed as last authors (which is often held by principal investigator or supervisor of the research project) (Table 2), female first-authored papers receive higher citation impact and are published in journals with higher IF (Fig. 4). These differences are even more conspicuous when Chairs are corresponding authors (main investigators of the research project) (Table 2; Fig. 5).

Co-authorship Network Analysis

Details on CERC co-authorship collaboration network can be found in Table 3. Degree centrality is higher for women, which shows that female researchers are more collaborative than male researchers involved in CERCs’ co-authorship collaborations. However, men are more productive and average clustering coefficient is lower for men in the network. This confirms that direct collaborators of a female author are better connected if she is removed from the network, highlighting important position of male researchers within the network.

Share of F-F collaborations are the lowest in CERC authorship collaboration network and majority of collaborations are between two male researchers (Fig. 6), which is expected due to the low share of women involved. Moreover, M-M collaborations are shown to be the strongest ties among other collaboration types (Fig. 7). At individual level, the female CERC have repeated her collaborations with other female authors at a higher rate than her male authors. However, among 20 male CERCs, this trend is only observed for three Chairs. The findings also reveal that only 17% of female researchers and 22% of male researchers involved in more than one paper with CERCs, repeat their collaborations more with their female colleagues. Hence, it can be concluded that for both genders, repeating an authorship collaboration with a male researcher is preferred.

![Figure 6. Share of different collaboration type](image)

![Figure 7. Collaboration repetition rate (edge weight) per collaboration types](image)

Along these lines, average citation impact of papers forming F-F collaborations are the highest compared to those creating F-M and M-M collaboration (Fig. 8). Therefore, in the CERC co-authorship collaboration network, female authors are collaborating with other female authors on highly cited papers.

---

*This is not associated to the data size, 86 distinct papers are identified for F-F collaborations, 192 papers for F-M collaborations and 303 papers for M-M collaborations.*
Figure 8. Average citation and journal impact of papers forming different types of collaborations

Since other centrality measures such as betweenness, eigenvector and closeness cannot be applied to disconnected networks, these measures are compared for researchers of each gender in each CERC cluster (CERCs and their connections to their collaborators). Female collaborators of the female CERC are associated to higher betweenness, eigenvector and closeness centrality compared to male collaborators of the CERC. Only 6 of male CERCs are involved in clusters where women have higher betweenness centrality and 5 male CERCs are located in clusters where women have higher closeness centrality and 2 in cluster with higher female eigenvector centrality, noting that these overlap. These measures show the important position of men in the network in majority of CERC clusters, denoting vulnerability of F-F connections and their strong reliance on a male researchers.

Visualization of CERC’s collaboration network is shown in Fig. 9. In this network node size is based on degree centrality of an authors and node colours represent different roles of authors. Edges are differentiated based on the collaboration type. The visualization also highlights a presence of male collaborators with high degree centrality where higher shares of female authors and F-F collaborations (orange links) are present, highlighting the fragility of F-F links and their reliance on collaborations with men.

Figure 9. Visualization of co-authorship collaboration network of CERCs
Conclusions

The main purpose of this study is to shed light on gender differences in scientific production and impact of publications induced by Canada Excellence Research Chairs program and to examine co-authorship collaboration patterns that are formed as a result of the introduction of this program. This program is highly male dominated: women account for only 13% of total authorship engendered by CERC program. However, share of female authorship is higher (25%) among CERC collaborators. Although only one woman has been selected as CERC since 2010, female collaborators of CERCs have shown to be as influential as their male collaborators by being involved in papers with higher or equal scientific impact as those of their male peers. Matilda effect (Rossiter, 1993) might be present at the level of citations, based on which when women are lead authors, their scientific work receive lower recognition (citation rate) than the rate that is expected to be received from the journals their papers are published in (Ghiasi et al., 2015; Larivière, 2014). When Chairs are listed as main investigators of the scientific work (either last or corresponding authors), female-led papers receive higher rate of citations and are published in journals with higher impact. This finding reveals that women make the largest contribution to high-impact publications of Chair-supervised projects.

Although average citation impact of papers that are forming collaborations with women (which include F-F or F-M collaborations) are the highest, more than 78% of researchers of each gender repeat their collaborations, with their male peers on authoring more than one paper. Last but not least, based on the network visualization and the centrality measures, this study concludes that F-F collaborations are fragile and might be strongly dependent on the presence of central male researchers. Therefore, this can be said that contribution of women to high impact research is effective as long as they are under the shadow of more central, influential and popular men. The results of this study might benefit Canada’s limited S&T gender-related policies, with a specific focus on development and implementation of systematic strategies to increase participation of women in Chair programs as students, colleagues and professionals. The results of this study underpin the importance of collaboration with female researchers, which is often overlooked in retention and inclusion policies of women in S&T, and can provide a baseline to develop gender-responsive policies facilitating forming collaborations with women and favouring the participation of female researchers in CERC.

Abstract
In the present article, we propose and analyze the consequences of using a specific aggregation rule for measures of individual scientific impact into collective level measures (institutions, departments) for real populations of academics in a specific science field. The point of departure of our argument is that current aggregations of collective unit scores, such as those employed by the influential international rankings, but also national evaluation policies is that these are prone to ‘the exploitation of the great by the small’ (Olson 2002, 35), that is the high influence exerted by the top ranked units in the evaluation exercise. We construct our research question from this observation, focusing on the issue of measuring inter-institutional differences in terms of scientific impact in skewed populations, where such differences are obscured by high intra-institutional variance. We extend the initial scope of the Characteristics Scales and Score (CSS), in order to address this question. We analyse scientific impact by two measures, total number of citations and a rational variant of Egghe’s g-index. Our main findings relate to the properties of the ‘fair’ category within the CSS: linearity and proportionality. Our main argument is that an aggregate level scientific impact, calculated as a population’s central tendency measures on the basis of individual scores is methodologically more relevant, and also politically more appropriate when calculated on the basis of "fair" category. We use data from a real population of scholars: the academics in medicine schools within the six health sciences universities of Romania. As such, our study addresses the general issues outlined in the research question, in a particular setting, touching upon what we consider an under-researched topic in scientometrics: that of the characteristics of real populations of academics and its links with policies.

Conference Topic
University policy and institutional rankings

Introduction
In the past decade, evaluation of both individuals’ and universities’ or departments’ performance has become common place for funding higher education (Sabic 2015; Vercruysse și Proteasa 2012), not only rankings (Hazelkorn 2011). Amongst the different activities put under scrutiny in this endeavour, university research features probably most prominently.
Research is generally evaluated by appraising scientific productivity (number of articles), scientific impact (as measured through the number of citations, $h$-index, $g$-index etc.) or both. Individual results are aggregated into collective level score at institutional or departmental level, using elementary mathematical operations, such as sums or averages, or more complex measures, such as the successive or second order $Hirsch$ index (Schubert 2007). These operations represent the mathematical formalization of one of the big issues in social sciences: the micro-macro aggregation.

The point of departure of our argument is that current influential rankings based on overall sample mean citations and/or other h-type indices are prone to ‘the exploitation of the great by the small’ (Olson 2002, 35). We construct our research question from this observation, focusing on the issue of measuring inter-institutional differences in terms of scientific impact in skewed populations, with a severe intra-institutional variance. We develop our argument from the analysis of a real distribution of bibliometric research outputs: the population of six medical schools in Romania. As such, our research can be seen as a study case, but we use the data we collected for a significantly more general purpose, that of discussing the merits of the Characteristics Scales and Scores (Glänzel 2007, 2010; Glänzel și Moed 2002; Schubert, Glänzel, și Braun 1987) in shedding light on the truncated median part of real populations of scholars. We end up proposing a measure of the central tendency, which incentivizes achievement along a wider share of academics, which are relevant for the research activities of academic departments. In the discussion section, we address some of the characteristics of real populations of academics in contrast to bibliometric populations, as well as the link between bibliometrics and policy.

**The problem and the research question**

D’Angelo and Abramo (2015) argue that the purpose of bibliometrics is to provide support for policy-making and decision-making in the achievement of institutional objectives, through the provision of methods and indicators for the evaluation of performance. However, when the evaluation refers to the performance of the collective level entity (department, institution) we enter a situation which has striking similitudes with one of the ‘classical’ theories in social sciences, the theory of collective action (Olson 2002). In short, Olson argues that if a group is large enough, individuals will have the tendency to act as free-riders i.e. to expect others to contribute while not-contributing. He advances some solutions: informal coordination, internal organizations, and selective benefits; at the same time, in small groups collective goods can be produced if few individuals pay the entire costs, “*a surprising tendency for the "exploitation" of the great by the small*” (Olson 2002, 35).

If we conceive the department score as a collective good, issues of production and consumption can be raised. In terms of consumption, the reputational benefits or the surplus or deficit budget associated with aggregate scores is distributed to the members of the department according to institutional frameworks and internal decisions. In terms of production, in the absence of effective informal coordination, internal organization or selective benefits, some department members may tend to behave like free-riders in Olson’s theory and exploit the greater contributors. We find this problem particularly relevant due to the skewness of scientific production and impact (Seglen 1992). We argue that the aggregation rules used by the indicators which produce distributional consequences are very important in such situations. They may either highlight, or obscure the contributions of some individuals or groups of individuals, by reducing these to a single collective level measure or index.

Let us illustrate this fact by briefly looking at how three influential rankings quantify research: Shanghai Jiaotong’s Academic Ranking of World Universities (ARWU)\(^ii\), Times Higher Education’s World University Rankings (THE)\(^iii\), and Quacquarelli Symonds’ World University Rankings (QS)\(^iv\). In terms of bibliometric measures, QS uses citations per faculty,
THE uses publications per faculty, while ARWU uses also publications, absolute counts and per faculty. All these measures are prone to „the “exploitation” of the great by the small” (Olson 2002, 35), due to the aggregation procedure: averaging, and summing – only in the case of ARWU. Without entering lengthy discussion, we will note that the other measures: reputation and research funding from competitive sources, are also prone to the same phenomenon, determined by different mechanisms.

Therefore we consider aggregation to be more than a methodological option and we will discuss it having in mind its political implications. We consider aggregation of collective level research scores to be an instance of a wider methodological problem in the social sciences: the micro-macro transition, or how do we aggregate, in a meaningful way, properties of the individuals in order to make valid inferences at collective (social system) level?

Due to the extreme skewness of individual scientific impact, we reformulate the problem as how can we measure the collective level inter-institutional variation, when the intra-institutional variation (differences in measures of individual scientific impact) has such a magnitude. A second, kindred methodological challenge, arises, namely that of dealing with the magnitude of top achievers’ impact. We use the Characteristic Scores and Scale (CSS hereafter) to account for the inter-institutional variance, with the aim to compare not entire populations, but rather truncated segments of the distributions. Thus, we further detail our research questions:

(1) Can we identify within the CSS an appropriate gauge of inter-institutional variance? We judge appropriateness both in methodological terms - a measure that is able to differentiate between various institutional performance levels - as well as in political terms, namely as relevance for a public policy aiming to raise the collective levels of scientific impact by providing incentives to larger segments of individuals

(2) Is that measure stable in the face of rare occurrences of very high citation?

The data we use comes from a real population of scholars: the academics in medicine schools within the six health sciences universities of Romania. As such, our study addresses the general issues outlined in the research question, in a particular setting.

Data and methods

The population we studied comprises of 3374 academics from the departments of medicine within the six health studies universities in Romania. We compiled the personnel lists from public sources: websites and reports. We established a comprehensive list of academics at department level, of their publications (including single and co-authored) and their respective citations from Scopus data base for a 5-year window between 2009 and 2014, excluding authors’ self-citations. The data were collected between November 2014 and May 2015. Full counting was used. We disambiguated manually authors’ name and their respective set of publications and, consequently, the corresponding citations to this set of publications, irrespective of the author’s affiliation at the time of the publication. We included in our research all the academics which we considered relevant for the medical sciences – persons teaching various medical, surgical and paraclinical subjects – according to an official categorization of the health studies in Romania, plus the fundamental sciences. These are the large majority of the academic staff in the medical schools in Romania. We also excluded a set of publications that not only were outliers in terms of citations, but also not actually belonging to the realm of research papers: guidelines, medical procedure recommendations, and definitions.

We analyse the distribution of total citations within the academics in our data base. As we are also interested in a particular policy context, the Romanian one, we add a second measure to our analysis. We prefer to use a rational variant of Egghe’s index instead of the measure of impact within the official funding methodology. The indicator within the methodology is a compound measure constructed on the basis of Hirsch index at 2/3 power as the individual
measure of impact, calculated for each of the three data bases, Web of Knowledge, Scopus and Google Scholar, and averages as aggregation rule. We adapted from (Tol 2008) the following variant of Egghe’s index:

\[ g_{\text{rational}} = g + \frac{\sum_{i=1}^{g+1} c_i - g^2}{(g + 1)^2 - g^2} \]

where \( g \) represents the value of Egghe’s index and, \( c_i \) represent the citations received by the \( i \)-th paper of the author, ordered descending after the number of citations.

This variant has the advantage of preserving the monotonicity properties of the G index and yet it introduces differences in the subunit interval. It does so by dividing the subunit in \([ (g + 1)^2 - g^2 - 1 ]\) equal intervals. Its specter of subunit values is discontinuous and increases with the value of \( g \). Its value is determined by the citations of the papers in the \( g \) core, plus the citations ascribed to the \( g + 1 \)th paper, where the papers are ranked decreasingly after their citations. For the population we study, its distribution is strongly correlated with that of the Hirsch index at 2/3 power: 0.91, Pearson correlation. The Hirsch index has the disadvantage of a discrete and rather limited range of values: for more than 99% of the authors the index takes values lower or equal to 10, while for almost half of the population (47.87%) the value is zero.

Findings

At a general descriptive level, the distributions we obtained by ordering decreasingly the academics according to their total citations can be fit with a fixed growth function (power law, but also reasonably an exponential or logarithmic, with one exception – the logarithmic fit of citations), which illustrates the skewness of the distributions. We added a unit to the entire distribution, in order to calculate logarithmic regression models – see (Thelwall 2016) for a detailed discussion on the method.

Other scholars use functions belonging to the same set to describe such distributions (Albarrán et al. 2011; Chatterjee, Ghosh, și Chakrabarti 2016; Perianes-Rodríguez și Ruiz-Castillo 2015; Radicchi, Fortunato, și Castellano 2008; Waltman, Jan van Eck, și Van Raan 2012). Similar curve estimations and comparable fit (\( R^2 \)) was obtained by (D’Angelo și Abramo 2015) for real populations of academics in various scientific disciplinary fields in Italy. Even three extreme outliers are not included in the citations’ model, the logarithmic fit increased considerably to a square \( R \) of .653, while the exponential and power law fit increase marginally.

We plotted each of the six the medical schools’ distributions on the same graph in Figure 1, below, also capping the upper end of the distributions for illustrative purposes. The advantage of analysing the two measures comparatively is that they vary in terms of skewness (internal variance). We note that the six distributions, each of them associated with a medical school, follow similar patterns to the populations. The distributions are shifted to the right of X axis, revealing differences in magnitude (number of academic staff) and also slightly upwards on the Y axis, revealing higher values of the bibliometric measures for some of the medical schools. One can also notice that the distributions tend to merge at the top, reflecting similarities as
regards the top achievers. They also converge towards the same minimum, but have different
tails reflecting differences in size. The graphic illustration cannot provide an answer to the
question: are there significant differences between the six distributions or they differ only in
terms of magnitude?

Figure 1: Distributions of citations and values of Egghe’s G index, the rational variant

Since the data are skewed and do not match a normal distribution, we test the null hypothesis
of no significant differences of scientific impact between the six departmental groupings of
academics with a Kruskal-Wallis test. The Kruskal-Wallis test is a chi-square distribution of
the sum of the squares of the group mean ranks. The null hypothesis is rejected at .000
significance level, thus we conclude that the six distributions differ not only in terms of size
different N), but also in terms of scientific impact, on both citations and g-index.

Once we established that the distributions exhibit differences which can be attributed to
differences in collective level scientific impact, we can further our analysis in order to answer
the research question of this article: how can we measure the inter-institutional variation, when
the intra-institutional variation has such a magnitude?

We proposed to use CSS to account for the inter-institutional variance, with the aim to compare
not entire populations, but rather truncated and thus comparable segments of the distributions.
In the original article, the authors split a population of articles based on their citedness into five
segments: uncited, poorly cited, fairly cited, remarkably cited and outstandingly cited. The first
cut-off point is determined by computing the average of the non-zero distribution, the second
cut-off point is determined by computing the average of the distribution above the first cut-off
point and so on. The authors use the categories to compare journals on the basis of the
proportion of articles in each category, mentioning that a similar approach can be used also for
department comparisons. The CSS had been used by (Albarrán et al. 2011) and (Albarrán, Perianes-Rodríguez, și Ruiz-Castillo 2015) for comparisons of distributions across 219 sub-fields, respectively 36 countries, (Ruiz-Castillo și Costas 2014) for comparisons distributions over 30 broad scientific fields, and (Perianes-Rodríguez și Ruiz-Castillo 2015) for comparisons of distributions across 500 universities in the Leiden ranking. Generally the CSS is used in relation to citedness, but, as the distributions of the two impact metrics have a reasonably similar shape, we extend the use of the CSS to Egghe’s index, the rational variant.

We thus use the characteristic scores and scales for the analysis of both citations distribution and rational g-index distribution as a way to truncate and meaningfully compare sub-samples of the entire populations, relevant for our policy evaluation purposes. As Glänzel (2010) argues, both h-type indices related indicators and characteristic scores proved useful for truncating the ranked sample and/or for selecting ‘top publications’. Furthermore, CSS can also be used for ranking various entities (journals) according to the amount of 'highly' cited papers they publish. Alternatively, we are instead interested in selecting 'fair' type units as we consider those more appropriate for our “real populations” departmental evaluation purposes and also, for the reasons explained above, opt for the rational g variant instead of the h-index.

One of the main methodological reasons why we adopt such a strategy is the fact that the six distributions are commensurable up to at least the 95th percentile, when extreme variation starts to occur (see Error! Reference source not found.). The intervals between the 50th and the 95th percentile are fairly stable, the universities' distributions grow linearly having comparable slopes.

Figure 2: Percentile analysis

Such a behaviour of the data is similar to the findings of previous articles that studied citations distributions across scientific fields (Crespo, Li, și Ruiz-Castillo 2013), respectively across universities (Perianes-Rodríguez și Ruiz-Castillo 2015).

A measure or inter-institutional variance based on the CSS

We adjusted the categories defined in the original version of the CSS in order to fit our purpose of comparing the six distributions. Due to the size of our population, we limited the CSS categories to three: (1) the “low” contributors – the academics with a value of the metric less or equal to the average; (2) the “fair” contributors – the academics with a value of the metric which is greater than the average and lower than the second average; (3) the “high” contributors - the academics with a value of the metric higher than the second average. A similar approach was adopted by (Ruiz-Castillo și Costas 2014). Unlike the original version of the scale, we included in the „low” category the academics with zero impact as well. They constitute the bulk
of the population of the medical schools and we presume that their percentage in the departments reflects the interplay between national policy and internal organization. We used Chi-square to test whether the two averages divide the six populations in quasi-similar proportions in all six medical schools for the two measures taken into consideration. The null hypothesis is rejected both for both impact measures, thus the six institutional distributions of the both measures are fairly similar and stable. This is in line with the conclusion of Glänzel (2007), who shows the class proportions or the characteristic scales are fairly stable across time and across fields.

Table 2: Chi square tests for CSS proportions

</tbody>
</table>

The 'fair' category of the CSS falls roughly within the 50 – 95 percentiles discussed in the percentile analysis in Figure 2. Glänzel (2007) notes that the class sizes of the individual subfields may somewhat differ from the generally applied rule of thumb (75–18–5–2%), but the deviations from this 'standard' are not dramatic. The variation among the scores is nonetheless considerable. We checked for the linearity of the distributions within the 'fair' category against that of the 'high' category, by comparing the determination coefficients $R^2$ to assess the goodness of a linear function fit. The results are presented in Table 3, below:

Table 3: Linearity of the 'fair' categories

</tbody>
</table>

As it can easily be seen, the "fair" categories in both "raw citations" and "Egghes's g-index rational" distributions approximate very well linear functions (high $R^2$ coefficients for the linear fit), whereas the "high" categories' values are considerably less linear. In Figure 3, below, we plot the 'fair' category distributions within the six populations for illustrative purposes. A shift to the right reflects differences in size, whereas a vertical shift reflect differences in citation impact.
Figure 3: The 'fair' categories of the six medical schools

By using the CSS to truncate the distribution and select the ‘fair’ partition, not only we translated the research question from the analysis of a power law function to a linear one – which consequently makes comparisons amenable to parametric testing, but we also controlled for much of the distributional variation inside the medical schools. The segment represented by the 'fair' category behaves approximately similar in all six cases. Since the characteristic scales are similar, we should thus be able to control the intra-institutional variance of scores in order to compare those across the institutions in a meaningful way. We assessed the capacity of the CSS ‘fair’ partition to be used for comparing departments by carrying out a Kruskal-Wallis H test for citations as well as for the g-index. The results are presented in Table 4, below:

The results of both tests are significant at .000 level for both citations and g-index (a Chi-Square coefficient of 162.813***, df = 5), rational variant (a Chi-Square coefficient of 184.722***, df = 5), which demonstrates the robustness of the conclusion that there are indeed differences in scientific impact between the institutions with reference to the sum of ranks (Kruskal-Wallis test). We also computed a Median test for the ‘fair’ partitions, and the results are similar: there are differences also in terms of medians for both citations and the rational variant of the G-
index, and the tests are significant at the .000 level. Methodologically, the 'fair' partition is able to tap a significant share of the collective (institutions) level variance in scientific influence and thus to produce meaningful comparisons between institutions. Moreover, due to the similarity and quasi-linearity of the distributions we can control the within groups variance. Thus the 'fair' category could be considered representative for the collective level performance when aggregated from the level of individuals. It includes most of the research active academics whose performance are nonetheless not in the outstanding range and thus could be attributed to institutional rather than personal factors. Besides, it constitutes a robust measure that is independent of the size and shape of original distributions, being based on a parameter-free approach to citation-impact classification (Glänzel 2007, 2010).

Discussion
To resume our contribution, we used CSS, a parameter-free approach to citation-impact, to compare ‘inter-institutional’ performance in the condition of high ‘intra-institutional’ variance in six highly skewed distributions of bibliometric data associated with the medical schools in Romania. Our analysis represents a study case on a real population, which is primarily determined by tenure in the departments under research, while most of the populations of individuals studied in scientometric research are determined differently. Such populations, termed ‘bibliometric’, are inferred from the scientific outputs (articles) indexed in major databases (usually Thompson Reuters or Scopus datasets) based on the subject field taxonomies used by these databases (Albarrán et al. 2011; Albarrán, Perianes-Rodríguez, și Ruiz-Castillo 2015; Chatterjee, Ghosh, și Chakrabarti 2016; Perianes-Rodríguez și Ruiz-Castillo 2015). This strategy is common in the study of publication, as analysts "frequently lack[...j] information on the realities of labour, due to the absence of databases on the researchers, and on their institutional, discipline and field affiliations" (D’Angelo și Abramo 2015). However, the real population approach was used by other authors as well, see for example (Abramo, D’Angelo, și Di Costa 2008) when individual productivity was analysed according to the administratively determined area in which each surveyed researcher operated. The difference between the two types of populations is not only ontological, but has some important conceptual and methodological implications. The ‘real population’ we study is more heterogenous, as it includes academics with different profiles, obligations, attitudes and orientations. Thus, numerous academics are either not indexed in the reference database (Scopus), or uncited – almost half of the population, more precisely 47.87%, fall in this category. Usually these academics are not included in ‘bibliometric populations’. Furthermore, most of the cited academics have relatively low scores: only 2.34% of them have a value of Hirsch’s index which is greater than 5. Thus, the lower, most part of the distribution violates the condition of non-triviality (Bouyssou și Marchant 2014) because for more than half of the individuals, a ranking cannot be produced. However, we believe that such a characteristic of the population may not be exceptional, as similar difficulties are reported by other authors (Anania și Caruso 2013). Such an observation is backed up by empirical studies as well. For example Ruiz-Castillo & Costas (2014) found that 68% of authors in all fields published only one Web of Science indexed article over a period of nine years; their research spans over the period 2003-2011 and includes an impressive sample of 17.2 million disambiguated authors. The uncited academics may not be relevant for measures meant to quantify the ‘institutional quality’ through presence in an elite league of achievers, but their behaviour can be illustrative for their interaction with the institutional context. For example, not all of the uncited academics in the population we studied are new entrants i.e. generally assistants – see the left side of Figure 4. According to both accumulation effects and the normative definitions of tenure, the lower ranks academics are expected to be less prolific in terms of research results – this relationship is illustrated in the right side of Figure 4. However, we consider the high percentages of uncited
academics from the higher ranks indicate that impact is insufficiently incentivized. We presume that the proportions of uncited academics in departments are not accidental, nor random, but rather a reflection of the interaction between what Olson terms ‘internal organization’, ‘informal coordination’ and selective benefits, institutionalized through the policy context.

**Figure 4:** University ranks of uncited academics (left) and percentage of uncited academics within total, per university ranks (right)

Individual impact is evaluated only in relation to tenure, which is mostly determined through centralized standards, agreed by academic nominees. A brief inspection of the institutionalization of the professorship reveals that impact (citations, or citation derived measure) has not been traditionally included among the requirements for professors and associated professors – where national standards are in place since 2005. Furthermore, the tenure requirements which institute individual evaluations are only associated with promotion, not with day to day activity. This is an explanation of the fact that a significant share of professors and associated professors are uncited. Scientific impact is usually evaluated on a yearly basis only at the collective level, mostly for the institutional funding policy, but the aggregation rules are prone to ‘the exploitation of the great by the small’, or ‘free-riding’ phenomenon.

**Conclusion**

Kwiek (2015) argues that the achievements of the top 10% performers in a representative sample of academics in eleven countries in Europe (Romania not included) can be explained through ‘individual’, not ‘institutional’ factors. Though our research employs a different perspective and different metrics of performance, we consider that a similar interpretation can be proposed for the distribution. The achievements of the top academics, mainly concentrated from the 95th percentile to the high end of the distribution, can be seen as determined by agency, rather than by structure, whereas the achievement of the ‘fair’ category can be representative to ‘institutional’, structural factors.

We started our contribution from a particular problem – that of the obscured contribution of most of the academics within real populations to some influential collective research evaluation exercises. For this purpose we used conceptual tools which are specific for the theory of collective action and we analysed a real population of academics, within six medical schools – a rather limited sample, but exhaustively aggregated from the real population of Romanian medical schools.

However, in dealing with the particular situation of Romania, we touched upon some wider conceptual and methodological aspects related to the evaluation of research for policy purpose. We discussed in details methodological aspects regarding the quantification of quality in highly skewed populations. Without entering the lengthy debate regarding the universality of distributions (Chatterjee, Ghosh, și Chakrabarti 2016; Kaur, Radicchi, și Menczer 2013; Peterson, Pressé, și Dill 2010; Radicchi, Fortunato, și Castellano 2008; Waltman, Jan van Eck, și Van Raan 2012), the populations we studied have reasonably similar shape with those studied.
by other scholars. We also extended the initial scope of the CSS, on one hand, we used it on a rational variant of Egghe’s g-index, while it was traditionally employed for citations or publications. Our option was motivated by the similarity of the shapes of the distributions. On the other hand, we used it for a different purpose, that of identifying a measure of ‘inter-institutional’ variance among a set, be it limited to six distributions with very high ‘intra-institutional’ variance. In doing so, we touched upon an important methodological problem in the social sciences: the micro-macro transition, or how do we aggregate, in a meaningful way, properties of the individuals in order to make valid inferences at collective (social system) level. Our main findings relate to the properties of the ‘fair’ category within the CSS. These segments of the distributions include researchers whose scientific impact can be measured above a trivial level and, for our population, they exhibit two important features: linearity and proportionality. These properties make the ‘fair’ segments of the distributions amenable to comparing medians between institutions. In contrast, the "high" category distribution includes individuals that exhibit severe dispersion in terms of individual scientific impact. Such a behaviour of the populations reduces considerably the linearity of the data, and hence the relevance of aggregation using central tendency measures. Moreover, the aggregation of the 'high' categories are more sensitive to what economists term as ‘king effects’, which obscures the relation between the individual and the institutional level scientific impact.

Our main argument is that an aggregate level scientific impact, calculated as a population's central tendency measures on the basis of individual scores is methodologically more relevant, and also politically more appropriate when calculated on the basis of "fair" category. The study-case approach, though it was useful to shed light on what we consider an under-researched topic in scientometrics: that of the characteristics of real populations of academics, has obvious limitations in terms of the generalization of results. Further research should test the robustness of this measure by extending it to a larger population of universities. Although our study includes a high number of individuals, the corresponding collective entities are rather few. Extending the research to more universities and different subject fields will bring more important evidence on how aggregation from individual to collective level could be possible.

Abstract

In this paper we study the effect of granularity on Characteristic Scores and Scales (CSS). Unlike the traditional indicators that are mostly based on means and quantiles, CSS require the reduction of the citation distributions collaboration of the underlying reference population to four states (classes) and thus higher a different level of granularity. While the question of the choice of granularity is at higher levels of aggregation usually not critical since countries and university have rather multidisciplinary profiles, at lower aggregation levels specialisation becomes more typical. Inappropriate granularity might not warrant the depiction of the publication profiles at these levels in a correct and adequate manner and thus not add accurate citation profiles either.

In order to be able to process one complete annual volume of the Web of Science, we decided to calculate CSS thresholds and classes for two levels of granularity, namely sub-fields and WoS Subject Categories. With about 5\% deviation, we did not find a real significance. However, we identified journals with similar impact measures but different citation profiles, independently of the granularity.

Finally, we have pointed to the limitations in the choice of granularity – in terms of both too broad and too narrow subjects.

Conference Topic

Citation and co-citation analysis; The application of informetrics on evaluation; Indicators

Introduction

The question of granularity in the application of subject-based standards remains a constantly recurring issue. The gain of higher resolution and precision of details at zooming on the hierarchy of subject assignment is lost again by growing ambiguity and increasing fuzziness. Apart from randomness, Bookstein (1997) has identified two other demons being challenges to the measurement in informetrics and quantitative science studies. He pointed to fuzziness as the second demon reaching beyond probabilistic uncertainty as it is related to the impossibility to accurately represent concepts by traditional variable sets. Finally, ambiguity pushes the idea of fuzziness to its extreme: The conceptual basis for measurement itself is often weak although we aim at accurate measurement. These demons do also affect the possibility of accurate subject assignment in bibliometric applications as the conceptual basis underlying subject delineation and classification is often weak. In particular, we can identify two main weak points regarding subject classification. The first one concerns the way how subject assignment is made and the second one relates to the granularity of subject hierarchies. The need for accuracy is often confronted with the practical limitations as well. These limitations may results from indirect assignment (e.g., through journal classification), hard clustering or even by changes in context and perspective, that is, by the question of research in a special topic is still relevant for the subject in question or for the activity of a department under study. While at higher level of aggregation this effect may still be tolerable and benchmarking may still lead to acceptable results if high-level subject classification is used, for instance, in national comparison of publication activity and citation impact in fields like chemistry or biosciences, at lower levels of aggregation, at least at the level of scientific journals, university departments and research
teams this approach is stretched to its limits as the profiles of these units are very specific and require more individual approaches. Also different publication types might require different levels of granularity as Adams and Testa (2011) stressed in the context of the – at that time – newly introduced Book Citation Index (Thomson Reuters, now Clarivate Analytics – BKCI). At lower aggregation levels also first dramatic conflicts between subject delineation and classification become blatantly obvious. In other words, acceptable delineation is often not possible by using standard classification alone. Ideally quasi-unique paper-based assignment of high resolution would be a solution but in practice this might turn counterproductive as further zooming in may result in highly grainy blow-ups that may destroy the details, thus shapes and contours become fuzzy. The desire to correct ambiguity and fuzziness and to sharpen the blurred picture by supplementary but arbitrary human decisions and selections resembles a bit the allegory of reality, dream and interpretation shown using the example of the photographer’s interaction with material and technology in Michelangelo Antonioni’s film “Blow-Up” (1966), where the attempt to blow up a photograph to gain more information and lucidity and to get evidence finally resulted in the destruction of the detail structure just leaving even more room for obscurity, imagination and speculation (cf. Lehman, 2013).

Coming back to bibliometrics, we will study the effect in borderline applications. We have used two levels of granularity for achieving this objective, the level of scientific journals and the Web of Science Subject Categories.

**General methodological issues**

The question of granularity has been raised and analysed in recent studies. Among those studies we would like to bring out three articles that have been devoted to the analysis of the stability of relative indicators in the light of granularity. The authors of the first one (Zitt, Ramanana-Rahary & Bassecoulard, 2005) observed a certain “instability of impact measures should not be interpreted in terms of lack of robustness but rather as the coexistence of various perspectives each having their own form of legitimacy”. In default of ‘one best level’ of observation they therefore pled for particular prudent in interpretation of citation indicators instead of just choosing or preferring one of the possible worlds. Adams, Gurney & Jackson (2008) have tested the hypotheses stated by Zitt et al. using the example of the 2001 UK Research Assessment Exercise (RAE) and found that the correlation between average normalised citation impact and peer-reviewed grade varied according to the hierarchical selected level. Both studies use journals and different hierarchical levels of subject classification. When interpreting the results, we have to take two important issues into account. The first one is simply a methodological one; journals form a partition, while subject classification do not. Subjects always overlap to a certain extent, where the extent depends on the hierarchical level and, of course, on the underlying scheme chosen for the exercise as well. In order to overcome the usual challenge of overlapping subject categories and disciplines, Zitt et al., have forced single subject assignment of journals to subject categories and of subject categories to disciplines thus reaching partitioning the document space in all cases. Although this seems to be quite reasonable and convincing at the first sight, we have to point to the following crucial issue. The second issue is much more critical as it is of conceptual nature. Although in the Clarivate Analytics Web of Science Core collection (Wos) and the Scopus databases subject fields are defined on the basis of journal assignment, there is a fundamental difference between journal- and subject-based standards. Authors are bound up with their specialty due to education, their skills and career choices, but the discipline is not individually selected for each publication. Yet in the case of journals authors do decide where to publish their manuscript. Thus journals always reflect certain aspects of publication strategies since the authors have the – admittedly sometimes limited – freedom to choose the journal standard along with the scope for the target audience. In order to illustrate this, we refer to our plain old indicator triplet consisting of the mean observed, (journal) expected and field expected citation rates (MOCR, MECR and FECR, cf.
Glänzel et al., 2009). MECR and FECR provide two different expectations and the comparison of these two baselines reveal interesting details about the analysed unit’s publication profiles and strategies. For instance, MOCR > MECR > FECR means that the factual citation impact is above both expectations, where scientists affiliated with this unit, on an average, publish in journals with citation impact higher than the field standard, while MECR > MOCR > FECR means that the unit exhibits a factual citation impact above the expected subject-based standard and it does publish in high-impact journals but this standard is, on an average, not reached. What remains, is the comparison of granularity effects at different hierarchical level indeed. In 2009 we have made therefore an experiment using the example of 676 European universities with at least 50 publications each in the period 1999–2001 that have been selected from a total of roughly 2000 institutions (see Glänzel et al., 2009).

The three-year citation-window based field-expected citation rate (FECR) was determined on the basis of different hierarchical levels of subject classifications, the WoS subject categories, the 60 sub-fields and 15 major field according to the Leuven-Budapest subject classification...
scheme, which is built upon the WoS categories (cf. Glänzel and Schubert, 2003). Two of the results are shown in Figure 1. NMCR stands for the ratio of observed and field-expected citations rate using different granularity.

According to the expectations, the correlation between the ECOOM subfields and the WoS subject categories proved very strong \( r^2 = 0.971 \), while the correlation between the highest (major fields) and lowest hierarchical level (subject categories) was distinctly weaker, but still quite strong \( r^2 = 0.844 \). This goes with a larger variance and, most notably, the large number of outliers in the bottom diagram might cause problems in practice. The most significant observation is, however, the closeness of the slope to the value 1.0. This means that the choice of the hierarchical level, i.e., the granularity, has practically no “scale-effect” on the relative indicators. In the present study we repeat this exercise in the context of the Characteristic Scores and Scales (CSS), which can be considered a distributional extension of the notion of ‘relative indicators’. Also here we applied both the ECOOM subfield level and the original WoS subject categories. Before we present and discuss the result, we briefly introduce the rudiments of the CSS method.

The granularity of CSS – Methods and results

1. On the granularity of indicators at the meso level

As we have mentioned in the previous section, CSS can be considered a non-linear (distributional) extension of field-standardised citation rates. The basic idea is to replace citation indicators by citation profiles that are based on a given number of “performance” classes. The idea behind the method was two-fold, firstly, to favour a parameter-free solution for the assessment, that should be insensitive to outliers, subject-specific peculiarities, publication time and citation window, and provides unique assignment of publications to classes, and, secondly, to overcome the traditional linear projection of a multi-faceted, multi-dimensional reality. The “reduction” of the original citation distribution to performance classes as proposed by Glänzel & Schubert (1988) seemed to be the ideal way to achieve this objective. Since then a number of studies has analysed the properties of CSS and confirmed the robustness of the method. An analysis of the granularity has, however, not yet been conducted. However, as CSS has recently been applied also to lower levels of aggregation, notably to institutions, journals and individuals, this might be critical because journals, research teams, and individual scientists might have specific publication profiles that are not sufficiently or adequately covered at the level of standard disciplines. Before we analyse the effect of the choice of the hierarchical level of subject assignment for the calculation of CSS classes, we briefly recall their definition and basic properties.

In a nutshell, characteristic scores are obtained by iteratively calculating the mean value of a citation distribution and subsequently truncating this distribution by removing all papers with less citations than the conditional mean. The number of profile classes used for the evaluation is the only “arbitrary” number that needs to be defined in the beginning. Usually four classes are sufficient. In order to obtain fours classes, the process is stopped after three iterations. The four classes stand for ‘poorly cited’ (Class 1), ‘fairly cited’ (Class 2), ‘remarkably cited’ (Class 3) and ‘outstandingly cited’ (Class 4) papers. Papers in class 3 and 4 can be considered highly cited. Although the method is based on mean values, the huge number of publications underlying the base-line guarantees that the influence of outliers remains marginal. A further issue in comparative assessment at practically any level of aggregation arises from the peculiarities of scholars’ communication behaviour in their research domains and disciplines. This results in different disciplinary standards of publication activity and citation impact. In order to be able to apply the method to the assessment of national research output and to multidisciplinary universities, one has to apply kind of “fractional” normalisation, when calculating the threshold values for class assignment. The detailed description of the procedure
and its mathematical background is documented in previous studies by the authors (e.g., Glänzel, Thijs & Debackere, 2014).

Just as all citation indicators, the CSS scores, too, are strongly dependent of the subject matter, but the distribution of papers over the citation classes defined as the intervals between these scores proved largely independent of the subject, publication year and citation window (Glänzel, 2007; Glänzel, Thijs & Debackere, 2014). Although CSS classes are not directly linked to percentiles, notwithstanding that, the baseline derived from the complete population provides a distribution of papers over classes of about 70% (Class 1), 21% (Class 2), 6%–7% (Class 3) and 2%–3% (Class 4), independently of publication year and citation window. Also Albarrán & Ruiz-Castillo (2010) found a similar 70–21–9 rule when they combined the two upper performance classes for papers published between 1998 and 2002 and using a 5-year citation window. This robustness has made the method attractive as universal bibliometric profiling tool.

Before we further elaborate the CSS scheme for studying the effect of granularity, we go briefly back to a more general question. The research profiles of the units of macro- and meso-level analysis reflect multi-disciplinary or at least activities in broader subjects. The effect of specialisation, even within subject areas that are, otherwise, relevant for the units under study, becomes more pronounced at lower levels of aggregation and most notably at the micro level. The specialisation of individual scientist as reflected by their publication profiles can often hardly be captured by pre-defined disciplines or subject categories. The same applies to research topics and sub-disciplines. Scientometrics as a topic or discipline might serve just as an example: The discipline is, on one hand, a highly specialised sub-discipline within information & library science, and, being a truly inter-disciplinary field, is, on the other hand, related to many other fields as well and its metrics thus need to be compared with various different subject standards. The relationship with other disciplines is established cognitively by the actual application and practically through the journal assignment to the relevant subject categories. However, none of most subjects outside information science is representatively covered by scientometrics. The topic standard may also be distinctly different from that of its mother discipline meaning that gauging literature in a sub-discipline against the main-discipline standard would result in a distorted picture. In the case of scientometrics, actually a higher standard has to be assumed in order to obtain a realistic benchmark (see Glänzel, Thijs & Debackere, 0000). These are the reasons why the application of subject classification schemes might fail if applied as a basis for the benchmarking specialised topics and the citation impact of individual scientists. The same effect of incomplete or not representative coverage may occur at the meso and micro level, if (specialised) subsets of disciplines do not necessarily represent the standard of the discipline. In both cases the question of the granularity of the underlying classification system emerges. Even, if ambiguity is sufficiently compensated by subject fractionation and weighting (see Glänzel, Thijs & Debackere, 2014), unlike in the case of higher aggregation levels such as universities and countries (cf. Figure 1), the granularity might not prove appropriate to provide results of acceptable accuracy if we break down data to the topic, journal or team level. This is the reason why we decided to use an experimental approach to adjusting the “CSS resolution” for subject/topic selection in journal analysis. In order to be able to conduct large-scale analyses, we will study the effect of granularity at the journal level. This allows us to process all data of a complete volume of the WoS data base including the SCIE, SSCI and A&HCI editions in a systematic way.

For the present study we have chosen the complete 2013 volume of the WoS journal editions. We have only taken so-called citable items, that is, documents of the types: article, letter and review, into account. Again we have used the two hierarchical levels, the 74 ECOOM disciplines and the roughly 250 WoS subject categories we have used for subject assignment. First we calculated field standardised citation rate for journals according at both levels of
aggregation. Quasi as a by-product, we obtain a subject-insensitive citation metric that would allow journal ranking across subject fields. Yet, our intention is to overcome linearity in depiction citation impact, therefore we use these measure just as auxiliary tools. Figure 2 shows the plot of subject-normalised mean citation rates for the three-year citation window 2013–2015 based on ECOOM subfields vs. WoS Subject Categories. Only journals with at least 10 papers in 2013 are plotted and analysed. Since many journals are rather small, i.e., more than half the journals published less than 100 citable papers in 2013, we expected a larger variance and outliers being more frequent than in the case of universities. However, the correlation still proved to be strong and the slope of the linear regression is again close to the value one, substantiating that the level of subject assignment does not affect the scale of the standardised citation index.

![Plot of subject-normalised mean citation rates based on ECOOM subfields vs. WoS Subject Categories for 11964 journals covered by the WoS database](Data sourced from Clarivate Analytics Web of Science Core Collection)

In the second step we calculated the CSS class distributions for the complete population, that is, for all citable papers indexed and all journals covered in the 2013 WoS volume. The ECCOM classification resulted in the class distribution of 70.0% (Class 1), 21.4% (Class 2), 6.2% (Class 3) and 2.4% (Class 4), while the corresponding distribution based on WoS categories 69.8%, 21.4%, 6.3% and 2.5%. No statistical test is needed to understand that the deviation of the two distributions from each other is negligible. Nevertheless, we applied a $\chi^2$ homogeneity test to test the deviation of class distributions to all individual journals with at least 10 citable papers in 2013. Using the critical value of 7.81 at a confidence level of 0.05, we found that 94.6% of all journals do not differ significantly if the two levels of subject assignments are applied, while deviation of 5.4% of the journals must be considered significant. This is practically in line with the assumed confidence level.

2. Characteristic Scores and Scales in journal assessment

From the historical viewpoint, the use of the CSS in the context of journal assessment was the first application and this was actually the application the method was designed for (see Glänzel & Schubert, 1988). Unlike subject assignment or the profiles of individuals and research units or countries, journals do not require multiple assignments of papers. Journals form a true partition of the document space that is covered by a bibliographic database and also of any paper set under study. If papers are to be assigned to journals on the basis where they have been
published, assignment is always unique and thus no fractionation is needed. This property essentially simplifies the application of bibliometrics to journal indicators. On the other hand, journal analysis is still an important methodological topic in scientometric research and an indispensable fundament for supplementing bibliographic databases by journal metrics (cf. Journal Citation Reports (JCR), Scimago Journal Ranking (SJR), Scopus CiteScore metrics) and as long as journals serve as the basis of subject classification, journal indicators remain essential issues in bibliometric studies.

Table 1. Examples of selected journal pairs with almost identical mean citation rates (MCR) but different CSS profiles in 2013 with three-year citation window, based on ECOOM subfields (1st row) and WoS Categories (2nd row) [Data sourced from Clarivate Analytics Web of Science Core Collection]

In the first applications, CSS were applied to chemistry journals to gauge journals Mean Citation Rates against the CSS standards calculated for each subfield of chemistry. At that time the share of uncited paper was still used as a supplementary Class 0 (below the poorly cited articles). Later on we restrained from this solution because of lacking robustness: The share of uncited papers strongly depends on both the citation windows and the subject matter. The reason for the instability is that this is the only class that is defined on a fixed criterion (i.e., uncitedness), while all other classes are based on variable thresholds that depend on time and research topic. The basic idea at that time was to provide additional information about the journals’ position in a discipline beyond the usual ranking exercises. Schubert et al. (1989) already applied CSS to journals, now on the basis of two scores only and with the purpose to gauge national contribution to journal impact but not to compare class distributions by journals. Now we will use CSS class distributions as an alternative to journal ranking. This also demonstrates a new and completely different application context. Although this kind of application does not allow any linear ranking and the interpretation of CCS class distributions is not always straightforward, the added value of information and the more detailed picture of citation impact that we obtain compensates for the lack of simplicity. The surplus of information
results from two sources that have been addressed many times in the scientometric literature, first the subject-specific peculiarities of citation impact and, second, the various shapes of citation distributions underlying journal impact. Glänzel and Moed (2002) and Glänzel (2009) have given examples of journals with almost identical Mean Citation Rates but different distribution shapes. We have computed Mean Citation Rates (MCR) and CSS class distribution for all journals in 2013 using a three-year citation window. We have applied the fractionation process for subjects according to the procedure described in section 3.2 since many journals have multiple subject assignments. Table 1 gives the MCR values of 5 selected journal pairs with almost identical citation impact (MCR) each but distinctly different profile types according to their CSS class distributions. We have chosen journals representing different “standards” to illustrate that this phenomenon might occur in all impact classes ranging from high to low standard.

3. Granularity at the limits – journal-based benchmarking

In the previous two sub-sections we have applied bibliometric field-based indicators at two different levels of granularities to the profiling of journal impact. Experience showed, on the one hand, that broad fields, such as the 15 major fields according to the Leuven-Budapest classification scheme or the 22 science areas of Clarivate Analytics Essential Science Indicators (ESI) are less suited to serve as the basis of reference standards. In particular, the major fields and broad science domains combine theoretical, experimental, methodological, empirical and applied research in one field. In contrast to this high level of aggregation, Table 2 shows the aggregate impact factors of ten selected subject categories in physics in the 2015 science editions of the Journal Citation Reports. It is clear that there can hardly be found a common reference standard for, e.g., condensed matters (CMPh) and mathematical physics. The barrier for applying broad fields is therefore two-fold, we are faced with cognitive reasons (comparability – why compare mathematical physics or acoustics with CMPh?) as well as different metric standards (commensurability) if we choose to broad subject fields for subject normalisation.

On the other hand, if the narrower fields or disciplines, such as the WoS subject categories are chosen, the already discussed issues of fuzziness and ambiguity challenge both methodology and its implementation. Multiple journals assignment to subjects becomes more frequent and results in sometimes exuberant fractionation and weighting that is needed to calculate and apply reference standards and CSS scores. Without this the application of such procedure the choice of an appropriate reference value would be impossible as has been shown using the example of
the journal *Bioinformatics* that took deviating positions in journal ranking according to the different WoS categories it was assigned to (cf. Glänzel, 2011). An arbitrary restriction to single assignment at this level would, however, hardly be justified from the cognitive viewpoint nor provide accurate reference standards for any indicators to be built on the assignment.

Recalling the results by Zitt, Ramanana-Rahary & Bassecoulard (2005), who referred to “the coexistence of various perspectives each having their own form of legitimacy”, we see a further limitation to increasing the resolution, even if we respect the legitimacy of different granularities. As we already have confirmed this notion in the context of relative mean citation rates in our section on general methodological issues, subject- and journal-based reference standards do reflect different perspectives. We have calculated the journal based relative citation rate (RCR) as well its sub-field based pendent (NMCR). The different concepts underlying these structures becomes apparent from the comparison of the national indicators that are given in Table 3. For this table we have compiled a list of the 25 most active countries.

All citation indicators have been calculated on the basis of the 3-year citation window 2013–2015. The low NMCR values of India, Iran, Turkey, Russia and Brazil are contrasted by their
moderate or even high journal-based counterparts (RCR) indicating that these countries are publishing in rather low-impact journals. The direct comparison of the two underlying expected citation rates make this even more visible: For Iran, Turkey and Russia, the ratio of the journal and discipline based expectation ranges around 0.6. The comparison of the corresponding CSS classes confirms and deepens these observations. The first observation here concerns the baseline itself. The distribution of papers over CSS classes in the complete population changes towards a lower share of poorly cited and a consequently higher share of fairly and highly cited papers. This has also a strong effect mainly on countries with low impact: In countries with low citation impact, the share of poorly cited papers calculated from journal model is usually greater than the corresponding field-based share. Countries with generally high citation impact are not affected by this trend, on the contrary, as can been seen for Denmark, Switzerland, the Netherlands or Belgium. For these countries we also observe somewhat higher field-based than journal-based expectations. The ratio here amounts to about 1.3. In both extreme cases, we have looked at, we see the effect of national “publication strategies”, namely, in favour of publishing in low or high impact journals with respect to their corresponding subject standards. In this context we would like to recall the effect of choosing publication channels and fora already mentioned in the introduction.

However, apart from these perspectives a real barrier emerges, namely that given by the rules of mathematical statistics – at least in the context of CSS. And in this context we have to stress that the limitation applies to the population, not to the size of the sample units under study. The commonly accepted minimum for the application of mathematical statistics to mean-value and quantile based statistics lies around 30–40 items (cf. Vincze, 1974). WoS subject categories meet this criterion but about one quarter of all journals have less than 30 citable paper per year. For the calculation of reference standards for mean values and shares this is still acceptable. Now, analogously, the use of journals instead of subject categories or disciplines could be an interesting extension to journal-based expectation also in the framework of CSS. In other words, journal-based characteristic scores and scales could supplement the field based CSS giving another perspective to citation-class profiling. However, here the distribution based approach is stretched to its limits. For instance, if we assume a size of 40 items in the reference journal, the share of Class 4 items of 2.5% of the reference distribution would correspond to exactly 1 item. This might, however, challenge the robustness of the method. For this reason, we do recommend a selective extension of CSS to journal-based profile classes.

Conclusions

We have calculated characteristic scores and scales for journals covered by the Web of Science Core Collection at two levels of granularity, 74 disciplines and the WoS Subject Categories. The results of the overall comparison did not show any substantial deviations that would tell against the robustness of the method. The comparison of CSS and mean citation rates have again substantiated that citation impact is not one-dimensional and should not be mapped by linear functions. Journals may have very similar mean citation rates (impact factors, or more generally, impact measures), while their CSS class distributions distinctly differs, independently of the underlying granularity. Our findings are partially presented on a limited selection of journals. In an extended later version of this study we intend to present data on more journals in a supplementary online material according to the corresponding journals publication policies.

Unlike traditional mean-value or quantile based bibliometric indicators CSS needs somewhat larger reference sets to obtain robust reference distributions. The reason is the higher resolution of the underlying distribution based reference classes. According to the experience made in this study, subject categories already meet this requirement, journals are less suited to build the reference classes for characteristic scores and scales.
Summarising, the proper choice of granularity has two limits, both the heterogeneity of too broad subject fields and an increased resolution towards too narrow topics could affect the validity of results. As so often, when turning theory to practice, the optimum is somewhere in between.

What factors are associated with more authors? A case study of Danish Economics

Abstract
The number of authors is increasing in the social sciences, but co-authorship studies often explain these increases in the number of authors by referring to authorship studies in the natural or life sciences or by using anecdotal evidence. Thus, a deeper understanding of why the number of authors is increasing in most field is necessary, as well, as whether there are changes in the research or in the researchers’ behavior. This study will examine the changes in research in Danish economics, and investigate to what extent these changes can be explained by external factors in the research culture. The study finds that articles with empirical research, quantitative research and/or survey have a slightly higher average number of authors than theoretical, interview, data and qualitative research. However, the average number of authors increases for articles with all types of research and research approaches, and it seems like something more than external factors are affecting researchers’ collaboration behavior.

Conference Topic
Science communication, Science of Science

Introduction
Research collaboration has become the norm in most research fields, and research is increasingly being communicated in co-authored peer-review research articles. Studies have shown that the average number of authors is rising in most research fields (Henriksen, 2016; Lariviere, Gingras, Sugimoto, & Tsou, 2015). The main focus is often on high energy physics and biomedicine with extreme co-authorship tendencies, where the norm in some areas is hundreds of authors and it is no longer uncommon with thousands of authors in the byline of an article (Cronin, 2001). The tendencies in these research fields often overshadow that the same tendency is occurring in other research fields, though it is occurring at a smaller scale in the fields of social science. Furthermore, these increases are not the results of a need for big laboratories or expensive equipment as in the natural and life sciences (Birnholtz, 2006).

Several studies have documented a steady increase in co-authorship in economics (Hudson, 1996; Laband & Tollison, 2000; Sutter & Kocher, 2004). The studies suggest various explanations for the increases based on general anecdotal evidence. For example, that a rapid growth of knowledge, increasing complexity of research, and interdisciplinary research have required more collaboration among researchers which the increase in co-authorship reflects.

These suggestions are aligned with conclusions from authorship studies in the health and natural sciences, which have found that the increasing more technical nature of the disciplines and larger data material would require more manpower and attribute to more labor-divided research tasks (Colledge, Elger, & Shaw, 2013; Laband & Tollison, 2000). These arguments thus suggest that the increase in co-authorship can be attributed to an increase in empirical studies based on quantitative methods and the uses of more advance statistical, while theoretical and qualitative work would be less likely to be co-authored authored (Corley & Sabharwal, 2010; Fisher, Cobane, Vander Ven, & Cullen, 1998). Furthermore, the general growth of the professions creates more opportunities to find suitable co-authors, as well as the lower travel costs and innovations in information and communication technologies make it easier to collaborate for distant researchers.

All of the above suggestions focuses on changes in conducting research, technological advances, research environment and travel costs. However, the changes in attitude to the requirements of co-authorship could also be a factor. For example, researchers’ have become quicker to require their names being added as co-authors when assisting others, exchanging data, mentoring, and engaging in collaborations, and reciprocating others contributions with offering of co-authorship. This can be seen as a natural consequence of the “publish and perish”
mantra that has been dominating academia in the last decades, and makes it necessary for researchers to add their names to more publications and improve the productivity on their resume. This mantra is also dominant in the mindset of funding agencies and research institutions, which encourage researchers to engage in collaborations, since collaborative research is perceived as being of higher quality, more visible, and more cited in a time of research publication production overload (Thelwall & Sud, 2016). Furthermore, research collaborations and co-authoring lower the risks of having a no-publishing period caused by negative results, data sampling problems or long peer review process.

This study addresses the suggestions by other studies to investigate deeper why there has been an increase in the number of co-authors per article and the share of co-authored articles. Previous studies often refer to how changes in research conduct and methods have affected the tendency to collaborate, which increase in co-authorship reflects. This tendency can be refer to as external changes in research culture, which are explicit and possible to observe, measure and document.

On the other hand, the internal changes in research culture affect researchers’ perceptions and practices of co-authorship, research collaboration, reward system, science communication system, and research responsibility. This study examines which kind of social science research articles have more co-authors, and if the increase in co-authorship corresponds to increase in certain research approaches and methods? These findings can contribute to a discussion of how external and internal changes in research culture can effect co-authorship tendencies.

Therefore, this study is a necessary step in the authorship studies to gain further knowledge about how the practice and frequency of co-authorship is changing. This study will address this lack of knowledge by examining the characteristics of economic articles, and thereby gain further knowledge about co-authorship practices. It begins with a review of how certain characteristics of the articles are related to co-authorship, followed by a methods and data section presenting the coding algorithm and the statistics. The results section presents first descriptive statistics followed by regression models. It concludes with a discussion of these results in relation to external and internal changes in research culture and the effect on co-authorship.

**Literature review of factors**

*Is theory the lone scholars’ game?*

Previous studies often find that empirical articles compared to theoretical articles are more co-authored (O'Neill, 1998; Sacco & Milana, 1984). Piette and Ross (1992) investigated 15 economics journals, and found that empirical work has a greater tendency to be co-authored. This corresponds to the suggestions that empirical research tasks sometimes requires researchers with different expertise and skills to collaborate, and the tasks can be divided among them (Barnett, Ault, & Kaserman, 1988). Furthermore, the development of online survey tools, easier access to data via online databases, and different software programs to analyze the collected material have made empirical work more accessible. Therefore, the study expects that an increase in co-authorship will have occurred over time in empirical research articles.

*Does the methodological approach affect the number of authors?*

The literature of social sciences co-authorship suggests that quantitative research compared to qualitative research are more likely to be co-authored, since it offers greater opportunities to work in a team-production model (Adams, Black, Clemmons, & Stephan, 2005; Ossenblok, Verleysen, & Engels, 2014). Few studies have further investigated the notion that quantitative research is more co-authored. Nowell and Grijalva (2011) used the Journal of Economic Literature (JEL) to determine if the publication is based on quantitative research, and find that quantitative research is not the only factor in the increasing likelihood of co-
authorship. Hunter and Leahey (2008) examined the key parts of the papers to assess if they contained quantitative or qualitative research, and they found that quantitative publications is more likely to be co-authored.

Quantitative research tasks are often easier to divide among team members, thus the tedious tasks of producing or/and cleaning data can be divided and executed by multiple team members. Furthermore, the data analysis often uses statistical methods, which can involve one or more team members. The data of qualitative studies often consist of interviews, focus groups, observations and/or text data, which may not always be easy to divide among members of a team, depending on the ontological and epistemological position. Therefore, this study expects that articles based on quantitative research methods instead of qualitative research methods will probably be co-authored.

Is the number of authors affected by whether the data is primary or secondary

The collection of data for a research project is often a labor-intensive task, and there are pros and cons depending on the kind of methodology and data collection usage in a research project. Particular quantitative research in economics uses secondary data, such as data from archives, databases or registers. Secondary data is probably easier to share among research collaborators, since the data is already available in archive etc. and this will encourage people to collaborate to obtain a synergy and more knowledge in the collaboration. It requires less work to collect, but may require a great deal of work for preparing such data for analysis. On the other hand, the labor-intensive tasks of collecting data can require and be divided among multiple people engaged in collaborative research project, which will be reflected in the number of co-authors of a publication.

These different aspects and advantages of primary and secondary data both give indication of how and why there can be more authors on a publication. It is therefore difficult to assess whether one can expect differences in how many authors of an article depending on the kind of data. The previous studies of authorship and research collaboration do not provide a clear answer to this question. Fisher et al. (1998) suggest that both large-scale primary data collection efforts and the increasing availability of large secondary datasets in archival depositories have increased the proportion of co-authored publications. However, they only find 3.1% of the political science articles in their sample using primary data, so they excluded the results from their study. Hunter and Leahey (2008) investigated whether the usage of primary data vs. secondary data is a factor in the increase of co-authored sociology articles. Their hypothesis is that secondary data are easier to share when collaborating, and they expect that it is more likely to be co-authored. However, they found that the proportions of co-authored articles have increased for both articles with primary and secondary data, and that in 2005 it is at the same level. This study examines the association of secondary data with a higher number of authors.

Do international and interinstitutional co-authored articles have a higher number of authors?

The increase in co-authored publications is found to contribute to an increase in international collaborations. The share of internationally co-authored publications doubled between 1990 and 2000 in the sciences, and at a more rapid speed than national co-authored publications (Nomaler, Frenken, & Heimeriks, 2013; Wagner & Leydesdorff, 2005). However, if one limits the study to solely the social sciences the findings are mixed. Lariviere, Gingras, and Archambault (2006) and Henriksen (2016) found that there has been an overall increase in international co-authorship in the social sciences, while Hunter and Leahey (2008) do not find any support for an increase in international co-authorship in sociology, they do find a slight increase in interinstitutional collaboration.

One of the reasons that international and interinstitutional co-authorship have increased could be due to the electronic development that has made it easier to interact and work with researchers from other institutions and countries. However, studies have shown that researchers
still have a tendency to collaborate with people in a close geographical proximity (Wagner & Leydesdorff, 2005). Perhaps because face-to-face meetings still are necessary, as well as neighboring countries often have more shared cultural values that make it easier to collaborate. This study focuses on Danish economic research, and since Denmark has a very small population, it would be normal for the researchers to find collaboration partners outside of their own institution and country. Three variables including the geographical distance (GCD), the international collaboration (IN), and the interinstitutional Danish collaboration (II) are used to investigate if the mean number of authors are higher because of collaborations outside one’s own institution.

*Normalized Journal Score NJS*

Previous studies of co-authorship and research collaboration often focus of the relationship between more co-authors and citations, and whether there is a connection between number of authors and the journal impact factor (JIF). There are very different view on whether there are a positive or negative relationship between number of authors and JIF. Studies propose that more co-authors shows that the research is of higher quality, thus researchers will strive to publish in journals with a high JIF. Hence, it will give the article a pre-quality seal of approval, more visibility (more citations), more prestige, and in some cases give the researchers a financial bonus.

Other studies, that found a negative correlation between the JIF and the number of authors, suggest that researchers will prefer to publish alone in high JIF journals to secure that the citations and credit do not have to be shared (Rutledge, Karim, & Reinstein, 2011). However, this argument assumes that researchers decide to be more inclusive in the selection of who fulfills the authorship requirements, regardless of the researchers’ contribution, as well as requiring a higher standard for who can be included as an author if they deem the article to be able to be published in a high JIF journal. This study is dealing with a social science fields, so the measurement of the journal will instead be the Normalized Journal Score NJS from CWTS Journal Indicators.
Methods and data:
All research articles with at least one Danish address belonging to Economics subject category were downloaded from the Web of science Social Science Citation Index on 19 October 2015. The period spans 35 years from 1980 to 2014. The sample contains 3,157 Economic articles. The data are divided into different time periods to show the development in co-authorship and changes in the article characteristics.

Data coding
Bibliographic information about the articles were downloaded in the original sample. This was followed by a retrieval of and matching data about authors’ institutional and national affiliation. The variables international (IN) and interinstitutional (II) collaboration was dummy coded. Followed by the calculation the variable GCD, NJS and interdisciplinarity. However, the coverage of social science references before 1995 are scarce, and the interdisciplinarity variable can only be used in the analysis of data after this year, and will only be included in the last regression model.

The publication content data was manually coded with regard to the content of the publications. This required accessing the full-text of each article. After the full-text of the article was located, a strict algorithm was used to assess the content of the article: First, it assessed whether the article were theoretical or empirical by examining the method or data section for usage of data or data collection. Second, if the article is empirical, it is further coded depending on whether it is quantitative, qualitative or mixed method. If it is assess to be quantitative if it uses survey, secondary data (register or archival data), and experiments. If the article uses interview, ethnographic or anthropological methods or documents in their study it is assess to be qualitative, and if it uses both quantitative and qualitative methods it is mixed method. Third, the usage of interviews, surveys, secondary data, document data or other are coded. All of the content variables are dummy coded, for example 1 for survey and 0 for not survey.

Regression count models
This study uses Poisson regression (Poisson) and negative binomial regression (NBR) count models to examine how the different factors influence the number of authors. The reason for using two different count models is because dispersion for the outcome count variable “number of co-authors per article” varies across fields and sub-periods, in some cases being over-dispersed and in others having a dispersion parameter almost equal 1. Thus, when it is over-dispersed it fits the criteria for a NBR model, and when the dispersion parameter is almost equal 1 or the variance and mean number of authors do not differ, it fits the criteria for a Poisson model. Because the analysis uses count models, the exponent of the different coefficients is calculated to make a more clear interpretation of the results. Thus, if all the variables are kept constant in the count model, then the exponent are the changes in the dependent variable (number of co-authors).

The formula for count models can be written as

$$N_{co-\text{authors}} = \text{Intercept} + \beta_1 x + \beta_2 x + \beta_3 x$$ ...

The previous studies of co-authorship emphasize multiple factors associated with more authors or co-authorship tendencies, thus this study will use different models to investigate what factors are associated with more co-authors, since some of the factors overlap. Each regression model will be presented for the overall period and for the three time periods (1980-1994, 1995-2004, and 2005-2014). The first period focuses on the pre-internet period, followed by a period with better long distance communication possibilities as well as cheaper travel opportunities. Last is a period, where in Danish context there have been a greater tendency to focus on research performance and new public management in the university sector. The variables NJS, GCD, IN and II are included in all of the models, and will therefore only be thoroughly discussed the first time they are presented in the models.
**Results**

The study finds that the productivity of Danish researchers in international journals increases during the last 35 years, as well as the total number of both theoretical and empirical articles increases, which corresponds with the general increase in the number of researchers and productivity in that period. The graphs in figure 1 and 2 show how co-authorship, the mean number of authors and the number of articles are distributed over the 35 year time period. The mean number of authors for the total number of articles increases by 98.41% (1.26 authors to 2.50 authors). In the first period, the mean number of authors and the median number of authors are similar for theoretical and empirical articles. However, this changes over time and the mean number of authors increases for empirical articles by 111.2% (1.25 authors to 2.64 authors) and for theoretical articles by 70.63% (1.26 authors to 2.13). However, the median number of authors continues to be similar for both kinds of articles.

*Figure 1: The evolution of the mean number of authors and the number of economic articles (N authors <= 10)*

The descriptive results for economics show that the share of articles with empirical research has consistently increased from 30.5% in the 1980s to 71.1% in 2010s (see figure 1 and 2), as well as the total number of articles have increased rapidly over the years. The development shows a shift in Danish economics research from being a theoretical focused research field to a more empirically focused research field. The rise of co-authored articles are similar in both theoretical and empirical economics.
The majority (90%) of empirical articles uses quantitative methods, while the last 10% is a mix of qualitative methods and mixed methods. Because of the great overlap between quantitative methods and empirical articles the descriptive statistics are fairly similar; thus they show that the share of co-authored articles goes from approximately 27% to 85%. Few of the economic articles uses qualitative research, but those that do, show that there are clearly differences in the share of co-authored articles as well as that the mean number of authors are lower for qualitative articles during the 35 years.

Figure 3 show the development of mean number of authors and number of articles depending on research methods. The mean number of authors have increased for all types of research, but mostly for articles using survey studies. The mean number of authors is very high for survey studies in the period 1995 to 1999, which is caused by a low number of articles and two articles being with 10+ authors. However, in the last period there are 144 articles with survey studies, where 91% of these are co-authored, so this to some extent confirms that using this kind of research method corresponds with working in larger team. Thus, the tasks involving
conducting a survey can be allocated to different team members, and thereby increasing the number of people involved. Interestingly, interviews studies have also increased in both number of articles and mean number of authors, perhaps because different tasks such as the designing, interviewing, transcribing, and analyzing can be assigned to different team members. Furthermore, the usage of secondary data is the kind of method that has increased the most in number of articles, but also by more than 1 author in the mean number of authors. This is perhaps because the usage of data from external sources makes it easier to share the data and the burden of data cleaning. Not to mention that some of these articles use and collect data using more than one method; the articles with 24 and 26 authors in the byline have both conducted a survey and used data from a database. This could require researchers with different skills and therefore increase the number of authors on the final product.

**Regression models**

The first model in Table 4 is based on the formula below:

\[ N_{co-authors} = \text{Intercept} + \beta_1 PG + \beta_2 NJS + \beta_3 GCD + \beta_4 IN + \beta_5 II + \beta_6 \text{Empirical} \]

1208
In the first period, the model indicates that NJS have small positive effect on the number of co-authors. If the article is empirical, it has 7% less co-authors compared to theoretical articles. The results correspond with the fact that 67% of the articles are theoretical in the first period, and the mean being similar for theoretical and empirical articles. The GCD do not seem to have any effect on the number of co-authors, while the variables IN and II are very influential, so an international co-authored article will have on average 8.70 times more co-authors, and an interinstitutional Danish article will on average have 7.09 times more co-authors than an article with only internal collaboration or no collaboration. The results for the variables NJS, GCD and empirical are not so robust when examining the confidence interval and p-value, while the IN and II seems reliable.

In the second period, IN and II have 4.79 and 3.30 times average more co-authors than non-international and interinstitutional Danish articles. The coefficient of the variable NJS becomes negative, while GCD seems unchanged. The empirical articles show 1.80 times more co-authors than theoretical, which fits the results from figure 2, where the mean number of authors for empirical articles is higher than theoretical. In the third period, NJS show 1.03 times more authors, meaning it has a very small influence on the number of co-authors. If the article is empirical, it is equal to 1.38 times more co-authors. IN and II articles show 3.46 and 2.94 times more co-authors. In the last two periods, the confidence interval and p-value for NJS shows that the results are not reliable, while the rest of the results seems robust. The results from the whole period show that international or interinstitutional Danish co-authored articles in general have a higher number of co-authors

The coefficients for the variables IN and II are very high, and especially IN are influence by being highly correlated (0.65) with co-authorship. Hence, the study examine whether these variables still would be influential if the sample consisted of solely co-authored articles. The model was recalculated, and even though the coefficients are lower, the variables remain influential one the number of co-authors, since IN now gives approximately 1.3 times more authors in the whole period and in each period, and II gives between 1.1-1.3 times more authors.

The first model shows that international and interinstitutional Danish collaborated articles have tendency to have more co-authors in the entire period. However, the GCD shows that these international co-authored articles probably are from neighboring countries. From the first period to the second in the model is there a clear shift in empirical articles being more influential on the number of co-authors, though the coefficient becomes smaller in the last period. This is align with the results for the whole period that confirms that empirical, international and interinstitutional Danish collaborated articles have a positive influence on the number of co-authors.

The model was recalculated with the variable quantitative instead of the empirical variable using the formula below:

\[ N_{co-authors} = \text{Intercept} + \beta_1 \text{MJNS} + \beta_2 \text{GCD} + \beta_3 \text{IN} + \beta_4 \text{II} + \beta_5 \text{Quantitative} \]

There are a 0.76 correlation between the empirical and quantitative variable for economics articles, and the results for this model are very similar to the first model. Hence, the quantitative articles have approximately 1.42 times more authors for the whole period. In comparison, the empirical articles have 1.49 times more co-authors than theoretical articles. Further details can be provided by the author.
The final model includes variables focusing on the research methods used in the articles:

\[
\log(N_{\text{authors}}) = \text{Intercept} + \beta_1PG + \beta_2NJS + \beta_3GCD + \beta_4IN + \beta_5II + \beta_6Empirical + \beta_7quantitative + \beta_8Data + \beta_9Interview + \beta_{10}Survey
\]

</tbody>
</table>
In the first period, interview, survey and document based research articles have a tendency to have in average fewer authors in the first period (~10-35% fewer co-authors), while the usage of data do not seem to have any influence either positive or negative. This changes for articles using survey and data in the second period, where a survey article have 195% and a data article 100% more co-authors. The coefficient decreases in the third period, but these types of research methods still have a positive effect on the number of co-authors. Articles using interviews have a negative coefficient in the second period, but it increases in the third period, so interview give 35% more co-authors in average in the third period. The coefficient for document analysis articles remains negative for the whole period, and it seems that researchers using this kind of data collection prefers to be single authors. The numerous tasks in relation with data collection and preparation for interview and surveys could be the reason these types of research have more co-authors. Similar, the link between a higher number of co-authors and data could be because it requires some data preparation, but it can also be easier to share data obtain from archives or databases. The model for the whole period show that the results seems robust except for the variable NJS and document.

**Conclusion**

This study shows there have been changes in scholarly communication and collaboration. Danish economics research have experienced a shift from mainly working as a theoretical field to a more empirical field. It finds that even though the field of economics is quantitative based, it has become more diverse in its research approach during the last couple of years. It seems that when researchers conduct quantitative studies with primary data, such as surveys, there are a greater number of authors than when the data sample is from registers or databases. However, articles with interview studies are generally less co-authored and have fewer authors, but this also seems to change in the last period.

This study examines how the number of authors have changed in Danish economics, and how changes in external factors, such as the kind of research methods and approaches applied creates changes in co-authorship. This study finds that to some extent the changes in economics have contributed to the increasing number of authors and co-authored articles. Nevertheless, it also finds that since the increase in the number of authors is occurring across the field of economics, no matter the research methods or approaches. These changes indicate that the research culture is changing. The question is whether researchers nowadays collaborate more or the increases in number of authors is a reflection of changes in how researchers perceives and practices co-authorship.

Introduction

This paper describes the forecasting methods used to analyze the future demand for domain names under the ccTLD (country code Top-Level Domain) “.it”. The aim of this analysis was to examine the trend over time of the demand for .it domain names. This is firstly to assess whether we are in a phase of growth and expansion or at a point of saturation. Secondly, this analysis enables us to compare the .it domain name market with those of other ccTLDs (.de, .uk, etc.) or of other gTLDs - general Top-Level Domains (.com, .edu, etc.).

Methods

In order to forecast the trend of demand for .it domain names, the main forecasting methods available in the literature were used. Before applying these forecasting methods, there was an analysis of the trend and seasonality of the series “variation in growth of .it” domain names. This is none other than the difference between registrations and cancellations recorded in the quarter x of year t.

In general, a historical series can be broken down into a seasonal component, a trend and an erratic component. These components are usually estimated using the moving average. However, this method, albeit commonly used in the literature because of its ease of calculation, has some disadvantages. These are associated both with the limited accuracy of the estimates obtained and the loss of data relative to some terms due to the smoothing of the moving average.

On the basis of these considerations, the trend, the seasonality and the erratic component of “.it” domains were estimated using the loess method which, differently from the abovementioned method, gives more accurate estimates (Ricci, 2005). Subsequently, in order to estimate the forecasts of the .it domain names registration, some forecasting methods were applied. These included exponential smoothing methods, such as the Holt-Winters (additive and multiplicative) (Holt, 1957; Winters, 1960), which consider the presence of the trend and seasonality, and the stochastic processes like ARIMA - Auto Regressive Integrated Moving Average models (Box and Jenkins approach) (Box and Jenkins, 1976), in particular the SARIMA (seasonal ARIMA) version. The parameters of the various models were calculated using the maximum likelihood estimation. To assess the accuracy of the forecasts, resulting from the various forecasting methods, a range of indicators were used and analyzed which were able to give a measurement of the forecast error. These included the ME (Mean Error), MAE (Mean Absolute Error), RMSE (Root Mean Squared Error), MPE (Mean Percentage Error), MAPE (Mean Absolute Percentage Error) and MASE (Mean Absolute Scaled Error). The latter indicator, was proposed by Hyndman and Koehler (2006) as an alternative to using percentage errors when comparing forecast accuracy across series on different scales. Furthermore, due to the predictive accuracy of the methods considered, also other indicators were analyzed such as the Akaike Information Criterion (AIC), Corrected Akaike Information Criterion (AICc) and Schwarz Bayesian Information Criterion (BIC). Finally, in order to identify the best forecasting method, also the correlogram of the residuals of the various models were analyzed (ACF-Fuction of autocorrelation and PACF-Fuction of partial autocorrelation). The application of these forecasting methods and statistical indicators was carried out using the “R” statistical environment. The registrations and cancellations of .it domains were extracted in the .it domain names database managed by the Institute for Informatics and Telematics (IIT) of the CNR (National Research Council) in Pisa. The analysis was done taking into account the time period of nine years, from 2008 to 2016. Each year was subdivided into four quarters.

Results

From the analysis of the calculation of the trend and seasonal components, our time series shows a trend (slow growth during 2008, steadying between 2008 and 2009, reaching its maximum in the first half year of 2011, decreasing after 2011 until 2014, renewed growth to subsequently steady again). Furthermore, there is a seasonal component, given that the registrations and cancellations of .it domains were extracted in the .it domain names database managed by the Institute for Informatics and Telematics (IIT) of the CNR (National Research Council) in Pisa. The analysis was done taking into account the time period of nine years, from 2008 to 2016. Each year was subdivided into four quarters.
seasonal component, so as to make the series stationary, due to the seasonality in the demand for domain names. The choice of this model, compared to other ARIMA models, was made based on an analysis of the residuals and their correlograms (ACF and PACF).

Besides the ARIMA model, the other models applied to our series were both the Holt–Winters model with damped trend (Gardner and McKenzie, 1985) and additive seasonal component, and the Holt-Winters model with multiplicative trend and seasonal component. Also in this case the choice of these models instead of others was determined by considering the residuals and their correlograms. Figure 1 shows application of the abovementioned models to the .it domain name time series (registrations - cancellations).

As shown in figure 1, the ARIMA model fits our data better than the Holt-Winters models, above all in the first years (in particular in 2008 the values calculated by the ARIMA model are equal to the observed values).

| Figure 1. Estimates and forecasts of .it domains using Holt-Winters and ARIMA models. |
|---|---|---|---|
| Period | ARIMA | H-W Multiplicative | H-W Additive Damped |
| Q1 2017 | 54,995 | 52,379 | 48,920 |
| Q2 2017 | 16,732 | 17,031 | 26,313 |
| Q3 2017 | 32,776 | 29,968 | 24,596 |
| Q4 2017 | 30,470 | 37,228 | 39,065 |
| Q1 2018 | 54,781 | 54,201 | 48,454 |
| Q2 2018 | 16,613 | 17,624 | 25,941 |
| Q3 2018 | 32,709 | 31,010 | 24,299 |
| Q4 2018 | 30,433 | 38,523 | 38,827 |

Table 1 Forecasts of .it domains using Holt-Winters (H-W) and ARIMA models.

Discussions and Conclusions

The estimates of the parameters of the Holt-Winters damped additive model indicate that the estimate of the level at the current time point is based on the less recent observations (the less recent observations have a greater weight than the more recent ones). On the other hand, for the Holt-Winters multiplicative model the estimate of the level at the current time point is based not only on the less recent observations but also on the most recent ones.

From analysis of the forecasts, the ARIMA model is the one which better fits the historical data compared with the models of exponential smoothing. This conclusion is valid, both when observing the graphs relative to the diagnostics of the residuals and the statistical indicators relative to the accuracy of the estimates. In fact, all the statistical indicators that give a measurement of the error of the estimates (ME, MAE, RMSE, MPE, MAPE and MASE) are lower when applying the ARIMA model, compared to the other two models.

As regards the diagnostics of the residuals, the p values for the Ljung-Box statistic in the various lags are higher for the ARIMA model, indicating that the hypothesis of absence of autocorrelation of the residuals, for all the lags, cannot be rejected. On the contrary, for the Ljung-Box statistic of the Holt-Winters models, the p values are very low compared to the ARIMA model and in some cases the test rejects the hypothesis of uncorrelated residuals. The same applies to other indicators which give a measure of the degree of fit of the models used. AIC, AICc and BIC are much lower for the ARIMA model than for the models of exponential smoothing.

In conclusion, according to the results in Table 1, the .it domain name registrations will be greater than the cancellations in both 2017 and 2018.

In summary, notwithstanding the forecast of a growth in domain names in the 2017-2018 two-year period, the increase is however limited, tending to reach a phase of saturation of the “.it” market.

Abstract
This study aims to explore the applicability of Altmetrics in the evaluation of scientific journals. Based on a sample of 10,041 journals, it provides a comparison between Altmetrics metrics and citation metrics, taking correlation analysis as the main method. It also discusses the applicable scope of the Altmetrics metrics in journal evaluation from four aspects. Results indicate that the Altmetrics metrics calculated with the Altmetrics data of articles can reflect the influence of journals. Also, these metrics have good discrimination on the academic quality of journals. In most cases, sum metrics of Altmetrics metrics are more stable and are more able to reflect the academic influence of journals. The choice of Altmetrics data sources will affect the journal influence it reflects. Currently Altmetrics is not applicable for specific disciplines or publishing areas. Altmetrics achieves better results in journals in Social Science and Health Science, but does worse in Natural Science especially Computer Science and Mathematics. In addition, the Open Access status of journals will affect the evaluation results obtained by Altmetrics.

Conference Topic
Altmetrics; Indicators; Journals, databases and electronic publications; The application of informetrics on evaluation

Introduction
Journal evaluation is an important application realm of Bibliometrics and Scientometrics with citation analysis as its main approach. However, as the academic environment changed and new publishing ways appeared, the inadequacies of citation databases and citation metrics for scientific evaluation are gradually exposed (Agrawal, 2005; Lange, 2002). Papers in journals are no longer the sole carrier of scientific output, since there are many other alternative options including books, proceedings, reports and those come from the Internet (e.g., websites, blogs, academic communities and social media) (Barjak, 2006; Rowlands et al., 2011; Shema et al., 2012). However, citation databases mainly cover journals rather than other means of scientific knowledge diffusion (Mongeon & Paul-Hus, 2016), and the citations to non-source publications could have a significant effect on rankings (Butler & Visser, 2006). Meanwhile, the Internet provides diverse platforms and approaches for scientific outputs to be published and disseminated, but citation metrics neglected that Internet was an approach for the diffusion of knowledge (Gonzalez-Alcaide et al. 2012). These metrics highly focus on citations instead of other usage. Thus, it gets more difficult for citation analysis to satisfy the requirements of evaluation.

Considering the inadequacies of citation analysis for scientific evaluation and the characteristics of academic communication in the Internet, the concept of Altmetrics was raised. Different from the traditional methods based on citations, Altmetrics emphasizes on the data generated in the online academic communication, especially the data from social networks. Altmetrics studies the application of such data, and provides a method of measuring impacts from different aspects, which can be a useful supplement to the traditional evaluation approaches. Now related theoretical studies and practices are being performed. In studies on Article-level Metrics, some metrics of Altmetrics already have plenty empirical studies and have put into use. Therefore,
this paper aims to study the extent to which Altmetrics is applicable in the evaluation of scientific journals, for feasible methods with online data and better evaluation results.

**Literature Review**

Studies on Altmetrics began since 2008. Li, Thelwall and Giustini (2011) adopted CiteULike and Mendeley as the data sources, and concluded that online reference manager tools could be used to measure the academic influence of articles as supplementary data source. Priem, Piwowar and Hemminger (2012) took articles published by PLoS as sample and presented a study on the correlation between Altmetrics and citation metrics. They found that the influences reflected by these two metrics are different, so it cannot describe the academic influence completely with just one of them. Costas, Zahedi and Wouters (2015) had similar conclusion on metrics from Altmetric.com and citation metrics, and they found that social media provided low value of Altmetrics metrics, and disciplines including social science, humanities, medicine and life science got high value of metrics.

Studies focusing on specific Altmetrics metrics present their applicability and characteristics. The number of readers in Mendeley and the number of tweets arose plenty of interest. Results of the correlation analysis showed that the correlation coefficient between citation number and reader number was stable at 0.6 (Maflahi & Thelwall, 2016). The reader number of Mendeley could be used to measure the influence of articles published in different time. The data distribution of Mendeley metrics was most similar to that of citation metrics (Costas, Zahedi & Wouters, 2015), while the citation behavior was quite different from the behavior on Twitter (de Winter, 2015). However, using the data from both of Mendeley and Twitter would cause differences between disciplines. The reader number of Mendeley was more correlated to citation metrics in social science than in the humanities (Mohammadi & Thelwall, 2014). Twitter paid more attention to the medicine and the social science while the humanities, the nature science and the engineering science achieved lower value of metrics from social media (Costas, Zahedi & Wouters, 2015).

Further studies made it more comprehensively. Thelwall et al. (2013) selected 208,739 articles with at least one Altmetrics data record from PubMed to conduct a study on 11 Altmetrics metrics. They found that in the medicine and the biological science, 6 Altmetrics metrics have significant correlation with citations including, Google+ posts, Tweets, Facebook wall posts, research highlights, blogs, mainstream media and forums, while there was no correlation found between citations and LinkedIn, Pinners, Q&A and Reddits.

Plenty of empirical studies on Altmetrics to date are about Article-Level Metrics. Apart from this, there are studies considering Altmetrics on journal level. Bollen et al. (2011) compared a set of network metrics generated from citation and download data with ISI IF. Results indicate that, although social network metrics and ISI IF rankings deviate moderately for citation-based journal networks, they differ considerably for journal networks derived from download data. Schlögl et al. (2014) chose two journals on information systems as sample and made the correlation analysis between the numbers of downloads in Science Direct, the citations in Scopus and the number of readers in Mendeley. They found that these two Altmetrics metrics had correlation with citations but there were also some differences existed. Sotudeh, Mazarei & Mirzabeigi (2015) studied the relationship between the bookmarks in CiteULike and the traditional impact metrics on the level of journals and scholars. They concluded that the bookmark data could be used as a supplement to the traditional metrics, but cannot replace them. Fan, Peng & Shen (2015) presented an empirical analysis taking Scientometrics as the sample, and concluded that when applying Altmetrics to the journal evaluation, researchers should differentiate data from different sources, increase analysis on the evaluation time and identify the manipulation of attention.
Given that studies on Altmetrics have a good start on journal level, this study aims to present a further exploration. Since most of studies on Altmetrics adopted correlation analysis as the main method, and the results are helpful to find out the similarity and difference between metrics, this study takes correlation analysis as the main method to explore the relationship between citation metrics and Altmetrics on the journal level. Also, we will discuss and summarize the applicability of Altmetrics in the evaluation of journals from various perspectives.

Methodology

Sample
The sample of this study is selected from the Scopus Source List (November 2015). There are four source types in this list, and only Journal and Trade Journal were adopted by this study. For identification, only unique records with Print-ISSN or Electronic-ISSN or both of them were included. Records which failed to be obtained SJR2014 or Altmetrics data were excluded. These resulted in 10,041 journals as the sample of this study. In the following section, the publication types of journals are identified according to their Print-ISSN and E-ISSN. The disciplines are identified according to the All Science Journals Classification (ASJC) code provided by Scopus, and some interdisciplinary journals have more than one ASJC code. Therefore, the numbers of journals in Life Sciences, Social Sciences, Physical Sciences and Health Sciences are 2,386, 2,699, 2,032 and 4,257.

Data
The Scopus Source List (November 2015) was downloaded for the sample of this study. The information of sample journals was extracted from it including Source Title, P-ISSN, E-ISSN, Coverage, Open Access Status, Publisher’s Country and ASJC. The citation data adopted by this study comes from SCImago Journal Rankings (2014). We matched journals by ISSN and collected their SJR, H-index, total number of documents published in 2014 (Total Docs. (2014)) and from 2011 to 2013 (Total Docs. (3 years)), total number of references cited by documents published in 2014 (Total Refs.), total number of citations in 2014 of documents published from 2011 to 2013 (Total Cites (3 years)), total number of citable documents from 2011 to 2013 (Citable Docs. (3 years)), average number of citations per document in the last 2 years (Cites / Doc. (2 years)) and average number of references per document (Ref. / Doc.).

Altmetric Explorer was used to collect Altmetrics data. With its filters “In these journals” and “Mentioned in the past”, we obtained data of papers published in sample journals and mentioned in the past 1 year. As a result, Altmetrics data of 1,149,369 articles from 10,041 journals was collected including total number of articles, usage of various sources, number of readers and Altmetrics score.

Metrics
Metrics of journals are divided into 3 groups according to their data sources, shown as Table 1, Table 2 and Table 3. Altmetrics Comprehensive Metrics group includes metrics calculated with data from various sources. Altmetrics Source Metrics group includes metrics coming from single data source. Citation Metrics group includes metrics related to citation data.

Procedures
In the following sections, firstly we calculate the correlation coefficients of citation metrics and Altmetrics metrics on journal basis, and provide a detailed comparison between different metrics and discuss the applicability of Altmetrics metrics. Secondly with coefficient of variation, we make a discussion on the discrimination of Altmetrics metrics. Thirdly we present
a comparison and discuss the applicable scope of Altmetrics metrics from four aspects: discipline, publishing area, publishing type and Open Access status.

**Findings**

**Altmetrics comprehensive metrics**

Table 4 shows the correlation coefficients between 12 Altmetrics comprehensive metrics and 6 citation metrics. Most of Altmetrics metrics have positive correlation with citation metrics...
except for 1-year Altmetrics Scores Median and Altmetrics Scores Median. With low coefficients, both of the two median metrics cannot reflect the academic influence or the quantity of articles. Differently, Readers Median has moderate positive correlation with citation metrics. It can reflect recent influence rather than accumulated influence. However, compared with Readers Mean and Readers Sum, its ability to reflect journal influence is inferior. Therefore, median metrics are not applicable in the evaluation of journals.

</tbody>
</table>

Comparing Readers Mean, 1-year Altmetrics Scores Mean and Altmetrics Scores Mean with their sum metrics, the coefficients of sum metrics are all higher than 0.7, obviously higher than mean metrics. It shows that sum metrics are more able to reflect journals’ academic influence, while they are also indicating other influence as Altmetrics metrics.

Articles Sum is the number of articles, which had been mentioned in the last year, captured by Altmetric.com of a journal. It roughly shows the online usage of the journal. The correlation coefficients of Articles Sum with Total Docs. (2014) and Total Docs. (3 years) are 0.706 and 0.683, indicating high correlations. This shows that the visibility of a journal is related to the scale and recent status of the journal, but there exist some factors affecting the online usage of journals. Except for Articles Sum, other Altmetrics metrics have higher coefficients with Total Docs. (2014) than coefficients with Total Docs. (3 years). It once again shows that Altmetrics metrics are more sensitive to the recent status of journals.

In order to know further about the window of Altmetrics Scores, we compare 1-year Altmetrics Scores with Altmetrics Scores. Both the mean and the sum in 2 windows have very close coefficients with citation metrics. Therefore, the window makes little effects on the applicability of Altmetrics Scores in the evaluation of journals.

Comparing coefficients between Altmetrics sum metrics and SJR2014, all of them show moderate to high positive correlations. Readers Sum achieves the highest coefficient at 0.811, while Accounts Sum gets the lowest, and Altmetrics Scores Sum is between two of them. It shows that Readers Sum can get the evaluation results closest to that of citation metrics. As the data used by a metric contains data from more social media sources, the metric tends to reflect more complex influence of journals. As a result, when Altmetrics is applied to evaluation, online reference manager tools and social media should be differentiated as two different data...
satisfactory. It is meaningful to consider how to combine them for evaluation to get a more comprehensive result.

Table 5 shows the correlation coefficients between 9 Altmetrics comprehensive metrics. Obviously, 6 sum metrics have high correlation between them with coefficient higher than 0.85. 3 mean metrics have weak positive correlation with Articles Sum, which shows that Altmetrics metrics are also affected by the scale of journals. Therefore, mean metrics can help to reduce such effects.

</tbody>
</table>

Accounts Sum is the number of users of a journal in social media, while Readers Sum is the number of users of a journal in reference manager tools. The correlation coefficient between them is 0.886, showing a high correlation. It indicates that the numbers of users of a journal in different online platforms are similar. But since they are platforms with different types of content, reference manager tools and social media are quite different when being used as Altmetrics data sources. Comparing the correlation of Altmetrics Scores Sum with Accounts Sum and Readers Sum, the coefficient of Accounts Sum is significantly higher than that of Readers Sum. This is due to the data sources of Altmetrics Scores. Since reference manager tools only take up a small part of the online platform, social media will have greater effects on Altmetrics Scores.

**Altmetrics source metrics**

Table 6 shows the correlation coefficients between 15 Altmetrics source metrics and 6 citation metrics. All Altmetrics source metrics have positive correlation with citation metrics with coefficients from 0.13 to 0.72. Src_tweeters, Src_msm and Src_fbwalls have high coefficient, while Src_linkedin and Src_pinners have the lowest coefficient compared with other sources. Since LinkedIn is a business and employment-oriented social networking platform and Pinterest is a photo sharing website, both of them focus on a specific field which is not related to scientific research. Online platforms with more comprehensive interests turn out to be more suitable in scientific evaluation.

The coefficients between Altmetrics source metrics and Total Docs. (2014), and the coefficients between Altmetrics source metrics and Total Docs. (3 years) are calculated. Figure 1 shows the difference between them. Sources with higher coefficients of Total Docs. (3 years) includes LinkedIn, Pinterest, policy documents, Q&A sites, videos and Wikipedia. Except for LinkedIn and Pinterest, which focus on a specific field, other 4 sources have less social activities or are
updated more slowly. Sources with active social connection such as Twitter and Facebook have greater coefficient differences. Also, platforms require quick update have obvious differences such as news outlets and blogs. In other words, the short-time change of journals can be reflected more easily in the platforms with faster update speed. Therefore, a feasible combination of different Altmetrics sources will help to make a more comprehensive evaluation of journals’ impact.

Figure 1. Coefficient difference of Altmetrics source metrics between Total Docs. (2014) and Total Docs. (3 years)

Correlation coefficients between Altmetrics source metrics are calculated. All of them have positive correlations. Similar as above, Src_linkedin and Src_pinners show great differences with other metrics. Src_policies, Src_peer_review_sites, Src_qna and Src_weibo have weak correlation with other metrics. It shows that the similarity between these sources depends more on the characteristics of themselves.
Table 7 shows the correlation coefficients between Altmetrics comprehensive metrics and source metrics. Src_fbwalls, Src_feeds, Src_msm and Src_tweeters have the strongest correlation with Altmetrics comprehensive metrics with coefficients higher than 0.75. Since Twitter achieves the highest coefficient, it can obtain the evaluation results closest to that of Altmetrics comprehensive metrics when we adopt only one Altmetrics source.

Figure 2. Coefficient of variation of metrics
Discrimination of Altmetrics metrics

In order to get further understanding of the discrimination of Altmetrics metrics, Figure 2 shows the coefficient of variation. Compared with citation metrics, except for Articles Sum and Altmetrics Scores Mean, all coefficient of variation of Altmetrics metrics are significantly higher than that of citation metrics. It shows that using Altmetrics metrics to evaluate the influence of journals can obtain a result with obvious difference. Altmetrics metrics make good discrimination in the influence level of journals.

The coefficients of variation of Altmetrics comprehensive metrics are from 129% to 880%, lower than source metrics but higher than citation metrics. It shows that Altmetrics comprehensive metrics have better discrimination than citation metrics. Articles Sum, Readers Mean and Altmetrics Scores Mean have relatively low coefficients. Using Altmetrics comprehensive metrics for the evaluation of journals will make the difference between journals more obvious.

All of Altmetrics source metrics have high coefficients of variation, from 600% to 2300%. Since Altmetrics source metrics directly come from the data of different sources, it means different journals might have different influence in each online platforms. There are great difference between the raw data from Altmetrics sources, so such data has to be processed scientifically for better application.

Applicable scope of Altmetrics metrics

For a deeper understanding of the applicable scope of Altmetrics metrics, we provide an analysis from four aspects: discipline, publishing area, publishing type and Open Access status.

Figure 3. Correlation coefficients between SJR2014 and Altmetrics metrics in disciplines

Figure 3 shows the correlation coefficients between SJR2014 and 5 Altmetrics metrics across disciplines. Obviously, the coefficients in Natural Science are relatively low, indicating that using Altmetrics for the evaluation of natural science journals will have great difference with traditional evaluation results. In these four disciplines, Altmetrics is more suitable for the journal evaluation in Social Science and Health Science. Readers Sum can help to obtain results closer to that of citation metrics, while Altmetrics Scores Mean gets the most different one.

Figure 4 shows the correlation coefficients between SJR2014 and Altmetrics metrics across publishing areas. There are 81 countries or areas in our sample, and Figure 4 shows the top 20 with most number of journals published. Except for the Altmetrics Scores Mean in United Arab Emirates, all Altmetrics metrics have positive correlation with SJR2014. The applicability of sum metrics are stable in journals of different areas, while the applicability of mean metrics
obviously varies. Journals published in India, Brazil, China, Russia and United Arab Emirates are not suitable to be evaluated with Altmetrics. Meanwhile, the mean metrics of Altmetrics are not applicable for the evaluation of journals in New Zealand and South Korea.

Table 8 shows the correlation coefficients between SJR2014 and Altmetrics metrics in 3 different publishing types. The correlation coefficient achieves the highest for printed journals and the lowest for electronic journals. It shows that if a journal is exposed in the Internet more, the evaluation results of Altmetrics will have greater difference with that of citation metrics. Also, the component of influence of such journals will be more complicated.

Open access status is one of the most influential factor affecting journals’ impact in the Internet. Table 9 shows the correlation coefficients between SJR2014 and Altmetrics metrics in Open Access status. It shows that readers metrics are more able to reflect the academic influence of non-OA journals, while Altmetrics Scores and Accounts Sum do better for OA journals.

Discussion and Conclusions

Based on a sample of 10,041 journals, this study presents a comparison between Altmetrics metrics and citation metrics to discuss the applicability of Altmetrics in journal evaluation.

First on the overall applicability of Altmetrics metrics, according to our findings, the Altmetrics metrics calculated with the Altmetrics data of articles can reflect both of the short-term and long-term influence of journals to some extent, and it does a better job in the former one. In this study we find that Readers Sum, Accounts Sum and Altmetrics Scores can get evaluation results highly correlated to traditional results. Also, these metrics have good discrimination on the academic quality of journals. Because the influence of journal in the Internet is more complicated, Altmetrics are more able to reflect the influence which are exposed in the Internet. It can indicate the influence in the Internet in addition to reflecting the academic influence. Therefore, Altmetrics metrics are helpful to point out journals with greater comprehensive impact in a short period.

Second on Altmetrics data sources, the choice of data sources will affect the journal influence it reflects. Altmetrics data mainly comes from reference manager tools and social network. Data from reference manager tools can provide results more correlated to traditional results, while using data from social network is opposite. Further, data sources with a mature social network and fast update speed tend to be more able to indicate academic impact. One possible reason is that they have network structures, which are similar to citation data with citation network.

Third on the use of Altmetrics metrics, sum metrics can get results closer to traditional results compared with mean metrics. In most cases, sum metrics of Altmetrics metrics are more stable and are more able to reflect the academic influence of journals.

Fourth on the applicable scope of Altmetrics, currently it’s limited and not all journals are suitable to be evaluated with Altmetrics. In this study we find that Altmetrics is not applicable for specific disciplines or publishing areas. Altmetrics achieves better results in journals in Social Science and Health Science, instead of Natural Science especially journals in Computer Science and Mathematics. In addition, the Open Access status of journals will affect the evaluation results obtained by Altmetrics.

As for the future study on Altmetrics, one question worthy of attention is the difference between article level and journal level, since journals are the aggregation of articles while they show obvious difference in Altmetrics. Besides, the connotation and algorithm of Altmetrics should be emphasized. Since the usage of academic literatures on the Internet is very complex, the motives behind different behaviours can help to find out the characteristics and influence of journals. Because the data source of Altmetrics has a great influence on the evaluation, a scientific design of metrics for Altmetrics will be meaningful to use data from different sources effectively and obtain feasible method for the future scientific evaluation.

Does Monetary Support Increase the Number of Scientific Papers?
An Interrupted Time Series Analysis

Yaşar Tonta

yasartonta@gmail.com
Hacettepe University, Ankara (Turkey)

Abstract
One of the main indicators of scientific production is the number of papers published in scholarly journals. Turkey ranks 18th place in the world based on the number of scholarly publications. The objective of this paper is to find out if the monetary support program initiated in 1993 by the Turkish Scientific and Technological Research Council (TÜBİTAK) to incentivize researchers and increase the number, impact and quality of international publications has been effective in doing so. We analyzed some 390,000 publications with Turkish affiliations listed in the Web of Science (WoS) database between 1976 and 2015 along with about 157,000 supported ones between 1997 and 2015. We used the interrupted time series analysis technique to test if TÜBİTAK’s support program helped increase the number of publications. It appears that the support program has had negligible impact on the increase of the number of papers. We discuss the implications of findings along with the possible causes of the ineffectiveness of the support program.

Conference Topic
Country level studies

Introduction
The number of scholarly papers and citations thereto are indirect indicators of the level of scientific development of countries. The number of scholarly papers with Turkish affiliations listed in citation indexes has increased tremendously over the years and Turkey ranks 18th in the world in terms of number of publications. Over 36,000 papers were published in 2015 alone, although their scientific impact in terms of the number of citations they gather is well below the average of the world, the European Union (EU) and the OECD countries.

In 1993, the Turkish Scientific and Technological Research Council (TÜBİTAK) has initiated a monetary support program (UBYT) to incentivize researchers and increase the number, impact and quality of international publications authored by Turkish researchers. Considerable percentages of papers with Turkish affiliations were supported in the early years of this program, even though the rate of support has gradually decreased (to c. 30%) over the years due to the steep increase in the number of published papers with Turkish affiliations.

As part of the program, some 157,000 publications (93% of which were papers/articles) were supported between 1997 and 2015. The amount of support paid for each paper has been determined on the basis of the impact factor of the journal in which it was published.

The total amount of support was about 124 million Turkish Liras (in 2015 current prices; equal to c. 35 million USD). The number of papers supported, the total number of publications, and the amount of support increased four-, 10- and 13-fold, respectively, during this period.

The support program has been in place for almost a quarter century. Yet, its impact has not been evaluated in the past. We have been asked by TÜBİTAK to evaluate the effectiveness of the program and given the payment records of 157,000 supported publications. They included, among others, journal information (name, year, its class based on Journal Citation Reports’ subject categories), type of contribution (e.g., article, review) and the amount of support.

Based on the payment records provided, the characteristics (i.e., impact factors) of journals in which supported papers with Turkish affiliations appeared have been analyzed, the functioning of the support algorithm has been studied, and the effectiveness of the overall
support program has been evaluated. Findings indicate that the authors of mediocre papers published in journals with relatively low impact factors have mostly been supported due to the use of skewed distributions of journal impact factors in determining the amount of support. The existing support algorithm, on the other hand, does not seem to function as conceived. This paper presents only the findings of the interrupted time series analysis with a view to find out if the support program has had any impact on the increase of the number of papers with Turkish affiliations. It is organized as follows: The Literature Review section briefly discusses the findings of relevant studies including those that provide some background on the Turkish case. The Data and Method section describes the data used and provides information on interrupted time series analysis. The detailed findings are presented thereafter (Findings and Discussion), followed by Conclusions and Recommendations.

Literature Review
Performance-based research funding systems (PRFSs) came into being in 1980s. Based on rewarding the outputs, the rationale of PRFSs is to provide more support to institutions (or individuals) with higher performances so that the ones with lower performances will strive to improve theirs in order to get more support (Herbst, 2007, p. 90). Yet, it is not clear if PRFSs based on outputs and competition increase the scientific productivity and the impact of outputs. In a relatively recent study comparing PRFSs and outputs of eight countries, countries with less competitive PRFSs such as Denmark turned out to be as effective as the ones with more competitive PRFSs such as the UK and Australia (Auranen & Nieminen, 2010, p. 830). Some researchers drew attention to the potential “side effects” of PRFSs based on competition, as they tend to “homogenize” research outputs, discourage experiments using new approaches, and reward researchers playing “safe” even though their contributions may not have any societal impact (Geuna & Martin, 2003, p. 296). The idea of increasing productivity on the basis of outputs and competition seems more complicated than what decision-makers have initially thought (Auranen & Nieminen, 2010).

There are mainly two types of PRFSs in use: (1) the ones based on peer review or informed peer review supported with bibliometric measures; and (2) the ones based solely on bibliometric measures such as journal impact factors. The UK’s Research Excellence Framework (REF) is the largest research assessment system in the world (De Boer et al., 2015, p. 113). Based on peer review, REF has been used since 1986 to distribute funds to research institutes and universities on the basis of their performances. Despite their shortcomings, PRFSs based on bibliometric measures only are on the rise, as they are, in comparison to peer review, easier and less costly to apply as a “proxy” to assess performance. Therefore, they tend to get preferred by increasingly more countries lately.

PRFSs and publication support systems based on bibliometric measures generally use the number of papers published in refereed journals and their impact in terms of citations as the main criteria to determine the research institutes and researchers to be supported. Impact factors (IF) and article influence scores (AIS) of journals are the two most commonly used metrics. Journal IF was originally proposed by the late Eugene Garfield (1972) to help librarians in their selection of journals for subscription. It is an indicator of the quality of a journal in general and measures the citation impact of an “average” paper published therein. It does not say anything about the quality of an individual paper in that journal and how many citations, if any, it would gather in a certain period of time after its publication (e.g., two years). Citation distributions used to calculate the IFs of journals are quite skewed, indicating that few papers published in a given journal get cited much more frequently while the majority get unnoticed or rarely cited (Marx & Bornmann, 2013). This is the case even for the most prestigious journals with the highest IFs such as *Nature* (IF=38) and *Science* (IF=35). As high as 75% of articles published in these journals get cited fewer times than their journal IFs.
indicate (Larivière et al., 2016, p. 4, Table 2). Journal IFs vary by scientific discipline, too, as the number of researchers in each field, publication types (i.e., journal articles as opposed to books) and scholarly communication patterns tend to differ. In general, some 9%-10% of all the articles listed in Web of Science collect 44% of the total number of citations (Albarrán, Crespo, Ortuño & Ruiz-Castillo, 2011). More importantly, there exists no positive relationship between the number of citations an article gets and the IF of the journal in which it is published (Zhang, Rousseau & Sivertsen, 2017, p. 14), and a large body of literature detailing the shortcomings of the use of journal IFs as a performance measure is readily available (e.g., Seglen, 1997; Glänzel & Moed, 2002; Van Raan, 2005; Marx & Bornmann, 2013; Casadevall & Fang, 2012; Wouters et al., 2015). Yet, rather than checking the number of citations to the papers of individual researchers, PRFSs based on bibliometric measures continue to use journal IFs to assess the performance of individuals. Journal IFs are quite misleading in predicting the number of citations that any given article might get. What follows are a few examples of PRFS using journal IFs as a research assessment tool.

PRFSs are reviewed by several researchers (e.g., Geuna & Martin, 2003; European Commission, 2010; Hicks, 2012; De Boer et al., 2015). Most EU countries, Norway, USA, Australia, New Zealand and China have some PRFSs in place. We provide a few examples of PRFSs that either solely use journal IF or use it in combination with peer review (excluding the ones based only on peer review such as REF in the UK).

Italy uses a PRFS where an expert panel decides whether to use citation analysis or peer review (or both) for each publication. Universities are ranked on the basis of a quality score consisting of citations and other journal metrics, which determine the amount of support each university gets. Some 30% of the research funds are distributed according to the outcome of this evaluation (Abramo, D’Angelo & Di Costa, 2011, p. 930; Abramo & D’Angelo, 2016, p. 2055; Abramo & D’Angelo, 2011, p. 348).

Similarly, Spain uses a mixed system, although researchers are encouraged to publish in journals that are listed in the top quarters of JCR’s subject categories. Researchers who publish in such journals receive monetary support that ranges somewhere between 3% and 15% of their monthly salaries (Osuna, Cruz-Castro & Sanz-Menéndez, 2011).

A number of countries such as Czech Republic, China, Finland, and Australia use journal IF exclusively to support research institutes and individual researchers. Finland, for instance, linked journal IF directly with research support by legislation (Adam, 2002, p. 727). Similarly, Australia and the Czech Republic make direct linkage between research evaluation and funding by counting scholarly outputs and assigning a score to each on the basis of bibliometric measures. These scores are then used to determine the amount of monetary support and papers that appear in refereed journals or journals with relatively higher IFs get the highest scores (Butler, 2004; Butler, 2003, p. 147-151; Good et al. 2015, p. 92, 96, Table 3). Norway also has a similar system based on weighting journals on the basis of various criteria and created three different journal lists (Schneider, 2009). China, on the other hand, uses journal IF most comprehensively in that academic recruitments and promotions, university rankings (and the amount of research support they get), support of Chinese journals that are listed in Chinese Citation Indexes all rely on journal IFs. The procedure seems to have been automated, as a researcher publishing in a journal with a certain IF knows how much support s/he would get. For instance, the author of a paper published in a journal with IF higher than 15 receives 300,000 Yuan (c. 43,000 USD) (Shao & Shen, 2012)!

Turkey is no exception: journal IFs are considered as an indicator of quality and have been used as an important criterion in academic promotions since early 1990s. In addition to individual universities, TÜBİTAK has initiated a nationwide monetary support system based exclusively on journal IFs. Journals classified under Q1, Q2, etc. in JCR’s subject categories have been used to determine the monetary compensation. More recently (2016), Turkish
Higher Education Council (HEC) started a new support scheme based mostly on journal IFs and the faculty whose scores are above a certain threshold in terms of number of academic activities (mostly publications) during the previous year get an additional 10% to 15% on top of their regular monthly salaries throughout the year.

It should be noted that performance-based research funding and publication support systems based on quantitative measures tend to have some adverse effects. Researchers seem to adjust to the requirements very easily and change their publication patterns and behaviors. Such systems are prone to "gaming", too, and researchers become more "opportunistic" (e.g., publication "inflation") and less ethical (e.g., "fake" citations) in time. Unintended consequences of PRFSs in several countries (e.g., Australia, Czech Republic, and Spain) were reported in the literature (Butler, 2003; Butler, 2004; Good et al., 2015; Osuna, Cruz-Castro & Sanz-Menéndez, 2011). For example, more papers tend to get published in journals with relatively lower IFs. A similar trend has also been observed in Turkey (Yurtsever et al., 2001, 2002; Önder et al., 2008; Kamalski et al., 2017, p. 298-301). As the Goodhart’s Law states, “When a measure becomes a target, it ceases to be a good measure”.1

It should also be noted that correlation between competitive PRFSs and the research productivity is not clear-cut (Auranen & Nieminen, 2010, p. 831). Excessive competition seems to reduce the time and energy otherwise to be expended for research. In this paper, we test the conjecture if TÜBİTAK’s publication support system has had an impact on the increase of number of publications listed in citation indexes with Turkish affiliations.

Data Sources and Method

We performed a search on Web of Science (WoS) (December 19, 2016) to identify all the publications with Turkish affiliations listed in Science Citation Index (SCI), Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI) between 1976 and 2015. More than 390,000 records were retrieved, 81% of which were full papers (articles) while the rest were other types of publications (e.g., reviews, notes, and letters to the editor).

TÜBİTAK provided the payment data for about 157,000 supported publications (93% of which were papers). These records were first cleaned, then coded as either “full papers” (articles) or “other” types of publications, classified under various criteria (e.g., year, class of journal, amount of support paid), ranked and combined, if necessary.

We used MS Excel and SPSS 23 for the detailed analysis of data and prepared both WoS and TÜBİTAK records for interrupted time series analysis outlined below (Interrupted, 2013).2

The interrupted time series (ITS) analysis technique (also known as quasi-experimental time series analysis or intervention analysis) is used in this paper to measure the impact of TÜBİTAK’s support program. ITS analysis measures if an “event” occurring at any given stage has an immediate or delayed effect on the time series data. For instance, an unexpected political development in a given country may increase the exchange rates, or a terrorist attack may reduce the number of tourists. These “events” (called “interventions”) may be planned or not planned. As ITS analysis is a quasi-experimental method, it is possible (by means of using a control group) to verify if the change has occurred because of the intervention. ITS analysis is based on the following statistical model:

\[
Y_t = \beta_{pre} + \beta_{post} + e_t
\]

1 See https://en.wikipedia.org/ s.v. “Goodhart’s Law”.
2 Time series data prepared for interrupted time series analysis can be had from the author.
3 This percentage should ideally be 0 (zero) in order for it to function as a true control group. Yet, we think that time series data prepared for interrupted time series analysis can be had from the author.
where $Y_t$ represents the $t$'th observation in the time series, $\beta_{\text{pre}}$ and $\beta_{\text{post}}$ represent the levels of series before and after the intervention, respectively, and $e_t$ is the error related with $Y_t$. The null hypothesis

$$H_0 = \beta_{\text{pre}} - \beta_{\text{post}} = 0$$

states that there is no statistically significant difference between the levels of series before and after the intervention (i.e., it has no impact on dependent variable (McDowall et al., 1980, p. 12). It is assumed that the parameters in time series models stay the same before and after the intervention and that no other events that affect the parameters take place. ITS analysis can be applied to both static and dynamic (“ergodic”) time series. The ARIMA model is used for non-static series whose arithmetic means, variances and co-variances change as time passes. This model is expressed as ARIMA ($p, d, q$) where $p, d$ and $q$ represent the autoregressive operator (AR), the integrated operator (I), and the moving average operator (MA), respectively. If time series data is not stationary ($d$), it will first be made stationary to make its mean and variance constant over the years studied.

We have WoS data of publications with Turkish affiliations (1976-2015) and data of supported publications by TÜBİTAK (1997-2015). The program (“intervention”) started in 1993 and enough data points exist both before (1976-1992) and after (1993-2015) the intervention so as to be able to apply ITS analysis to time series data (Cochrane, 2002, p. 7-8). As relatively fewer researchers benefited from the support program in the early years, we thought that the effect of the program might be observed with some delay (lag). Therefore, we measured its impact one (1994), four (1997) and 10 years (2003) after of its start.

We have no data on papers (full articles) whose authors have not been supported. However, a relatively small group of authors of other types of contributions can function as a control group, as only 3% of the total amount of support on average was set aside for such contributions even though 19% of publications were of such nature. The authors of other types of contributions were paid half of what the authors of the full papers were, and a mere 1% of the support budget was allocated to them in 2013, for example. In other words, we can find out if TÜBİTAK’s support program has had any impact on the increase in the number of papers by comparing it with that of other types of contributions. If the number of other types of contributions that were not well supported did not increase but the number of papers supported increased, we can deduce that the source of the impact was the support program. Conversely, if, despite lack of support, the number of other types of contributions increased along with the number of papers receiving full monetary support, then the increase in the latter cannot be attributed to the program, suggesting that some factor(s) other than the support program may have played a role in this increase.

**Findings and Discussion**

The descriptive data about the number of papers and the total number of publications originating from Turkey are presented in Table 1 and Fig. 1. The rate of increase is quite steep, especially starting from 2000s. This rate of increase made Turkey in those years one of the fastest growing countries in the world in terms of number of papers, and Turkey moved up the ladder very quickly from 45th in 1983 to 25th in 1999 to 18th in 2008 in the world, contributing to 1.56% of the overall scientific production in the world.

A considerable percentage of these publications were supported by TÜBİTAK’s support program when it was first initiated in 1993. However, the support program seems to have not

---

3 This percentage should ideally be 0 (zero) in order for it to function as a true control group. Yet, we think that it can be used as a control group with some caution and the generalization should be interpreted accordingly.
kept up with the pace of increase of papers and the percentage of papers supported went down from 70% in early 2000s to below 30% in recent years (Table 2, Fig. 2).

Fig. 2. Number of papers listed in WoS with Turkish affiliations and supported by TÜBİTAK (1997-2015)
The detailed analysis of changes in TÜBİTAK’s support policies over the years is beyond the confines of this paper. Instead, we concentrate on whether TÜBİTAK’s support program has actually played a role in the steep rate of increase of papers by Turkish researchers. The time path of the number of papers listed in the Web of Science (WoS) originating from Turkey between 1976 and 2015 is given below (Fig. 3). The intervention point (1993) is marked on the graph. As there exists a trend of increase in the number of papers both before and after the intervention, we took the difference of the time series from the 1st level \((d=1)\) to make it stationary. Consequently, the auto-correlation function (ACF) and partial auto-correlation function (PACF) of the time series became static within the confidence intervals (Fig. 4).

Fig. 3. Time path of papers with Turkish affiliations (1976-2015)

Fig. 4. Correlograms of autocorrelation (ACF) and partial autocorrelations (PACF) functions
We then defined ARIMA (1,1,0) model for interrupted time series data and wanted to see the impact of TÜBİTAK’s support program in 1994, 1997 and 2003 (after one, four and 10 years of its start, respectively). The test statistic of the ARIMA model shows that the defined model is suitable for the time series data ($\chi^2 = 23.531$, DF = 17, $p = .133$) (Table 3). The parameters of the ARIMA model (estimates, SE, t- and p- values) are given in Table 4. The ARIMA Model did not produce statistically significant results (coefficient = .153, SE = .170, $t = 0.899$, $p = .375$). The coefficient for “Time series” in Table 4 gives the slope of the regression line before the intervention (14.051), which is used to analyze the different time points by taking into account the existing trend in data before calculating the effect of the intervention. The coefficient for “Before/after Support Program” represents the slope of y-axis when $x$ is equal to 0 (zero) and is used to measure the effect of the intervention in later time points. The coefficient for “Effect” (29.091) gives the difference between slopes before and after the intervention. By adding this difference to the value of pre-intervention slope (14.051), the value of the post-intervention slope (44.142) can be calculated (Interrupted, 2013).

</tbody>
</table>

In order to see the effect of the support program on the number of papers with Turkish affiliations, we continued with this model. The slopes of pre- and post-intervention are the same for all analyses. It is possible to see the direct effect of the intervention on the number of papers with Turkish affiliations (Table 5). According to the model, an additional 554 papers were published in 1994 because of the support program. However, the effect of the support program is not statistically significant ($p = .157$). The delayed effect of the program has not been materialized in later years, either, as additional number of papers published due to the program were limited (651 papers in 1997, and 826 in 2003) and the effect is not statistically significant ($p > .05$). As the effect of the program has been negligible, the formula of the effect of the intervention is not given.

Despite the fact that other types of contributions have been supported very little during the period of analysis, the rate of their increase is greater than that of generously supported papers (see Fig. 1). As a control group, the rate of continuous increase in other types of publications seems to confirm the results of the interrupted time series analysis. For instance, some 4,000-
7,000 other types of publications have been published annually in recent years, of which only a few hundreds got supported. Yet, the number of other publications continues to increase regardless of support, suggesting that TÜBİTAK’s support program is probably not the main factor causing the increase in the number of papers with Turkish affiliations.

</table>

It should be noted though that interrupted time series analysis has some limitations. The assumption that no other “event” or “events” occurred during the period of analysis that might have affected the time series data is one of them. For example, the prerequisite of having papers published in journals listed in citation indexes for academic promotion may have triggered this increase, as more than 90% of research in Turkey has been carried out in universities, and the number of academic personnel in universities has increased tremendously over the years. Moreover, in addition to the number of research personnel in universities, the number of papers may be increasing due to a number of other factors such as the number of researchers per 10,000 capita, and the share of R&D expenditures within the Gross National Product (GDP). As indicated earlier, even though some positive correlation between PRFSs and the number of papers has been observed, this may not necessarily point to a strong causality between the two. As was the case in Spain (Osuna, Cruz-Castro & Sanz-Menéndez, 2011), the number of papers with Turkish affiliations continues to increase perhaps not because of TÜBİTAK’s support program but because of other factors such as the growth in and the maturity of universities’ research systems including academic personnel.

We should also note that we carried out a multiple regression analysis and observed fairly strong correlation between the number of papers with Turkish affiliations and the number of supported papers. However, we decided not to report the results of the multiple regression analysis, as the Durbin-Watson statistic was rather small (0.921), probably indicating the existence of serial autocorrelation between variables and thereby making the results less reliable. This can to some extent be observed from Fig. 2: the correlation between number of papers with Turkish affiliations and the supported papers was positive and statistically significant between 1997 and 2006 whereas it was negative and not statistically significant between 2007 and 2015.

Conclusion

As part of TÜBİTAK’s support program, the authors of over 157,000 publications received more than 124 million Turkish Liras (in 2015 current prices, c. 35 million USD) as monetary support between 1997 and 2015. Yet, two thirds of all payments were less than 826 liras (or c. 230 USD). These “micropayments” might be one of the reasons why, according to the test results of the interrupted time series analysis, the program did not seem to have direct impact on the increase of the number of papers published by Turkish authors. It is likely that small amounts of payments were not much of an incentive for authors to publish more.

We should point out that the objective of the support program is not to increase the number of papers per se but to increase their impact and quality, as stated in the By-Law of TÜBİTAK’s support program (TÜBİTAK, 2016). Some authors may find the small payments satisfactory. Yet, if such small payments do not help achieve the program’s objectives, precautions should be taken to correct it. The support program seems to have functioned as a mechanism to transfer
small amounts of payments to authors without any considerable improvement in the impact and quality of the papers. Transaction costs of such small payments should be borne in mind as well as the costs of missed opportunities of increasing the impact and quality of papers.

Acknowledgments
This paper is based on a report (in Turkish) on the evaluation of TÜBİTAK’s Support Program of International Scientific Publications (UBYT), which is to be published by TÜBİTAK as a monograph (Tonta, in press). Research was carried out during my sabbatical year (2016-2017) at the School of Library and Information Science of Humboldt University in Berlin. I gratefully acknowledge the continuous support that I received throughout my stay from my family and colleagues who assumed some of my responsibilities as well as from my home and host institutions (Hacettepe University and Humboldt University) and TÜBİTAK. I thank all the people who provided the payments data; offered a pleasant work environment with access to information resources; and helped me in completing the research and writing the report.

References

Research competitiveness analysis refers to the measurement, comparison and analysis of the research status (i.e., strength and/or weakness) of different scientific research bodies (e.g., institutions, researchers, etc.) on different research fields. Improving research competitiveness analysis method can be conducive to accurately obtaining the research status of research fields and research bodies. This paper presents a method of evaluating the competitiveness of research institutions based on research topic distribution. The method uses the LDA topic model to obtain paper-topic distribution matrix to objectively assign the academic impact of papers (such as times of citation) to research topics. Then the method calculates the competitiveness of each research institution on each research topic with the help of institution-paper matrix. Finally, the competitiveness and the research strength and/or weakness of the institutions are defined and characterized. Case study shows that the method can lead to an objective and effective evaluation of the research competitiveness of given research institutions on given research field.

Conference Topic
The theory, method and principle of five metrics science concepts, that is, Bibliometrics, Informetrics, Scientometrics, Webometrics and Knowledgometrics.

Introduction
Research competitiveness analysis refers to the measurement, comparison and analysis of the research status of different scientific research bodies (e.g., institutions, researchers, etc.) on different research fields (Zhang, 2014). Improving competitiveness analysis methods can be conducive to obtaining the research status of research bodies, clarifying their strengths and/or weaknesses, and in turn promoting collaborative innovation among different research bodies and different research fields.

Generally, research competitiveness analysis is carried out based on research papers and involves three steps, i.e., research field (topic) recognition, competitiveness evaluation and competitiveness analysis (Gei, 2013). Research field recognition is important since different research fields are always not comparable, while topic recognition can result in a fine granular evaluation for strength and/or weakness characterization. For field recognition, a paper’s research field is usually determined based on partition standard provided by the scientific literature database providers, e.g., ESI, Incites, Wos, etc. (Chen & Shi, 2013; Dong, 2014; Li 2012; Cova, 2013). For research topic, it is often represented by keywords with high frequencies and their frequent combinations derived using certain analysis tools (e.g., CiteSpace) (Chen, 2006; Chen & Hu, 2012). When the fields (topics) are determined, the scientometrics criterions of papers are used for competitiveness evaluation of the corresponding institutions on the corresponding research fields (topics). Those criterions may include paper count, paper IFs, paper citation counts, etc. (Mkhnacheva, 2011; Morris, 2003; Small, 2009; Shibata, 2008). Finally, the ranking of competitiveness is given and the strengths and/or weaknesses are analysed (Liu, 2015; Small, 2014).

Those methods have made concrete progress on competitiveness evaluation; however, the following problems should be further considered. First, the mapping from papers to research fields and topics are too straightforward for a precise evaluation, since many multi-discipline papers cannot be simply partitioned into a unique research field, and a small set of frequent

* Corresponding Author
keywords may not be capable to represent a research topic. Second, in the current works, papers are all bounded to a unique research field, and papers relating to multiple research topics are considered contributing equally to each of the topics. However, this may not always intuitive since a paper always has certain main research points corresponding to one or more (but not all the relating) field(s) and/or topic(s).

Focusing on the mentioned problems, this paper presents a method of evaluating the competitiveness of research institutions based on research topic distribution. The method uses the LDA topic model to obtain paper-topic distribution matrix to objectively assign the academic impact of papers (such as the number of cited times) to research topics. Then the method calculates the impact of each research institution on each research topic with the help of institution-paper matrix. Further, the competitiveness scores of institutions are calculated and the research strength and/or weakness of the institutions are defined and derived. Finally, case study is carried out to show effectiveness of the proposed evaluation method. It is to be noted that in the proposed method, there is no need to distinguish research field and topic, since a research field can be viewed as a higher abstraction of research topics. That means by setting proper parameters, LDA can be used to model paper-field distribution.

**Evaluation Method**

The proposed method goes through the following steps for evaluation: 1) topic recognition, 2) impact allocation, 3) competitiveness measurement. We explained each step as follows.

**Topic recognition**

LDA is a document topic generation model (Blei, 2003). The model presumes that the words in the topic and the topics of the document are both subject to certain polynomial distributions. Hence generating a document can be seen as a repeated process of selecting a topic with a certain probability and then selecting a word in the topic with a certain probability. The model can be formally represented as $\Omega = \Phi \times \Theta$, where $\Omega$, $\Phi$ and $\Theta$ is document-word distribution, topic-word distribution and document-topic distribution respectively, $\times$ represents matrix multiplication, as demonstrated in Fig. 1. In Fig 1, we have 3 papers; each is composed of 2 topics and 3 words. The LDA model can be used to determine $\Theta$ for a set of documents by setting a proper topic number $n$.

\[
\begin{pmatrix}
\omega_{11} & \omega_{12} & \omega_{13} \\
\omega_{21} & \omega_{22} & \omega_{23} \\
\omega_{31} & \omega_{32} & \omega_{33}
\end{pmatrix} = \begin{pmatrix}
\varphi_{11} & \varphi_{12} \\
\varphi_{21} & \varphi_{22} \\
\varphi_{31} & \varphi_{32}
\end{pmatrix} \times \begin{pmatrix}
\theta_{11} & \theta_{12} & \theta_{13} \\
\theta_{21} & \theta_{22} & \theta_{23}
\end{pmatrix}
\]

**Figure 1 LDA Model of 3 papers, 2 topics and 3 words**

**Impact allocation**

Once we got the paper-topic distribution matrix $\Theta$, we can then allocate the academic impact of the papers to the relating topics using values in $\Theta$ as weights to get paper-impact matrix $\Gamma$ (that characterizes the impact of papers on topics). More formally, given $m$ papers, $n$ topics, paper-topic distribution matrix $\Theta = \{ \theta_{ij} | \theta_{ij} \in [0,1], i \in [1,m], j \in [1,n], \sum_{j} \theta_{ij} = 1 \}$, paper-impact vector $\mathbf{I} = [t_1, t_2, \ldots, t_m]^T$, the paper-impact matrix $\Gamma$ can be calculated as $\Gamma = \Theta^T \otimes \mathbf{I} = \{ \gamma_{ij} | \gamma_{ij} = \theta_{ij} \times t_j, \theta_{ij} \in \Theta^T, t_j \in \mathbf{I} \}$, where $\theta_{ij}$ is the weight of paper $i$ on topic $j$, $t_j$ is the impact indicator of paper $i$, $\gamma_{ij}$ is the calculated impact value of paper $i$ on topic $j$. Fig. 2 (a) shows an example with 3 papers and 2 topics.
In practice, a paper’s academic impact may relate to many aspects, e.g., times of citation, impact factor, and etc. We use a weighted composition of the aspects to make an overall evaluation of paper impact. That is, suppose we have \( l \) factors (that influence academic impact of a paper) whose values are given in the paper-impact matrix \( \Lambda = \{ \lambda_{ij} \mid i \in [1,n], j \in [1,l] \} \), the paper-impact vector is calculated as \( \mathbf{I} = \Lambda \times \mathbf{A} \), where \( \lambda_{ij} \) is the normalized impact value of paper \( i \) on factor \( j \). A \( \Lambda = \begin{bmatrix} 0.26 & 0.26 \\ 0.252 & 0.588 \\ 0.4 & 0.1 \end{bmatrix} \) \( \times \begin{bmatrix} 0.5 & 0.5 \\ 0.3 & 0.7 \\ 0.8 & 0.2 \end{bmatrix} \otimes \begin{bmatrix} 0.52 \\ 0.84 \\ 0.50 \end{bmatrix} \times \begin{bmatrix} 0.2 & 1 \\ 1 & 0.6 \end{bmatrix} \times \begin{bmatrix} 0.6 \\ 0.4 \end{bmatrix} \)

\[ \begin{bmatrix} 0.52 \\ 0.84 \end{bmatrix} = \begin{bmatrix} 0.7 & 0.2 \end{bmatrix} \]

\( \mathbf{I} \), the institution-impact matrix and \( \mathbf{A} \), the institution-impact vector.

Now we can measure the competitiveness of the relating institutions based on institution-impact matrix \( \Xi \). First, we calculate the average impact of all the institutions on each topic: \( \xi = \langle \xi_1, \xi_2, \ldots, \xi_n \rangle \), where \( \forall j \in [1,n], \xi_j = \frac{1}{v} \sum_{i=1}^{v} \xi_{ij} \), where \( \xi_{ij} \in \Xi \). Then, we calculate the difference matrix \( \Delta \) between \( \Xi \) and \( \xi \) as \( \Delta = \Xi \ominus \xi = \{ \delta_{ij} \mid \delta_{ij} = \xi_{ij} - \xi_j, \xi_{ij}, \xi_j \in \Xi, \xi_j \in \xi \} \), as exemplified in Fig. 4.

\[ \Delta = \begin{bmatrix} 0.18 & -0.02 \\ 0.04 & 0.14 \\ -0.22 & -0.12 \end{bmatrix} \begin{bmatrix} 0.652 & 0.688 \\ 0.512 & 0.848 \\ 0.252 & 0.588 \end{bmatrix} \ominus \begin{bmatrix} 0.472 & 0.708 \end{bmatrix} \]

Figure 2 Example of (a) calculation of paper-impact matrix and (b) calculation of paper-impact vector

Figure 3 Calculation of institution-impact matrix

Competitiveness measurement

The difference matrix \( \Delta \) can then be used to assess the research status of the institutions. Given a threshold \( \tau \) and a percentage \( p \), we can define, for example, 1) if \( \delta_{ij} \geq \tau \), then
research topic \( j \) is the strength of institution \( i \); 2) if \( \delta_{ij} \leq -\tau \), then research topic \( j \) is the weakness of institution \( i \); for a certain topic \( j \), after ranking the institutions according to \( \delta_{ij} \), let \( R_{ij} \) denote the ranking of institution \( i \) on topic \( j \). 3) if \( R_{ij} \leq \rho \), then institution \( i \) is leading the research on topic \( j \), and many other rules. Based on the definition, as to our example in Fig. 4, if we set \( \tau = 0.1 \), then we can say that topic 1 and 2 is the strength of institution 1 and 2 respectively; both topic 1 and 2 are the weaknesses of institution 3.

**Case Study**

In this section, we use case study to verify the effectiveness of the proposed evaluation method from two perspectives: 1) the rationality of LDA model, 2) the effectiveness of competitiveness evaluation.

For LDA model, we want to see whether various research topics can be identified by the model. For the purpose, we used \( SU = \) "computer science" and \( TS = \) "operating system"; \( SU = \) "computer science" and \( TS = \) "information security"; \( SU = \) "computer science" and \( TS = \) "artificial intelligence*"; \( SU = \) "computer science" and \( TS = \) "computer graphics*"; \( SU = \) "computer science" and \( TS = \) "software engineer*" as search strategies to search and download bibliographic data from Science Citation Index Expanded (SCI-EXPANDED) database. The data relates to 28421 research papers in five research topics of computer science, i.e., operating system (OS), information security (IS), artificial intelligence (AI), computer graphics (CG) and software engineering (SE). Then we extracted keywords from the data and input them to the LDA algorithm. By setting the topic number as 5, we got a paper-topic matrix of 28421 rows and 5 columns.

Fig. 5 demonstrates the topic distribution of a few of papers (21 papers) as an example. It can be seen that all the papers to some extent relates to all the topics. To verify the LDA model’s ability of identifying topics, we assigned the LDA topic with largest probability as a paper’s research topic (e.g., the topic of \( P_1 \) is \( T_1 \)) and recorded all the correspondences between the papers (in various research topics) and the LDA topics. The results illustrated in Table 1 show the correspondences of AI to \( T_4 \), CG to \( T_0 \), IS to \( T_2 \), OS to \( T_1 \) and SE to \( T_3 \). Table 2 shows the 5 most representative keywords of each topic. From the table we can see that the topics can be easily interpreted by a field expert, and the interpretation in the table can perfectly support the correspondences in Table 1.

*Figure 5 An example of paper-topic matrix*
For the effectiveness of competitiveness evaluation, we used AI ranking as example and compared the ranking resulted from our method with two other rankings. AI was chosen since there are numbers of public available rankings released by various third parties that can be compared. We reviewed three rankings, i.e., US News ranking 2016, CS Ranking 2016, and WUZHEN Ranking 2016. We found that the three rankings were similar with each other. For example, the Top 3 institutions in all the 3 rankings are Stanford University, Carnegie Mellon University and MIT. The Top 10 institutions in the 3 ranking also have many overlapping: in total only 16 institutions make up the 3 Top 10 lists. That is, in the 30 institutions of the 3 Top 10 lists, more than 40% of the institutions are overlapped. Consequently, we chose the most widely acknowledged ranking, i.e., US News ranking 2016, as our first reference for comparison. For the other reference, we want to compare the topic based method with the traditional method. That is, after topic recognition, we removed the concept of multi-disciplines from the paper-topic matrix \( \Theta \) so that each paper only contributes to the topic with largest probability. More formally, \( \forall \theta_j \in \Theta, \theta_j = 1, \text{if } \forall j \neq k, \theta_j > \theta_k ; \theta_j = 0, \text{else.} \) For example, the distribution of \( P1 \) on \( T1 \) to \( T5 \) in Fig. 5 will be 1, 0, 0, 0, 0. The following steps were all the same with the proposed method and the results were acquired for comparison. During the case study, citation counts and impact factors of papers were used for paper-impact vector calculation, and weights were set as 0.5 and 0.5. The results are presented in Table 3.

From Table 3 we can conclude that the topic based method is more effective than the traditional method for at least the following 2 aspects. First, 50% of the Top 10 institutions resulted by the proposed topic based method are the same as US News Ranking, much higher than the 20% of those by the traditional method. Second, for those toppest institutions, 2 of the Top 3 institutions resulted by the proposed topic based method are also in the Top 3 in the US News Ranking, and the Carnegie Mellon University is also ranked in Top 10. While for traditional method, none of the Top 3 institutions in the US News Ranking appears in the Top 3 list, and only Stanford University appears in the Top 10 list.

Finally, by setting $\tau = 0.15$, $p = 10\%$, then MIT, Stanford University, Nanyang Technological University, Microsoft, Chinese Academy of Sciences, Texas State University-Austin, and Carnegie Mellon University are leading the research on AI. While Beijing University of Posts and Telecommunications, Northeastern University, Wuhan University, Graz Technical University, Paderborn University, Malaysia University of Technology and many other institutions still need to improve their research on AI.

Conclusion

This paper presents a method of evaluating the competitiveness of research institutions based on research topic distribution. The method uses the LDA topic model to obtain paper-topic distribution matrix to objectively assign the academic impact of papers (such as times of citation) to research topics. Then the method calculates the competitiveness of each research institution on each research topic with the help of institution-paper matrix. Finally, the competitiveness and the research strength and/or weakness of the institutions are defined and characterized. Case study shows that the method can lead to an objective and effective evaluation of the research competitiveness of given research institutions on given research field.

It is to be noted that the proposed method formally defines the process competitiveness evaluation, i.e., topic analysis, impact allocation and competitiveness measurement. Many adaptations can be easily applied in practice. For example, one can integrate the process of impact allocation with expert preference by multiplying $\Theta^T$ with a weight vector. In the meanwhile, more indicators such as centrality of a paper in the citation network can also be considered for paper impact characterization. Besides, since LDA model can handle topics on multi-granularity, by considering different research bodies (e.g., countries, institutions or researchers), the method can be easily used to evaluate the competitiveness of research bodies and topics on various levels of details. Our future work will consider the mentioned adaptations for a more effective competitiveness evaluation. Other work like mining patterns among strengths and/or weaknesses may also be considered so that the relationships among topics can be further understood.

Abstract
The Web of Science now records the Open Access (OA) status of papers that it covers. Papers with OA = yes have grown rapidly since 2000 and the proportion has reached 18% of the total in biomedical research but only 4% in chemistry. Countries also vary greatly in their preference for publishing in OA journals: Brazil tops the list in four fields but not in physics where the Ukraine and Russia use OA the most among the 30 top publishers in 2015. Contrary to popular belief that OA papers would receive more citations, this appears not to be true, probably because the top-cited journals are not OA, some OA journals may have lower peer-review and editorial standards, and because in some countries (e.g., Brazil, Spain) many OA journals are not in English. However, there is some evidence that OA papers may be attracting more citations from researchers in lower-middle income and low-income countries.

Introduction
Whereas the traditional publishing model was that it did not cost researchers to publish their papers in peer-reviewed journals, there is now an increasing tendency to ask most of them to pay for this privilege (ones in low-income countries may be excused), but in return to provide free access online to their papers to everyone. This is the "gold" open access (OA) model. There is also the "green" OA model, where authors are permitted to self-archive their papers in an institutional repository while access through the journal is not available. Other models include "delayed" OA, whereby access to the content of the journal is freely available after an embargo period, typically 12 or 24 months, and "hybrid" OA, whereby some articles are freely available immediately because the author(s) have paid a fee: Scientometrics is in this category. Not all OA journals charge authors a fee: some are subsidised by academic institutions, learned societies or government agencies.

The question of whether OA papers receive more citations than non-OA ones is inevitably rather vexed because there are so many factors that can influence citation scores, and all of them need to be taken into account if the influence of just one of them, OA or not OA, is to be determined. This factor may also influence other supposedly independent variables, such as the decision of the authors on which journal to select for their paper based on their opinion on its likelihood of acceptance and perhaps its cost of publication. Thus some studies (Eysenbach, 2006; Gargouri et al, 2010; Sotudeh et al., 2015; Wang et al., 2015) show OA papers having a citation advantage, others (Davis et al, 2008; Davis, 2011; Torres-Salinas et al., 2016) the reverse, and some claiming that there is little difference (Moed, 2007; Björk & Solomon, 2012; Wray, 2016). A contributing factor seems to be whether the OA journals charge the authors: those that do appear to have a citation advantage (Solomon et al., 2013. There is also some dispute over whether OA leads to citations occurring earlier (Moed, 2007; Davis et al., 2008).
We wished to investigate how the practice of OA had grown over the years, to see which scientific fields embraced it most, and which countries had taken to OA with the greatest enthusiasm. We also hypothesised that low-income countries, whose institutions might not have been able to afford to pay for many subscription journals, would preferentially benefit from OA and that therefore their researchers would have a larger share of the citations to OA papers than of those of non-OA papers.

The Web of Science (WoS) now records whether papers are OA or not, but the positive marking refers only to journals that are completely OA, and not to hybrid ones where authors (usually the minority) may choose to pay for their papers to be OA. We used this marking to distinguish between OA and non-OA papers, and to investigate the temporal evolution of OA in five major fields and in different countries. We also looked at the five-year citation scores of different groups of papers, with particular attention to the countries that were citing them. For this purpose they were grouped into four categories by their gross national income per capita: the boundaries were:

- high income / $12,475
- upper middle / $4035
- lower middle / $1025
- low income

according to the World Bank in 2016 (World Bank, 2016).

**Methodology**

Articles were selected from the WoS for the 17 years, 2000 to 2016, in five major fields: biology & environment (BIOL), biomedical research (BMED), chemistry (CHEM), engineering & technology (ENGR) and physics (PHYS). These were chosen to cover the major areas of science. Chemistry and physics are discrete subject areas, but biomedical research was defined by means of address words and contractions indicative of the subject area (Lewison & Paraje, 2004), for example:

\[ AD=(BIOCH*M \text{ OR } CLIN \text{ OR } GENET \text{ OR } HLTH* \text{ OR } HOSP* \text{ OR } MED \text{ OR } NEURO* \text{ OR } PATHO* \text{ OR } P*EDIAT \text{ OR } PHARM* \text{ OR } SURG) \]

The two other fields were composites, formed of several WoS subject areas:

\[ SU=(AGRICULTURE \text{ OR } BIODIVERSITY \text{ OR } CONSERVATION \text{ OR } ENTOMOLOGY \text{ OR } ENVIRONMENTAL SCIENCES \text{ OR } ECOLGY \text{ OR } EVOLUTIONARY BIOLOGY \text{ OR } FISHERIES \text{ OR } FOOD SCIENCE \text{ OR } TECHNOLOGY \text{ OR } FORESTRY \text{ OR } MARINE \text{ OR } FRESHWATER BIOLOGY \text{ OR } MYCOLOGY \text{ OR } PLANT SCIENCES \text{ OR } REPRODUCTIVE BIOLOGY \text{ OR } ZOOLOGY) = BIOL \]

\[ SU=(AUTOMATION \text{ OR } CONTROL SYSTEMS \text{ OR } CONSTRUCTION \text{ OR } BUILDING TECHNOLOGY \text{ OR } ENERGY \text{ OR } FUELS \text{ OR } ENGINEERING \text{ OR } INSTRUMENTATION \text{ OR } MECHANICS \text{ OR } METALLURGY \text{ OR } METALLURGICAL ENGINEERING \text{ OR } NUCLEAR SCIENCE \text{ OR } TECHNOLOGY \text{ OR } ROBOTICS \text{ OR } TELECOMMUNICATIONS) = ENGR \]

After the papers were selected, the Open Access tab allowed the numbers in OA journals to be seen, and the numbers, year by year, in each field to be tabulated. It was also possible to tabulate the numbers from each country (up to about 190 in total) that were either OA or not-OA.

We selected pairs of countries and major fields, based on the above tabulations, for more detailed analysis of the numbers of citations in the five years following publication and the distribution of the citing papers among countries in those five years. The combinations selected were as follows; they were based on large numbers of OA papers in the country concerned:
The citing countries were characterised by their income levels, see above, and the percentages of citations from each group were tabulated. However, because of international co-authorship of many of these citing papers, the sum of the percentages for these four groups was greater than 100%, and so they were proportionately reduced to sum to this total. We found that many of the OA papers from Brazil were in Portuguese (69%) and those from Spain were in Spanish (26%), so it was unlikely that they would be cited as frequently as the non-OA papers (which proved to be the case) but perhaps more often cited by researchers from the 20 Latin American countries, so this was investigated.

**Results**

*Growth of OA in five fields of science*

There was a remarkable difference, particularly in the last seven years, in the numbers of OA papers in biomedical research, which reached over 18% in 2016, compared with the non-biological fields. Figure 1, below, shows the percentages of papers in OA in the five fields, as moving three-year averages so as to smooth out annual fluctuations.

![Figure 1. Growth of Open Access among papers in five fields processed for the Web of Science: BMED = biomedical research; BIOL = biology & environment; CHEM = chemistry; ENGR = engineering & technology; PHYS = physics. Three-year moving averages.](image)

Biology & environmental science initially led biomedical research, but its rate of increase decreased after 2008, although it still outpaced the three physical science fields, particularly chemistry where only 4% of papers were OA in 2016. Tables 2 to 6 show the positions of the 30 countries in each field with the most papers in 2015 relative to the world average in the four years, 2000, 2005, 2010 and 2015, in terms of percentages of OA papers, and the ISO2 codes for the countries are listed in Table 1.
Table 1. Countries with outputs in the top 30 in one or more fields in 2015, with ISO2 codes.

The tables show that for most countries there has been a regression to the mean, so that countries that either published many more (or many fewer) OA papers than the world mean...
in 2000 had become closer to the world average in 2015. One might have expected that, since it often costs researchers to publish in OA journals, that richer countries would have chosen OA journals more than poor countries, but this is not the case. The USA has been below the world average in all five major fields, and Switzerland (CH) in all except for physics (where the presence of CERN may have made a difference); on the other hand Brazil has been well above average in all fields except for physics, and India has been above average in physics, biomedical research and engineering, and only a bit below average in chemistry.

Citations to OA and non-OA papers
We investigated the citations to papers from five combinations of countries and major fields. The first of these was Brazilian papers in biology & environmental science. The mean five-year citation scores for OA and non-OA papers from 2006-11 were 2.2 and 6.1, showing that the non-OA papers were cited much more than OA ones. This was not surprising because so many of the papers were in Portuguese. A consequence was that 71% of the citations to the OA papers were from Latin American countries, including Brazil, but only 35% of the citations to the non-OA papers.

The second set of papers was biomedical papers from Sweden. These papers were all in English, and the five-year citation scores were very similar, 15.2 for the OA papers and 15.3 for the non-OA ones. An analysis of the citing countries in the five years broken down by income groups showed, as expected, that over 85% of all citations came from high-income countries. However, the lower-middle income countries accounted for 2.8% of the citations to the OA papers but only 1.8% of the citations to non-OA papers. There was an even bigger ratio for the low income countries: they provided 1.1% of the cites to the OA papers but only 0.3% of the cites to non-OA papers. So the OA papers were attracting more interest (cites) from the poorer countries than the non-OA ones, although these are only a tiny proportion of the total numbers of cites.

The third combination was chemistry papers from Germany. Here the non-OA papers again had an advantage over the OA ones in mean five-year citation scores, 12.6 cites to 8.7. And, as with the Swedish biomedical papers, the OA papers received a higher percentage of their cites from lower-medium income countries (7.0%) than did the non-OA ones (4.3%), and there was a bigger ratio for the low-income countries (0.2% compared with 0.034%). Once again, these represent a small minority of the cites, but OA is benefiting these poorer countries.

The fourth combination, Spanish papers in engineering & technology, showed a bigger citation advantage for the non-OA papers as 26% of the OA papers were in Spanish. The actual mean cite counts were 8.6 and 3.5 citations in five years. The lower-medium- and low-income countries did not benefit from OA, but the Latin American countries did, with 6.7% of citations compared with 4.9% for the non-OA papers.

Finally the fifth combination, of Russian physics papers was analysed. The citation scores were quite low, even though all the papers were in English: 5.4 for non-OA papers and 3.3 for the OA ones. But there were much more dramatic differences in the citing country percentages: the upper-middle countries (which include Russia) accounted for 45.6% of the OA citations compared with 29.1% for the non-OA papers' citations, and there was a small benefit to the lower-middle income countries as well (5.4% of cites compared with 5.0% for the non-OA papers).
Discussion
These are only samples, but they appear fairly consistent in showing that the non-OA papers enjoy a citation advantage over the OA ones. Because there are many other factors that can influence citation scores, this cannot be regarded as a definitive result, but it seems unlikely that OA papers enjoy a citation advantage by virtue simply of being OA. However, there is a very small but fairly consistent advantage for the lower-middle and low income countries in the percentage of citations that they provide.

A more detailed study would examine the relative citation advantages enjoyed by OA papers in hybrid journals. However, since OA publication is increasingly being required by a number of major funding bodies, such as the US National Institutes of Health, and the Wellcome Trust in the UK, and also by many universities, the division between OA and non-OA papers may depend on whether the papers have been externally funded after a rigorous peer-review. This will inevitably mean that funded papers will be more likely to be OA if they are in a hybrid journal, and we know that such papers tend to be of higher quality because of the acceptance of the research that they describe by a prestigious funder. This means that they will be more highly cited than papers without explicit contestable funding, whether or not they are OA.

The Next Generation (plus One): An Analysis of Doctoral Students’ Academic Fertility Using a Novel Approach for Identifying Advisors

April 30, 2017

Abstract
Scientific communities reproduce themselves by allowing senior researchers to train young scholars, in particular through the training of doctoral students. The primary purpose of this paper is to contribute to a better understanding of the self-reproduction of science by analyzing the probability of doctoral students to become advisors themselves. We present a novel approach employing machine learning techniques to identify advisors among (frequent) co-authors in doctoral students’ publications. This approach enabled us to construct a large-scale dataset of German doctoral graduates in applied physics and electrical engineering from 1975 to 2005. Keywords: self-reproduction of science, advisor identification, PhD training, advisor affects, academic careers, peer effects

Acknowledgement: This work was funded by the German Federal Ministry of Education and Research (BMBF) in its program „Forschung zu den Karrierebedingungen und Karriereentwicklungen des Wissenschaftlichen Nachwuchses (FoWiN)” under Grant 16FWN001.

1 Introduction: The production of scientists by means of scientists

Publications are the main output that scientists produce. In publications new results are described and disseminated to other researchers. Publications thus enable the cumulative nature of science, where each generation of scientists stands, as Isaac Newton famously phrased it, “on the shoulder of giants”. However, it is implicit in Newton’s metaphor that publications alone are not sufficient to keep science functioning. A second output is required to do so: a new generations of scientists willing and able to climb atop their predecessors’ shoulders.

Science is a self-reproducing system, and the training of doctoral students is a key step in the process of re-production. New members of scientific communities are spawned within these communities. Specifically, they are trained by existing
members of the community. This is most clearly observed in doctoral training: only established researchers - normally those who hold professorships - have the privilege to graduate doctoral students, i.e., admit new members to the community.

The relevance of producing doctoral students is recognized in the conventions by which reputation is allocated among researchers (e.g., in the notion that person X is “advisor Y’s student”, and also in disciplinary genealogies such as the Mathematics Genealogy Project). It is also a relevant parameter in many performance-based management systems set up by universities and national governments. However, only a fraction of all doctoral students will subsequently become advisors and produce doctoral students themselves, and it is not obvious, for example, whether successful self-reproduction is primarily due to having many offspring or more dependent on offspring quality. To learn more about the self-reproduction of science we therefore need to better understand the determinants of producing “fertile” students, i.e., those of today’s doctoral students that tomorrow will train the next generation of students, and also how these relate to student, advisor and organization characteristics.

The primary purpose of this paper is to contribute to a better understanding of the self-reproduction of science by analyzing the probability of doctoral students to become advisors themselves. To do so, we constructed an original dataset containing more than 20,000 matched student-advisor pairs for German applied physics in the time period from 1975 to 2005. Advisor information is not part of the standard bibliometric data for doctoral dissertations, nor is it otherwise collected and published in systematic form. Prior work therefore has often relied on ad hoc approaches to identify advisor-student pairs. As a second contribution of the present paper, we provide a detailed account of the more systematic new approach we developed. It employs a novel matching algorithm based on publications co-authored by doctoral students and their advisors.

The remainder of this paper is structured as follows. Section 2 develops the theoretical background of the subsequent analysis. It also formulates testable hypotheses. In Section 3 we outline our approach to identify doctoral advisors based on dissertation and co-publication data. Section 4 presents the results of analyzing the dataset developed on the basis of this approach. Section 5 concludes.

2 Theory and hypotheses

2.1 Socialization effects of young researchers

Doctoral training prepares junior researchers for an academic career by enabling them to independently advance the frontier of knowledge. Young researchers need to acquire a broad range of knowledge and skills to perform successfully in academia. These range from mastering the intricate details of their field to in-

\footnote{See: https://genealogy.math.ndsu.nodak.edu/, or for a comparable project in Germany: https://www.bibsonomy.org/persons.}
sights into research strategies and routines of professional etiquette. The various types of knowledge and skills can be learned in a variety of ways. The institutional setup known as Open Science (Dasgupta et al., 1994) provides researchers with strong incentives to codify and freely communicate knowledge via publications. Significant parts of the required knowledge can therefore be accessed by reviewing the relevant literature. However, there is a broad consensus that not all relevant knowledge can be acquired from the literature. For skills such as the handling of laboratory equipment learning from one’s own experience is crucial, often based on a process of trial and error. In addition, besides access to codified knowledge and own experience, direct face-to-face interaction with others is crucial for becoming a successful researcher (e.g. Collins, 1974; Stephan, 2012). Face-to-face interaction allows doctoral students to access non-codified or tacit knowledge that cannot be found in the published scientific literature.

It also enables vicarious learning from observing the behavior of others as well as the environmental reaction to this behavior (Bandura, 1986).

Professors have a strong position in the German university system, and traditionally the training of individual doctoral students has been in the hands of a single doctoral advisor (the Doktorvater). This suggests an important role of the advisor in shaping the knowledge, skills, and attitudes of doctoral students (Buenstorf and Geissler, 2014). In light of these considerations, it seems plausible that doctoral students benefit by learning from their advisor, and that more can be learned from better-performing advisors. In turn, the acquired knowledge enhances a student’s chances to remain in academic, i.e., to become an advisor himself or herself. It is well-established, however, that only a fraction of all graduated doctoral students pursue academic careers. This hold for various time periods and countries (Stephan, 2012; Waldinger, 2016) and also for leading departments (Conley and Önder, 2014).

Advisors are not only important sources of knowledge for junior researchers, but also important gatekeepers of the scientific community. The status that a given advisor enjoys in the community is an important precondition of their students’ ability to signal their quality. Being advised by a highly reputed researcher and/or co-authoring with them thus acts to certify student quality. Students of more highly reputed advisors may also be able to benefit from an extended Matthew effect (Merton, 1968) resulting in their work getting more attention. Advisors perform even more direct gate-keeping functions in referring students within the community (Baruffaldi et al., 2016) and by helping them secure academic jobs (a precondition for them becoming advisors). How well a given advisor can perform these functions is only indirectly dependent on their own performance. More directly relevant is their reputation in the community (which would be expected to be associated with prior performance), but even more their status and influence in the respective community.

We expect both advisor status and advisor performance to exert beneficial influences on their students’ probability to become advisors themselves, and will try to disentangle them in the empirical analysis. Specifically we predict the following effects on students’ academic fertility:
**Hypothesis 1** Doctoral students whose advisor is better positioned in the network of the respective scientific community have a higher probability to remain active in science and to become advisors themselves.

**Hypothesis 2** Doctoral students whose advisor has superior research output have a higher probability to remain active in science and to become advisors themselves.

### 2.2 Life cycle effects

Their advisors’ age and career stage at the time they worked with them may be another relevant factor in doctoral students’ subsequent career outcomes. It is not obvious, however, how the probability that students remain active in research changes over the career trajectory of their advisors.

On the one hand, we would generally expect that more senior advisors are better able to teach their students. We would also expect more senior advisors to be more established in their community. They should therefore be better positioned to leverage their own contacts to the benefit of their students, for example by arranging for talks and visits to research groups possessing complementary knowledge. In addition, doctoral advisors may switch positions during their career. Such moves would generally be expected from less to more highly reputed universities, suggesting that students advised at later career stages may enjoy a better working environment.

On the other hand, life-cycle models of individual research output (Levin and Stephan, 1991) argue that as researchers get closer to their retirement age, they have weaker incentives to engage in research activities. Instead, they may be more strongly inclined to engage in consulting work and/or decrease their own working hours. In addition, while being more experienced and possibly having a broader overview of their field, more senior researchers may lose touch with the most recent developments in terms of theories and empirical methods. Their research foci may increasingly diverge from those that are currently „hot“, which makes it harder for their students to find attention for their own work. As scientific knowledge tends to decay relatively rapidly, more senior advisors may thus be less well-positioned to teach their students. Furthermore, it is plausible that students of more senior researchers face stronger competition for the advisor’s scarce time and attention. More senior advisors will often have a larger burden of administrative and managerial duties in the research group and the department. With increasing group size, they also have to divide their attention between a larger number of students. It moreover seems plausible that with an increasing „stock“ of prior doctoral students, advisors’ interest in securing the „survival“ of their line of research, which requires students who become advisors of the new generation of students, is increasingly muted.

Based on the prior evidence of mostly adverse effects of seniority on research performance, we expect the second set of arguments (suggesting a decreasing likelihood of student fertility with increasing advisor seniority) to be more relevant than the first one (which suggest an increasing likelihood). We also expect
that the role of advisors’ accumulated stock of doctoral students can be separated from that of advisor career age. These considerations inform a second set of hypotheses:

**Hypothesis 3** *Doctoral students whose advisor has a larger number of prior doctoral students have a reduced probability to remain active in science and to become advisors themselves.*

**Hypothesis 4** *Doctoral students whose advisor has reached a higher career age have a reduced probability to remain active in science and to become advisors themselves.*

### 2.3 Peer effects and competition among doctoral students

Doctoral advisors are certainly not the only relevant source of knowledge and skills that doctoral students draw upon. Relevant face-to-face interaction primarily takes place in the setting of the research group or laboratory, with fellow students and co-workers (Krabel, 2012; Tartari et al., 2014; Hottenrott and Lawson, 2017) being important partners from whom doctoral students can learn. In the German context co-workers in the research group have mostly been selected and/or trained by the student’s own advisor. Accordingly, peer group effects exerted by fellow students and co-workers will generally not be independent from advisor effects. It nonetheless seems plausible that students benefit from being part of a strong cohort of researchers contemporaneously working the same research group or laboratory. Other group members are sources of knowledge and social capital, and they may also provide role models affecting the career choices that a student makes. This suggests a positive peer group effect on individual students’ performance and thus their ability and willingness to embark on an academic careers.

**Hypothesis 5.a** *Doctoral students have a higher probability to remain active in science and to become advisors themselves if they are trained together with larger numbers of contemporary peers having the same advisor who remain in academia and subsequently become doctoral advisors.*

The above argument for positive peer effects does not take into account, however, that doctoral students in the German system need to go through additional career stages before assuming their first faculty positions. To a considerable extent these post-doctoral career stages are taken in the same research group or laboratory in which the individual received her doctoral training, which seems to be associated with superior career outcomes (Bäker, 2015). This implies a competitive relationship among the student and her contemporary peers or ”siblings”, since often only a fraction of the graduated doctoral students can remain in the lab. Students may thus suffer from being trained together with exceptionally well trained ”siblings”, which informs a competing hypothesis on peer impact:
Hypothesis 5.b  Doctoral students have a reduced probability to remain active in science and to become advisors themselves if they are trained together with larger numbers of contemporary peers having the same advisor who remain in academia and subsequently become doctoral advisors.

3 Identifying doctoral advisors: a new approach based on co-authored publications

In this section we outline a new large-scale approach to identify the advisors of doctoral dissertations. This approach exploits information about co-authored journal publications and underlies the empirical analysis presented below. We first present the general approach before discussing its implementation for the present paper. To keep the discussion tractable, only the most salient features of the approach are presented in the main body of the article, whereas further technical details are provided in footnotes as well as in Appendix A.

Data Selection
- In our context we select all natural sciences in the dissertation dataset and applied physics publications

Preprocessing
- Standardizing Names and Affiliations
- WoS name disambiguation in two steps: first step based on affiliation, second step combines same affiliation groups

Record Linkage
- Based on first affiliation of disambiguated researchers

Feature Engineering
- All (German) co-authors are considered as potential advisors
- Features depending on individual PhD-coauthor pairs
- Features standardized on PhD-level

Model Selection
- Models trained on a dataset of laser-scientists (3-fold cross validation)
- Performance is evaluated on separated data

Figure 1: Overview of the data processing and machine learning procedure.

Our approach for identifying doctoral advisors (including the pre-processing stage) is summarized in Figure 1. It is grounded in the assumption that, if doctoral students publish scientific articles out of their thesis they are likely to do this together with their advisor. By tracking co-authors of papers related to a certain doctoral thesis we should be able to pick out the advisor with some certainty. In order to do so we need to identify doctoral students’ papers as a subset of all scientific publications. We are able to solve this task by using additional information on doctoral students that, as best we know, has not been used before (in large-scale analyses). Based on knowing who is a doctoral
student we can identify their publications. Tracking the publication output of doctoral students we can retrieve a full list of all co-authors, in which we expect the advisor to be included. For this group of co-authors we can then calculate several characteristics that we expect to reveal the advisor. By using a training dataset we are able to train a model that predicts the advisor with an evaluated accuracy.

3.1 Dissertation data

Our point of departure is information about the universe of doctoral dissertations completed in Germany. Scholarly interest in dissertation data has been limited, especially when used as individual data and linked to other bibliographic data. However, there is a lot of to learn from these data to understand the production of scientific knowledge (Morichika and Shibayama, 2016). We take our information on doctoral dissertations from the online catalog of the German National Library (Deutsche Nationalbibliothek or DNB for short). Since 1969 German universities have been legally required to deposit copies of all completed doctoral dissertations at the DNB. Universities, in turn, enforce mandatory deposit of doctoral dissertations vis-à-vis their doctoral students. To ensure compliance, the doctoral degree is granted only after the respective student has deposited the required number of copies. Due to this principle of mandatory deposit the DNB holdings of doctoral dissertations, and consequently the information in its catalog, are virtually complete. Identifying doctoral dissertations in the catalog is unambiguous as they are indicated within the catalog’s subsection of works from higher education institutions (Hochschulschriften), along with (non-standardized) information about the issuing university and the year of submission. After eliminating double entries (e.g., due to multiple versions - mostly print and online versions - or editions), a total of 894,086 unique authors of doctoral theses was identified for the time period from 1970 to 2010.

3.2 Publication data

Identifying doctoral advisors on the basis of co-authorships first requires us to identify publications authored by the doctoral students in our sample. We use the Web of Science (WoS) database to obtain these publications. Identifying doctoral students’ publications in the WoS requires solving the namesake problem in the first place. The namesake problem (also known as ambiguity or homonymous problem) arises out of individual scholars who share names and subsequently publish using the same author name (cf. e.g. Smallheiser and Torvik, 2009, for a detailed discussion of the namesake problem). Since WoS does not provide a unique identifier for each individual researcher, author identities have to be established by cleaning and standardizing the WoS data. Solving this problem is nontrivial for several reasons\footnote{This task is best be done by using reliable automated procedures for two reasons: a) number of publications is not feasible for manually processing and b) manual processed data seems to provide unreliable results, especially in the case of common names. Even if authors} and becomes especially challeng-
ing when very common names are considered (c.f. i.e. Smalheiser and Torvik, 2009). Our disambiguation procedure is a somewhat heuristic approach, and assessing its quality is complicated because we try to track publications records of doctoral graduates who frequently leave science after just publishing a few papers. CVs including publications records are frequently not available for these individuals, and using the available ones would likely be biased. Accordingly, we do not have a sample to systematically evaluate the disambiguation. We are nonetheless confident about its quality, which is corroborated by comparing distributions of papers attributed to highly frequent and very rare names (see Appendix A.1).

We decided to first identify individual researchers’ publication œuvres and then link them to the doctoral students3. The applied procedure involves two steps (as comparable to, e.g., Wang et al., 2012; Strotmann et al., 2009; Ferreira et al., 2012): First, we search for clusters of papers sharing author names (surname and first name initial) and affiliation. While the retrieved name-affiliation groups might be sufficient to track doctoral student publications, researchers generally tend to change affiliations during their careers. Therefore we apply a second disambiguation step. By disambiguating name-affiliation groups’ sharing author name (but not affiliation), we aim to identify all publications of individual researchers covering their whole career. This procedure has the advantage that (in the first step) same name-affiliations combinations are more likely to belong to an individual scientist, and, (in the second step) once name-affiliation groups are sorted into distinct individuals more information is available when comparing homonyms over different affiliations (i.e. self-citations are easier to identify if more papers are considered).

Before we divide authors by names and affiliation the WoS requires substantial cleaning and standardization. We first process author names (surname and first initial5) by correcting German ß and ë as well as removing punctuation and whitespaces (the latter is important for German data; cf. Schoen et al., 2014), and assign affiliations to single authors wherever possible5. We identify all German universities by comparing affiliations with a list containing decomposed variations of university names. Within all publications corresponding to one name and affiliation search for distinct clusters which represent one individual scientist active at this affiliation. Within groups, the cluster algorithm assigns authorship to one distinct researcher if at least one of the following crite-

---

3An alternative approach would be the use of an assignment procedure as recommended method Ferreira et al. (2012) and Reijnhoudt et al. (2014), where information on individual scientists is collected at first and subsequently publications are assigned to the known individuals. Our decision against the use of assignment procedures is based on the need to identify all publications attributed to the co-authors as well.

4Only in the latest years full author names are available in the Web of Science publication database.

5Author affiliations can be attributed to a single author in certain cases, i.e. for corresponding authors (for a detailed discussion see Reijnhoudt et al. (2014)). Similar to Reijn-houdt et al. (2014) we considered all affiliations listed in the paper as potential true affiliations of the authors whenever a clear assignment was is possible.
ria is fulfilled: same department is mentioned\(^6\), at least one common co-author (identified by name), authors share second name initial, self-citations between the considered articles can be found, authors use same e-mail address\(^7\), and identical (author) keywords are used. In contrast, author references are identified as different individuals if there is a gap of 10 or more years between articles without any intermittent publications. Different full first names and different second name initials divide publications into separate scientists as well.

Before applying the second step of the disambiguation procedure we exclude all subsets. Subsets emerge when a researcher is using several affiliations. Then it is not clear which affiliation is the main affiliation. We choose to decide for the affiliation most papers are assigned to, all others are deleted from the dataset. The homonym problem to solve now gets at a sample of authors assigned to different affiliations. We still observe some overlaps of one to several papers on different disambiguated name-affiliations groups, in the case of several affiliations mentioned on the paper. This might be the case when researchers change affiliations, but still collaborate with previous colleagues. In the case of overlapping publications two name-affiliation groups are attributed to one single researcher. Non-overlapping distinct name-affiliations are then identified as the same (or different) individuals based on the following criteria: shared co-authors (based on disambiguated name-affiliation groups), self-citations between papers of one group to the other, and shared author keywords. Again, authors are identified as different individuals whenever they have different first names, second initials or publication lags of 10 or more years. As mentioned above the quality of the applied disambiguation procedure is evaluated in Appendix A.1.

3.3 Matching dissertations with WoS authors

To obtain publications related to doctoral dissertations the pre-processed DNB and WoS records have to be linked to each other. The primary name matching procedure performs a simple name comparison of the authors’ surnames and first name initials, which however leads to a high number of false positive matches (as described by D’Angelo et al. (2011)). Therefore we additionally require the graduating university to be equal to the earliest researchers’ affiliation in the WoS data. To further reduce false positive matched pairs we only considered pairs to be true matches if they (a) either refer to a unique match (a doctoral graduate with a unique name in the whole DNB sample matches to only one of the identified scientists in WoS); or (b) some similarity between paper titles and thesis title could be found. Similarity between the titles is computed by using a longest common substring algorithm.\(^8\) We decide to only include those matched

---

\(^6\)The department is tracked from the remaining part of authors affiliations when country and zip codes, cities and universities where extracted. Frequently occurring terms as „dept.“ were eliminated as well. Because of the high variation in different spellings remaining department information was compared by computing a Jaccard-similarity.

\(^7\)E-mail addresses are assigned to individual authors on the basis of highest Jaccard-similarities between all authors and e-mail addresses.

\(^8\)Before we compare titles they are standardized by removing (German and English) stopwords. Removing punctuations and numbers as well as whitespaces. In case several authors
pairs with at least one word (with more than five letters) in common, i.e. „laser“.
As a consequence of these requirements, our approach is rather conservative, and
some author-thesis pairs may not be retrieved because they choose very different
titles. Matched pairs with lags between publications exceeding seven years are
excluded from the sample. Matching quality is evaluated by comparing author
first names whenever available. (Results are reported in Appendix A.2.)

3.4 Co-authors of doctoral papers and feature space construction

We expect doctoral students to publish results of their theses in co-authorship
with their advisor. Subsequently we should be able to identify the advisor among
the student’s co-authors. By using the matched papers of doctoral graduates we
can easily obtain a full list of co-authors. To identify the advisor among these
co-authors we calculate several individual characteristics for each of the co-authors.
These characteristics should describe the unique position and importance among
all co-authors for the respective student. Co-authors who started publishing first
after the first publication of a specific doctoral graduate are excluded from the
dataset. Specifically, we use the following characteristics to identify advisors
within the group of co-authors:

- Times published together (number of papers co-authored together):
  We assume that doctoral students likely publish larger shares of their
  thesis-related papers in co-authorship with their advisors as opposed to
  other individuals.

- Publication lag (time lag between first paper of focal student and first
  paper of co-author):
  We assume advisors be active in scientific publishing a certain time period
  before the PhD graduates. Since we do not have strong priors about the
  lag relation, we include the lag variable in a quadratic function.

- Betweenness centrality within the co-author network:
  We assume advisors to be in a very central position, bridging between all
  of the Ph.Ds. co-authors.

- Burt constraint, based on citations within the co-author network:
  We assume that the person who receives most attention among the co-
  authors (receiving most of the citations) can be interpreted as the person
  with a high impact on the group’s work.

- Number of publications and number of citations:
  We assume co-authors with higher reputation / seniority to be more likely
  the advisor. Because the relationship might be non-linear we include these
  measures in a quadratic function.

match same thesis and vice versa ones with highest score are taken, scores are set in relation
to length of dissertation title.
• Author name position on paper:
  We assume that group leaders are more likely to be named last on the paper. Being named last / or first might capture some information about the role of the specific author.

• Number of dissertations a co-author is mentioned on:
  We assume advisors contributing in various ways to many dissertations. Finding a co-author frequently appearing on other students’ papers might indicate who is the advisor of the considered thesis.

• Degree in co-authors network:
  The network degree in the co-author network provides information on who is connected to how many of the co-authors. Advisors might be on average connected to more co-authors because of their central role in the research group.

• Citations received by PhD papers (number of times previous work of the co-authors is cited by students’ papers):
  We assume that doctoral students tend to follow the research agenda of their advisors, which is reflected by citations received by co-author.

• Same university:
  Co-author is affiliated to the degree-granting university at the same time as the student.

• Co-author is PhD:
  Co-author is identified as holding a doctoral degree. Recently graduated students may not be indicated as holding a doctoral degree in our dataset, while already acting as a post-doc who might have a significant influence on students’ work.

We further include several thesis-related characteristics:

• Number of papers

• Number of co-authors

• Year of submission

Before applying machine learning algorithms, variables have to be standardized because we are interested in identifying one specific individual in the group of co-authors. Some groups have generally high values for some of the attributes (e.g., large numbers of publications) but not for others (e.g., citation rates). We use z-score standardization centered to the mean of all co-authors of the focal doctoral student to take this into account.
3.5 Machine learning algorithms

The final step of our identification approach for doctoral advisors is to use the characteristics of co-authors outlined above to find the doctoral advisor among them. To this end we separate our data in two parts. One is used for training algorithms and identifying best parameter settings. The other is used to evaluate the resulting models on an independent dataset. We train four different algorithms that are standard in the data mining literature: the regularized logistic regression model, support vector machine (SVM), random forests, and ada Boost. All algorithms are available as R packages; for a ed discussion see Bishop (2013).

The regularized logistic regression model performs logistic regression including additional penalty terms to the optimized error function to avoid overfitting by reducing the model’s complexity. However, the penalty parameter needs to be specified. We also need to define a threshold when the estimated probability is high enough to be classified in the true class. Support vector machines have been used i.e. for disambiguation tasks by Wang et al. (2012). SVM uses a hyperplane to separate data by maximizing the distance to the vectors (data points) that are closest to the hyperplane. Those vectors are described as support vectors. To make the observed data linearly separable they are transferred into higher dimensional space. This is done by using a kernel, in our case a radial kernel. To avoid overfitting false classifications can be allowed, which however are penalized. Two parameters can be specified: a penalizing parameter, and parameter gamma specifying the radial basis function kernel. Random forest builds on decision trees. Multiple decision trees are constructed by choosing a random set of features. Decision trees simply split the dataset to achieve best separation of two classes. Combining several splits leads to decisions regions. After training a specific number of trees, all trees are used together to give a majority vote on the class of an object. As parameters the number of randomly drawn features as well as the number of trees need to be specified. The ada Boost algorithm is a boosting technique specified for binary response that has also been used by Han et al. (2004) for author name disambiguation. We use it as a fourth method even though it is also based on decision trees. Different from random Forests, boosting trains classifiers in sequence. Depending on the classification output to the input data weights are assigned giving higher importance to misclassified data points. Afterward also all classifiers give a majority vote. Iterations and a shrinkage parameter need to be specified as parameters.

9Using the programing language R Version: 3.3.2 (R Core Team, 2016) we apply the following R packages: glmnet for the regularized logistic regression (Friedman et al., 2010); for SVM we used e1071 created by Meyer et al. (2015); for random forest we used the randomForest package of Liaw and Wiener (2002); and in the case of ada Boost we use ada (Culp et al., 2016).
3.6 The sample of doctoral students in applied physics and electrical engineering

Various constraints and restrictions of the general approach discussed above had to be made to adapt it to the requirements of the present study. First and most importantly, we require a test sample allowing us to assess the reliability of our co-publication-based approach. To this purpose we utilize the sample of verified student-advisor matches developed by Buenstorf and Geissler (2014), which encompasses the universe of German laser-related doctoral dissertations completed since 1960 and is based on information obtained by university departments as well as the names of examiners provided in the dissertations. In addition to completeness, a further advantage of this dataset is its longitudinal character. However, for our purposes it has one disadvantage. While our algorithm aims at identifying the „true“ advisor, the training set often includes only the first examiner of the dissertation. These two roles may differ, particularly if a doctoral student is advised by a postdoc or a researcher working at a non-university public research organization. The training dataset includes 6,389 doctoral students with dissertations completed from 1960 to 2007. However sample size is reduced for two reasons. First we are stricter about excluding medical dissertation projects than the original authors, and second the doctoral student needs to have at least one publication. This reduces our sample to 3,583 observations, of which 1,686 (47%) have publications identified and 1,367 have their advisor among their co-authors. Only the latter are included in the training dataset.

Second, to ensure that our matching is not biased by field-specific differences in the role of student and advisor characteristics we focus on the broader fields of applied physics and electrical engineering into which much of which laser research falls as a subset. This field is also characterized by a prevalence of publications in WoS-listed journals, a precondition for our approach to work. Specifically, we limit the sample to dissertations classified as science or engineering by the DNB.\footnote{We used the classification scheme of the DNB corresponding to the DDC (Dewey-Decimal Classification) which is an international standard used by libraries for subject classifications.} This entails that we exclude all theses classified as medical dissertations, which account for about 50% of all doctoral theses in Germany. These exclusions reduce the number of authors of doctoral dissertations to 185,860, which also helps to limit the problem of false positive matches caused by homonyms, i.e. non-identical doctoral students and article authors sharing the same names.

Publication data for this set of authors is retrieved from the subset of WoS articles contained in the Science Citation Index dataset. Starting from the full set of all articles, proceedings and reviews with at least one author affiliation in Germany, we further restrict the dataset to articles published in relevant fields. These are identified as follows. First all articles containing „laser“ in the title are selected. The set of relevant articles is then extended using title terms that frequently co-occur with „laser“. The journals in which these articles were published constitute our set of relevant journals.\footnote{We use only WoS publications listed in the science citation index with at least one Ger-}
334,945 articles is covered in the WoS.

The matching procedure of the dissertation data (DNB-dataset) and the publication records (WoS-dataset) resulted in 30,969 true positive matched thesis publication record pairs. We identified 25,856 linked records by finding similarities between the titles of the thesis and the corresponding papers and 22,777 were identified by using matched unique names on both datasets. The doctoral students in the dataset published on average 5.39 papers (median: 3) with 8.46 co-authors (median: 5). Because the sample size of the training data is limited, we use threefold cross validation within the training sample to find best parameter setting (Witten et al., 2011). In the cross-validation procedure we split into test and training set in 1:3 portions, rotating estimation and average results. From the cross-validation we take the best fitting parameter setting and use the algorithm on the evaluation set. As already stated, the models’ predictive power is then evaluated by using a separated partition of the dataset. Evaluation results are presented in Table 1.

Random Forests outperform the other algorithms in terms of precision and recall. Overall we can obtain an 83% precision and recall rate, which is similar to matching results in other contexts should provide sufficient statistical power to test the above stated hypotheses. We choose to use the random forest model for predicting advisors for the whole sample. Therefore we use the whole test training dataset and apply it to the whole database. Additionally we run algorithms with accepting lower recall aiming at achieving higher precision. We also tested a second set demanding a minimum recall of 0.6 and tried to maximize precision. However, this did not yield a substantial improvement. Nevertheless, we tested all our models applying SVM for classification.

4 Econometric Analysis

Based on the approach detailed in Section 3 we were able to match a total of 25,735 student-advisor pairs in German applied physics and electrical engineer-

---

1269

---

now we select all Web of Science disciplines with a high coverage of relevant journals: „Physics, Applied“; „Optics“; „Physics, Atomic, Molecular - Chemical“; „Engineering, Electrical Electronics“; „Chemistry, Physical“; „Physics, Condensed Matter“; „Materials Science, Multidisciplinary“; „Physics, Multidisciplinary“. Papers with more than 25 authors are not considered.

12Details of the tested parameter settings are provided upon request.
ing for the time period 1975 to 2005. We use this sample to test the hypotheses derived above about determinants of individual scientific fertility (i.e., the likelihood that a given doctoral student becomes a doctoral advisor him- or herself). Specifically, we estimate a set of logit models of the individual likelihood to be identified as an advisor of at least dissertation in our dataset. This likelihood is obviously affected by the time that a given individual defended her own dissertation, which generates a truncation problem that might bias our results. To limit the potential impact of truncation, we further restrict our sample in that we only consider individuals as potential advisors who completed their own dissertation no later than 1995. Accordingly, the final sample is further reduced to 5,373 doctoral students. Descriptive statistics of the used dataset are reported in Appendix B.

Doctoral students are not randomly matched to their advisors. In general, assortative matching of students and advisors can be expected (Azoulay et al., 2017). Students are often deliberately hired from within their future advisors’ networks (Baruffaldi et al., 2016). We are limited in the extent to which we can control for the bias this introduces in the analysis of advisor effects on students. However, we conjecture that the inherent quality of students, as well as the quality of the match with the doctoral advisor, is reflected by the early success of the student. This can be observed in the number of publications a student produces before completing their doctoral degree. Indeed, as is indicated in Table 6, this variable is strongly correlated with advisor characteristics. We further control for the number of co-authors a student accumulates in their early work, which can also be assumed to reflect the quality of students and their matching with the advisor.

Given substantial correlation between some of the explanatory variables, we first use them separately in individual models and then estimate a full model specification including all variables (Models 1 to 8 in Table 2). All models include a set of time dummies (5-year periods) for graduation years and advisors’ first publications, as well as fixed effects for degree-granting universities. We then repeat the same procedure controlling for student quality (Table 3), and again including advisor fixed effects (Table 4, where the number of observations is reduced to 5,140 because all advisors with only a single dissertation in the dataset and with all-positive outcomes are dropped from the estimation).

The role of advisor embeddedness in the scientific community is captured by three different variables: their presence in the principal component of the publication network ($adv_{maincomp}$), their Bonacich centrality ($adv_{bonacich}$) as well as their degree ($adv_{deg}$). Bonacich centrality is proposed by Ballester et al. (2006) as a suitable measure to identify key actors in networks. It goes back to Bonacich (1987) who used it to assess the power of central players, i.e., those who exert strong influence on surrounding players, by counting all paths to other nodes weighted by decay factor increasing with path length. We use a variation of this measure by only considering other advisors as relevant.\footnote{We also further introduce a cut-off value at a path length higher than 5 for computational reasons, as decay factor we chose $2^{- (k-1)}$ depending on the path length $k$.}
In Table 2 we find support for a positive effect of all three variables on students' likelihood to become advisors themselves (their academic „fertility“, as it were) in Models 1 to 3. In the full model, only advisor presence in the principal component remains statistically significant. Controlling for student quality (Table 3) moreover indicates the importance of selection. While we find that better students (in terms of more early publications; cf. Balsmeier and Pellens (2014)) are more likely to become advisors later on\(^{14}\), the coefficient of membership in the principal component is reduced substantially, and both Bonacich centrality and degree lose all of their explanatory power. In the within-estimator framework of the fixed effects models of Table 4, the role of advisor network membership is further qualified, mostly reflecting imprecise measurement because the respective variables mostly vary in the cross section but less so over time. Accordingly, we find only mixed support for the prediction of Hypothesis 1.

Hypotheses 3 and 4 focus on lifecycle effects, i.e. the question whether experienced/older advisors are more likely to turn out fertile students than less experienced/younger ones. We try to capture lifecycle effects by two variables: the number of dissertations advised prior to that of the focal student (\textit{adv\_prestud}), as well as advisor career age at the time of submission (time lag to their first publication; \textit{adv\_careerage}). Our findings point to negative effects of seniority on student fertility, as the coefficients obtained for both variables are mostly negative and often significantly different from zero. In particular, we find strong negative associations between the seniority measures and students’ likelihood to become advisors in the fixed-effects framework of Table 4, which controls for (time-invariant) advisor characteristics. Further support for this interpretation is provided by the significantly negative coefficient of the number of previous citations in the fixed effects model (Model 4 in Table 4).

Finally we look at the peer effects that were subject of Hypotheses 5a and 5b (\textit{fert\_siblings}). A complex pattern emerges. On the one hand, we find robust evidence suggesting a positive peer impact in Models 7 and 8 of Tables 2 and 3. This is consistent with benefits from working in groups where other students successfully embark on academic careers. On the other hand, in line with our above conjecture that peer quality is not independent of advisor quality, positive peer impact appears to be mostly cross-sectional. In contrast, in the fixed-effects models of Table 4, we obtain an even more pronounced negative association between the fertility of contemporaneous „siblings“ and the focal student’s likelihood to become an advisor herself. This indicates that the competitive effect predicted by Hypothesis 5b dominates.

\(^{14}\)The degree (number of co-authors) of students is generally negative and in some models marginally significant. This suggests that conditional on the number of early publications, having more co-authors is associated with a reduced likelihood to remain active in academia and become an advisor. In models without the publication variable, student degree is positive.

5 Discussion and conclusions

In this paper we presented a novel approach to identify the advisors of doctoral students based on co-publications and machine learning of matching algorithms. This approach enabled us to construct and analyze a large-scale dataset of German doctoral graduates in applied physics and electrical engineering from 1975 to 2005. We analyzed factors associated with the subsequent likelihood of these individuals to become doctoral advisors themselves, i.e. to be „fertile“ as academics and play an active role in the self-reproduction of science. We obtained substantial evidence indicating that advisor seniority is associated with a decreased likelihood of students to become advisors themselves. This finding, which was robust to controlling for student quality and advisor heterogeneity, suggests that finding good advisor early in their career is helpful for the academic career of doctoral students. One interpretation is that younger advisors are more in touch with current developments in their fields, and that this is more important than their academic reputation based on earlier success or their position in the publication network. This interpretation is consistent with the limited importance that we found for advisors’ network embeddedness or citations to their prior work. In addition, our results suggest a relevant role of competition for academic career opportunities among the students co-advised by an advisor at the same time. The dynamics that our results imply are consistent with dynastic relationships in science. However, in contrast to what is argued by Horta et al. (2010), they seem to be more suggestive of meritocratic processes than of navel gazing.

Both the methodological approach to match students and advisors and the specific results on academic „fertility“ are not without limitations. First and perhaps most importantly, we can only match individuals for whom we can co-authored publications in openly accessible databases. This excludes fields and disciplines in which the respective type of publication is uncommon. This holds for large parts of the social sciences and humanities. Second, our approach identifies those individuals as advisors who leave their mark on students in terms of how they conduct research. While we think that these individuals are indeed the key persons in socializing the next generations of scientists, they may differ from those who are officially listed as advisors, e.g., university professors „filling in“ as examiners for researchers lacking the formal qualification to do so. Third, we have so far only considered student-advisor pairs where both parties completed their dissertations at a German university. In an increasingly globalized system, this is an increasingly limiting restriction. It is likewise not clear whether our above findings on the determinants of student „fertility“ are generalizable to other fields and countries. Moreover, while we tried to control for the quality of students and the student-advisor match, a causal interpretation of our results would require randomized matching which is not what we have in our data.

### A Data quality proofs

#### A.1 Web of Science Author Name Disambiguation

Testing the assignment quality of the WoS disambiguation procedure we compare the number of publications attributed to very frequent and rare names.
To get accurate numbers of the name frequencies we use the DNB database on doctoral students. Because foreign names are overrepresented in unique name combinations we consider only doctoral students with German nationality in the two name groups. Doctoral students from abroad might suffer from systematic lower publication records, since they are more likely to leave Germany after graduation. We select 100 most frequent name combinations (surname and first name initial) in the whole DNB dataset (which covers about one million records) and compare these against names which occur only once. The distribution of the publication oeuvres should be equal if our disambiguation procedure applies. Figure 2 compares the two distributions, which indeed appear to be equal. We cannot find a significant difference between the mean number of publications authored by researchers with one of the 100 most frequent names and the ones with very unique names (means: 12.37, 13.36; p-value: 0.72). The median equals 3 for both groups.

![Graph showing density of publications assigned to 100 most frequent (German) names and unique (German) names.]

**Figure 2:** Density of publications assigned to 100 most frequent (German) names and unique (German) names

### A.2 Publication Dissertation Record Linkage

As robustness check of the matching between the dissertation data with the WoS scientists we use the first names, which we could not use in large scale. We
find for 6,466 pairs the full first name given on both sources. By comparing all first names manually finding 257 pairs with different name. This results in an error rate of 3.97% (or 96% correctly matched pairs).

Are Great Researchers Terrible Teachers?
How research and teaching performance relate at U.S. universities

Dakota Murray¹, Huimeng Zhao¹, Vanessa Minik¹, Nicolas Bérubé², Vincent Larivièrè², and Cassidy R. Sugimoto¹

Abstract
University professors engage in a variety of tasks in the domains of research, teaching, and service. There exists an abundance of research exploring a professor’s performance in any one of these domains, yet few have explored how they affect each other. To explore the relationship between a scholar’s research and teaching performance, we merged a dataset provided by the company Academic Analytics, which provides research performance data to U.S. universities, with another dataset collected from the popular teacher-evaluation website Rate My Professor. Using these data, we find that, controlling for all other variables, gender, discipline, age, and class difficulty were strong and significant predictors of professor rating. Differences are found by gender and by discipline, with women with the highest teaching evaluations tending to have the lowest research performance. The average quality scores of men are higher across all the broad disciplinary areas, with a wide gap in Engineering but the smallest in the Medical Sciences. Male professors are also rated as having more difficult classes, except in the humanities. This research is only the beginning of what large-scale quantitative analysis promises to contribute to the understanding of research and teaching performance.

Conference Topic
Science Policy; Research Evaluation; Teaching Assessment

Introduction
Criteria for promotion, tenure, and merit review revolve around three main tasks: research, teaching, and service. However, these categories are not weighted equally: research performance is the most highly weighted factor, followed by teaching and service (Boyer, 1990). It has been suggested that this is a zero-sum game—in which emphasis on one aspect of the professorial life comes at the expense of others. This so-called scarcity model of teaching and research had found evidence of the divergence between teaching and research activities (Lesyte, Enders, & De Boer, 2009). Other scholars have found correlations between research and teaching, demonstrating that active researchers tend to also be good teachers (Halse, Hobson, & Jones, 2007). A third body of research rejects the assumption of any generalizable relationship between teaching and research (Hattie & March, 1996; Figlio & Schapiro, 2017). Despite these exploratory studies, there is no consensus on the relationship between research and teaching in academic institutions. The extant literature suffers from small sample sizes, limited disciplinary diversity, a focus on tenured professors, and other factors that limit the external validity and generalizability of the findings. The present study seeks to address this gap by providing a large-scale study of the relationship between teaching and research at academic institutions in the United States.

There is considerable research on the relationship between demographic characteristics of the faculty, their research, and their teaching performance. Women, for example, tend to be less productive, hold less funding, and receive fewer citations (Larivièrè, Ni, Gingras, Cronin, & Sugimoto 2013; Larivièrè, Vignola-Gagnè, Villeneuve, Gélinas, & Gingras 2011) than their male counterparts. Teaching evaluations can be biased by the gender of both the professor and the student, with women receiving higher evaluations from female
students and lower ratings from male students (Basow, 1995). External factors, such as discipline (Cramer & Alexitch, 2000) and class difficulty can also affect student evaluations. For example, students in the Social Sciences and Humanities tend to rate their professors higher than students in the Sciences (Cramer & Alexitch, 2000). Several studies have examined correlations between the teaching evaluations and professor characteristics. For example, professors belonging to racial minorities are evaluated more negatively than white faculty on the site, and were also rated as holding easier courses (Reid, 2010). Other factors, such as age and attractiveness (Sohr-Preston, Boswell, McCaleb, & Robertson, 2016) as well as industry interactions (Gulbrandsen & Smeby, 2005) also influence the ratings received.

But data on teaching evaluations is limited, since these indicators tend to be held privately by institutions and instructors. One exception is the Rate My Professor (RMP) website, which provides a public mechanism for reporting and analysing teaching evaluations. This site, which allows student to review their instructors anonymously, was released in 1999 and has seen wide use in the United States.

This creates a tangled mess of variables, obscuring the relationship between teaching and research performance. To address this, we analyse the relationship between teaching and research portfolios of nearly 40,000 unique professors in the United States, across the disciplinary spectrum and taking into account demographic information, such as age and gender. This allows the first large-scale exploration of the degree to which research indicators are predictive of teaching evaluations, accounting for differences in the professor’s institution, discipline, age, and gender.

Data and Methods

Four sources of data are aggregated for this study, of which the two most important are 1) the 2014 release of data provided by contract from Academic Analytics (AA2014) and 2) professor ratings and comments sourced from the popular website Rate My Professor. Academic Analytics is a proprietary company that has constructed a database, using public or voluntarily supplied data, of individual professors and publications affiliated with one of more than 385 U.S. universities, and sells access and analysis of this data to university administrators for benchmarking purposes. Rate My Professor (RMP) is a website, popular among college students, that crowd-sources teaching evaluations, allowing (presumed) students to leave comments and rate their teachers along dimensions of helpfulness, clarity, course difficulty, and overall quality.

AA2014 contains information about individual professor’s scholarly performance and research funding between 2010 and 2014, except for number of books, which goes back to 2005, and for awards, which have an indefinite timeline. There are 301,673 total records in AA2014; however, records are duplicated for every department in which a professor holds an affiliation, and as such there are only 163,892 unique individuals represented.

We created a script to aggregate all of the individuals and comments on the Rate My Professor website into a single dataset (RMP). This dataset was collected in early September 2016, and includes profiles of 878,748 individuals, each manually entered by users of the sites, teaching in higher education institutions of all kinds in the U.S., U.K., and Canada. For each rating, a user is asked to rate the professor’s course on various dimensions, leave comments, and add community tags to summarize their experience. At the date of collection, there were a total of 14,735,325 user ratings.

These datasets were merged in order to evaluate the relationship between scientific and teaching indicators. Using the first name, last name, institution, and department of each professor, we matched 50,172 unique professors common to both AA2014 and RMP, comprising 88,980 total records when considering multiple departmental affiliations. Many professors appear in the RMP dataset, but have no ratings, thus leaving 37,202 individuals
after including only those with least one rating. To be consistent with AA2014, we selected only those RMP ratings occurring after 2010 (i.e., 531,359 total ratings) and using these, calculated the mean overall quality, helpfulness, clarity, and easiness for every individual. We also matched institutional names with data from the US News and World Report (USNEWS) and Carnegie Classification of Institutions of Higher Education (CC) datasets, enriching our data. Finally, we superimposed our own simple disciplinary taxonomy over Academic Analytics’ more fine-grained taxonomy. Details about each of the variables in the final aggregated dataset can be found in Table1.

</table>
Limitations

Concerns have been raised about the validity of both RMP and AA2014. It has been shown that the ratings on RMP may differ from formal in-class evaluations (Coladarci & Kornfield, 2007), and that ratings may lack external validity, with students rating a course on their first day, or years after (Davison & Price 2009). There are also entirely fabricated records; for example, RMP includes individuals such as Albus Dumbledore, professor of transfiguration at Hogwarts School of Witchcraft and Wizardry, with 121 student ratings. Despite these issues, there is also research that supports the validity of evaluations on the website (Sonntaga, Bassett & Snyder 2009), and RMP remains the only large-scale publicly available dataset for teaching evaluations. Similarly, the validity of AA2014 has been called into question. However, given the proprietary nature of the data, the allegations have been largely anecdotal. A large-scale validation exercise remains necessary to properly identify the degree of accuracy in both datasets. We acknowledge this as a limitation of the present analysis.

Results and Discussion

A regression was conducted with the mean overall quality rating from RMP as the dependent variable. Controlling for all other variables, research indicators do not demonstrate a strong effect on course evaluation ratings: Conference proceeding count has a small non-significant effect; Article count, while significant at the 0.005 level, has a negligible effect; Citation count have a trivial non-significant positive effect; Grant count has a negligible and non-significant negative effect. Of all the research indicators, having written or contributed to at least one book and having won at least one award have the strongest effects, both positive, yet this effect is still minor and non-significant. These findings reinforce the notion of a non-linear relationship between research and teaching indicators.

a. Dependent Variable: RMP Overall Quality
b. This parameter is set to zero because it is redundant
However, even when controlling for all other variables, the regression did provide evidence that gender, discipline, age, and class difficulty have the strongest effects and are significant predictors of professor rating \( (p < 0.000) \). Course difficulty, followed by gender, has the strongest effect of any variable. Men tend to receive higher ratings than women, and as course difficulty increases, average ratings tend to decrease. Analysing interaction effects among these variables may provide additional insight into the relationship between research and teaching variables. For example, Figure 1 depicts the gendered differences in each of the research indicators, by overall RMP score. As shown, women with the highest teaching evaluations tend to be those with the lowest article and citation counts. However, the inverse is true for male professors.

![Figure 1. Scholarly performance indicators by gender and average overall teaching quality. Brackets signify inclusivity of ratings, and parentheses indicate exclusivity](image)

Disciplinary differences by gender are also apparent, showing large statistically significant effects on teaching ratings. Although the average quality scores for men are higher across all the broad disciplinary areas, the gap is much smaller in the Medical Sciences and highest in Engineering. Furthermore, male professors are also rated as having more difficult courses, on average, with the exception of the Humanities—where female professors receive a higher average rating.
Conclusion
This paper begins to explore the various relationships between teaching and research, taking into account characteristics of the professor and institution. The regression suggests a non-linear relationship between research and teaching indicators. It also reveals that gender, discipline, age of professor, and course difficulty strong predictors of teaching evaluation ratings. Further analysis is necessary to more fully understand the complicated relationship when examining teaching and research indicators by gender and discipline. This aggregated dataset provides a useful and large-scale approach to begin analysing these questions.

Research or management? An investigation of the impact of administrative roles on the research performance of academic administrators

Yuehua Zhao¹ Wen Lou²* Yuchen Chen²
¹ yuehua@uwm.edu University of Wisconsin-Milwaukee (United States)
² wlou@infor.ecnu.edu.cn, 893781834@qq.com East China Normal University (China)

Abstract
The present study aims to investigate whether the research performance of academic administrators has been affected by their administrative services in a quantitative way. We sampled 116 academic administrators from 26 universities. Statistical methods were applied to compare the research performance of the sampled administrators before and after they accepted the administrative roles. The results suggest that administrative services have strongly affected academic leaders’ research performance. The extent of such impact varies in different disciplines. The impact appears to be higher on administrators serving in higher-ranking universities. In addition, the research outputs of both university presidents and department deans have been substantially influenced by the administrative services, whereas the impact on the university presidents is slightly stronger than on the department deans.

Conference Topic
The application of informetrics on evaluation; Science policy and research assessment

Introduction
It has become more and more common worldwide that after years of excellent teaching and research services in a university, a faculty would serve as a department or school leaders (Carroll, 1991). Besides the administrative affairs based on the establishment, monitoring, and modification of programs and curricula, staff matters, and student affairs (Boyko & Jones, 2010), the leaders are involved with scientific research and represent the top research level of schools and departments. The time management to balance administrative roles and research has caught the attention of higher education managers (Magana & Niebel, 1976). Investigation on job satisfaction in universities claimed that deans and chairs reported feeling overwhelmed at their job every day (Morris & Laipple, 2015). They believed it resulted from the lack of full preparation for the administrative roles because their career paths were only formed by years of scientific research (Amundsen & Martinsen, 2014). Therefore, we wonder whether their research productivity has been affected by administrative roles.

The relationship between research performance and administrative roles of university professors has been discussed in a few studies. Gu et al. (2014) compared the publications of 18 presidents from six universities on the period of both service and retiring and found that presidents in the US had been barely influenced by presidency service in terms of the research performance. Their study is quite close to our aiming but limited to the small objects and inadequate of statistical tests. García-Gallego et al. (2015) conducted a comparison analysis on the impact of research and administrative duties on teaching performance. On the contrary, more studies discussed the influences of university leaderships that can bring to staff management (Sheikha & Younis, 2006; Siddique et al., 2011) and the quality of teaching and learning (Hammond, 1999; Nkanata, 2013).

In summary, there were few empirical studies conducted on research performance of academic leaders. In this study, academic administrators refer to individuals who serve as leadership and
management roles within the university systems worldwide. Our aim is to explore, by answering the following four questions, how the administrative role as a university president or a department dean affects one’s research performance as a researcher.

RQ1. Do administrative services affect academic administrators’ research works?
RQ2. Does the impact of administrative roles on administrators’ research performance differ among different disciplines?
RQ3. Does the impact of administrative roles on administrators’ research performance differ among universities in different ranking levels?
RQ4. Does the impact on administrators’ research performance differ among different administrative roles?

Method

Sampling strategy
At first, 29 universities were selected based on 2017 Best Global Universities Rankings established by the U.S. News & World Report, whose rankings are at 1 to 10, 51 to 60, and 101 to 110. To explore the differences among different disciplines, we attempted to select six types of schools and departments, including art and humanities, psychology, law, business and management, engineering, and medical. We looked into the official website of every university to ensure these departments exist in the university. It appeared that the most common departments are Art, Business and Management, Engineering, and Medical. Besides that, the following two universities were excluded due to the lack of most of the departments. California Institute of Technology only has business and engineering schools, and Mount Sinai School of Medicine only has the medical department. Therefore, 27 universities with their presidents and four types of academics were selected for the next step.

To compare the administrative roles’ influence from different duties, the president of each university and the dean of each school or department were both collected. Firstly, and easily, we collected the name of every university president. Secondly, we looked through, in turn, the faculties, schools, and departments’ leaders, since some universities have mixed administrative structure. For instance, if a university has both Faculty of arts and humanities and School of Arts, we selected the leader of Faculty of arts and humanities. Thirdly, the leadership of schools or departments contains many different titles, such as chairperson, director, dean, research dean, and so on. We selected the most important leaders to guarantee there would be only one leader in each school or department. Interim leaders were selected only if a university or department had no official announced leaders yet. Additionally, University of Munich was excluded since we could not get more information of leaders due to the access of website and language issue. So far, 130 administrators were chosen in total.

Data collection
The very first information that we need to consider is which year these leaders were announced as the administrative roles. We collected the exact year from looking through those leaders’ CVs and LinkedIn pages, and university news and welcome letters on the websites if their profiles did not mention the year. Meantime, their career paths were recorded in the documents including every affiliation they have been as doctoral students or professors, which enabled us to identify their affiliations in Web of Science databases (WOS).

Full records of documents that published by sampled leaders were downloaded from WOS core collection. Data collection were conducted during January 31st to March 27th, 2017. We paid more attention to author addresses and research domains and areas to identify every leader due to the duplicated names and flaws of author identifier. Considering the different publication styles in different disciplines, comments, reviews, and other types of documents were all included in this paper. In the end, 116 leaders with publications will be discussed in the following sections since there were no publications of 14 leaders in WOS.
We measured the publication counts of each sampled leader during the following three periods: the pre-position period, the reference period, and the in-position period. The pre-position period means the years from when a leader published his or her first paper until the year he or she became the leader. The in-position period represents the years that a leader has been holding the position since the year he or she was announced to be the leader until the day we collected data. The reference period is inspired by the idea of Impact Factor. It balances the different periods of in-position and pre-position by limiting the time length of the pre-position period to make the length of time the same as the in-position period. For example, Michael D. Smith has been the dean of Harvard Faculty of Arts and Sciences for ten years since 2007. Then the number of publications during his reference period was counted from 1997 to 2006, which is the same length of time of his occupation. In addition, we excluded the publications published in the year that a faculty member became the administrator since we could not separate publications in this year from either pre-position period or in-position period.

Data analysis

To answer the above research questions, we adopted statistical methods to investigate the impact of administrative roles on administrators’ research performance in terms of the numbers of publications. The following null hypotheses were proposed and tested in the study.

H01: There is no significant difference between administrators’ research performance during the reference period and the in-position period.

H02: There are no significant differences among the four disciplines in terms of the impact of the administrative roles on the performance of academic administrators.

H03: There is no significant difference among the three levels of the university ranking in terms of the impact of the administrative roles on the performance of academic administrators.

H04: There is no significant difference between the two administrative roles in terms of the impact of the administrative roles on the performance of academic administrators.

The parametric tests (e.g. t-tests, analysis of variance) make assumptions about the shape of the population distribution (e.g. normally distributed), while non-parametric techniques do not include assumptions about the underlying population distribution (Pallant, 2013). Therefore, in this study, a series of non-parametric tests (e.g. Wilcoxon signed-rank test, Kruskal-Wallis H test) were performed to examine the null hypotheses. The significance level (α) for all tests is equal to 0.05. If the resultant p-value of a null hypothesis test is smaller than 0.05, the null hypothesis is rejected. Otherwise, the null hypothesis fails to be rejected. In the Kruskal-Wallis H test, the result includes both χ²-value and p-value. The χ²-value is presented as χ²(df, n). Here df stands for the degrees of freedom, and n stands for the sample size. Effect size indicates the influence of the independent variable (Pallant, 2013). In this study, the effect size statistics was reported as the r-value, and the median was reported as the Md value. We adopted the difference between the number of publications during the reference period and the in-position period to measure the impact of administrative services on faculty members’ research performance.

Results and Discussion

An overview

In total, we sampled 116 academic administrators, including 94 department deans and 22 university presidents, from 26 universities. The distribution of the publications in different time spans is displayed in Figure 1 where the X-axis represents each leader, and the Y-axis is the number of papers they published. The three lines, separately, indicate the number of publications yielded during the three periods: the pre-position period, the reference period, and the in-position period. In Figure 1, the pre-position publications outnumbered the in-position publications substantially. Therefore, we also calculated the papers published during the same
length of time they spent in the position before their posts to avoid the bias of time span. Given the consideration of the time spent, the decline of the research outputs was still evident.

Figure 1. Distributions of research performance of administrators during different periods

The Wilcoxon signed-rank test (also referred to the Wilcoxon matched pairs signed ranks test) is designed for the repeated measures (Pallant, 2013), and thus it was used to the to examine the hypothesis \( H01 \). The test results demonstrated that there was a significant difference between administrators’ research performance during the reference period and the in-position period \((z=-8.087, p=0.00<0.05)\). The resultant effect size \( r \) was 0.531, indicating a large effect size using Cohen’s (1988) criteria of 0.1=small effect, 0.3=medium effect, 0.5=large effect (Pallant, 2013). It suggests that administrative services significantly affect academic administrators’ research works.

Before performing the administrative services, on average, each leader yielded 111 publications. The average number of publications dropped down to six during their services. Among the investigated administrators, 114 out of 116 (98.3%) administrators performed better before the posts. On average, people published 105 more papers before they became the administrators. Considering the length of time, there are still 108 leaders produced more papers during the reference period. The average decline appeared to be 18 papers. It showed that most of the faculties were highly productive before accepting the administrator positions, but their research productivities were apparently affected by the administrative services.

Comparison among disciplines

In this study, the dependent variable for the Kruskal-Wallis H test was the difference between the number of publications during the reference period and the in-position period. The independent variable was the four defined disciplines: Art, Business and Management, Engineering, and Medical. The results of the Kruskal-Wallis H test revealed that there were statistically significant differences among the four defined disciplines in terms of the impact of the administrative roles on the research performance of academic administrators \( (\chi^2(3, n = 94) = 18.224, p = 0.000 < 0.05) \). In other words, hypothesis \( H02 \) was rejected. It suggested that the impact of the administrative services on faculty members’ research outputs were different.

To find out which of the disciplines were statistically significantly different from one another, a Dunn-Bonferroni test between pairs of disciplines (e.g. between art and medical) were carried out as the post-hoc test. As a result, there were very strong evidences of differences between the following pairs of disciplines: Art \( (Md=0) \) vs. Engineer \( (Md=8) \) with an effect size \( r=0.467 \), Art \( (Md=0) \) vs. Medical \( (Md=10) \) with an effect size \( r=0.531 \) and Business/Management \( (Md =1) \) vs. Medical \( (Md =10) \) with an effect size \( r=0.407 \). There was no evidence of a difference
between the other pairs. Figure 2 describes the distribution of the publication counts of administrators in the four disciplines during the three defined periods. The decline in the number of publications was more obvious in the medical field than in other three fields, whereas the impact resulted in the smallest changes in the art field.

Figure 2. Comparison of the impact on administrators in different disciplines

Comparison between universities in different ranking levels
Hypothesis H03 was tested by a Kruskal-Wallis test. The independent variable was the ranking levels of the universities. We classified the universities into three ranking levels according to their rankings on the U.S. News & World Report. For example, universities that were ranked at top one to ten were considered as universities at the first ranking level. The Kruskal-Wallis H test revealed the statistically non-significant differences in the impact of the administrative roles on the research performance of academic administrators across the three ranking levels ($\chi^2(2, n = 116) = 2.352, p = 0.309 > 0.05$). The resultant effect size $r$ was 0.218, indicating a small to medium effect size using Cohen’s (1988) criteria (Pallant, 2013). Administrators from the higher-ranking universities (i.e. ranking 1 to 10) recorded a higher median score ($Md=11$) than administrators from universities in other two ranking levels, which both recorded median values of 4. As displayed in Figure 3, the total number of publications produced by universities at all three ranking levels substantially decreased during the in-position period.

Figure 3. Comparison of the impact on administrators working in universities at different ranking levels

Comparison between different administrative roles
Considering the administrative role as a factor, a Mann-Whitney U test was performed to examine the differences between department deans and university presidents. The results showed no significant difference in the impact of the administrative roles on the research performance of the department deans and the university presidents ($U=954.5$, $z=-0.561,$
$p=0.575$. The resultant effect size $r$ equalled to 0.052, which would be considered a very small effect size using Cohen’s (1988) criteria. It suggested the impact of administrative services on department deans and university presidents were both massive (as shown in Figure 4) but not significantly different. The median impact of the administrative roles on the university presidents’ research productions was 4.5 compared to 2 on the department deans.

![Figure 4. Comparison of the impact on administrators serving different roles](image)

**Conclusion**

Academic administrators are central to the development of higher education. As a serial of demanding, stressful, and time-intensive positions, previous qualitative studies suggested that management positions have various negative effects on one’s personal life and professional career (Werkema, 2009). The present study has used statistical analysis to examine the impact of administrative roles on the research performance of academic administrators in a quantitative way. It has demonstrated that the administrative services significantly influenced faculty members’ research outputs. As for different disciplines, administrators in the medical field are affected more heavily by their management roles. Such impact appears to be larger on administrators who serve in the higher-ranking universities. Both university presidents and department deans are substantially influenced by the administrative services, while the impact on the university presidents is slightly stronger than on the department deans.

The above results are limited by the population sampled and may not be applicable to all academic institute settings. This study currently relies on the publication counts to measure the research performance of faculty members. Future research including the measurement of academic presentations and research impact may corroborate these findings. In addition, a more detailed comparison will be presented as well, such as the research performance considering the order of authors.

Authorship, inventorship and division of labor in innovative research: an analysis of paper-patent pairs

Philippe Mongeon
philippe.mongeon@umontreal.ca

Observatoire des sciences et des technologies (OST), Centre interuniversitaire de recherche sur la science et la
technologie (CIRST), Montréal (Canada)

Abstract
Collaboration has long become the norm in science, and research is performed by increasingly large teams. Collaboration can take diverse forms, bring together researchers from different fields, status, and skills, and may lead to different patterns of tasks division between team members. This complicates the attribution of credit to individual authors, undermines research evaluation processes, and potentially reduces the efficacy of the reward system of science. This work in progress investigates division of labor and among team members using discoveries that were disclosed in both a patent and a paper, both document thus forming a paper-patent pair (PPP). Since the inventor status on a patent is attributed, in principle, for specific types of contribution (namely, those of a conceptual nature), comparing authors and inventors lists of PPPs can provide new insights on the division of labor and credit attribution practices in scientific research. This work analyzes the relationship between the author and inventor lists of 1,568 PPPs from five disciplines. We find that the individuals who are both authors and inventors are polarized towards the first and last author position. However, there appears to be disciplinary differences in the distribution of inventors in the various positions of the authors list.

Conference Topic
Collaboration and division of labor
Authorship
Inventorship
Paper-patent pairs

Introduction
Science is increasingly collaborative (Wuchty, Jones, & Uzzi, 2007), which leads to an increase in the number of authors of scientific papers. The longer author list, but the diverse types of collaboration (Maienschein, 1993), team compositions (Smith, 1971), and ways tasks are divided among team members (Larivière et al., 2016) makes the attribution of credit and responsibility to individuals an increasingly complex task (Rennie, Yank, & Emanuel, 1997). This is especially true for authors who are in the middle of the list (Bennett & Taylor, 2003; Shapiro, Wenger, & Shapiro, 1994). In this context, it is very difficult to deduct the type and extent of individual authors’ contribution based on their position in the byline. This is problematic for researchers whose career advancement largely depends on the credit they obtain for their work (Birnholtz, 2006; Cronin, 1996). It also undermines the efficiency of the reward system of science which requires that the best researchers be properly identified and rewarded (Merton, 1957). The importance of these issues has led to many studies that investigated authorship practices, or more specifically the relationship between individual contribution and authorship using different datasets and using both quantitative and qualitative methods.

Research in some disciplines may sometimes lead to technological innovations for which the researchers may choose to file a patent application. Patents are sometimes used as indicators of the usefulness or the inventiveness of research (Meyer, 2003), and because patenting is often highly valued in research evaluations, inventorship becomes, like authorship, a way for researchers to build a reputation and advance their career (Desrochers et al., in press). The
resulting paper-patent pair (PPP) can be a useful tool to analyze the type and substantiality of the tasks performed by the individual authors, and on credit attribution practices within research groups. The value of PPPs for investigating authorship practices lies in the fact that publishing and patenting operate in different realms and come with their distinct sets of rules and norms (Packer & Webster, 1996). For example, not all publishable research findings are patentable, and vice-versa. Similarly, contributions typically rewarded with authorship (e.g., technical contributions, data collection, drafting of the manuscript) are often not sufficient to be named inventor on a patent (Haeussler & Sauermann, 2013). Indeed, to be inventor, one must have conceived the invention (In re Hardee, 223 USPQ 1122, 1123; Comm’r Pat. 1984). Also, formulating desired outcomes is not sufficient: the inventor must have developed a non-obvious and concrete solution (Ex parte Smernoff, 215 USPQ 545, 547; Bd. App. 1982). In this context, comparing the inventor list and the author list of a patent and a paper that report the same discovery may indicate which of the authors have performed the conceptual work, and which have performed the technical work or other types of task that do not, in principle, lead to inventorship.

A few previous studies analyzed the difference between the inventors and authors list of PPPs. Looking at a set of 40 PPPs, Ducor (2000) found that the first and last authors were more likely than middle authors to be named inventors. He also found that last authors were more often listed as inventors than first authors. Using survey data from 2000 life scientists who self-reported having both published and patented a research finding, Haeussler and Sauermann (2013) found that contributions that are conceptual in nature are strong predictors of both authorship and inventorship, but that other types of contributions lead to authorship but not necessarily to inventorship. They also found that past scientific accomplishments is a predictor of authorship and that hierarchical position is a predictor of inventorship, but not authorship. Our study complements the previous research by identifying PPPs using worldwide paper and patent data covering all discipline for a large-scale comparison of authorship and inventorship practices. We analyze the relationship individual researchers’ position in the author list and their inclusion in the inventors list of the associated patent. More specifically, the present paper provides answers to the following research questions:

**RQ1.** What is the difference between the average number of authors and number of inventors?

**RQ2.** What is the relationship between the position in the authors’ list and the probability of also being listed as an inventor on the patent?

While these two questions are the focus of the preliminary results presented in this paper, they will be complemented by the following third research question in further steps of the study:

**RQ3.** What is the relationship between the authors’ characteristics, such as academic age, gender, productivity and scientific impact on the probability of also being listed as an inventor on the patent?

**Data and methods**

We collected all patent applications filed between 2001 and 2013 at the United States Patents and Trademark Office, and all articles published between 2000 and 2015 and indexed in Clarivate Analytics’ Web of Science (WoS). The articles published before 2000 are not considered since under the United States patent law, inventions published more than 12 months prior to the patent application are considered to be part of the public domain and are therefore
not patentable. Also, only articles for which the abstract is available were included, as the abstract is used for the pairing of the papers and patents.

To form PPPs, we first paired all articles and patents with at least one author-inventor match, based on the last name and first initial, which yielded more than 20 million potential pairs. Then, similarly to previous work by Magerman, Van Looy and Debackere (2015), we measured the content similarity between the articles (title and abstract) and patents (title and description). The difference between our method and that of Magerman et al. (2015) is that we used noun phrases instead of words to calculate the similarity between each PPPs. For both documents forming a potential pair, we divide the number of matching noun phrases by the total number of noun phrases in the title and abstract. The average of these two values is the similarity score of the pair.

To validate the matched pair, we manually verified all cases where the first name of the author was available in the WoS record. A match is considered a true positive when the first name of the author matches the first name of the inventor. The results of this validation are presented in Table 1.

</table>

We see that very few false positives occurred for PPPs with a similarity score of 0.40 or above (less than 1% overall), while 24.4% and 39.8% of author-inventor matches were false positives at a 0.30-0.39 and 0.20-0.30 similarity ranges, respectively. Therefore, we chose to limit the following analysis to all PPPs with a similarity of 0.40 or above, including those for which the full names of the authors were not available. We manually verified each PPP to ensure that no false negative remained in the author-inventor matching, and then excluded from the analysis all PPPs for which at least one inventor is not in the authors list to ensure that all contributors are included in the analysis. When multiple patent matched with a single paper, two criteria were used to select a single best matching patent: 1) we kept the pair with the highest number of authors who are also inventors on the patent, and 2) we keep the PPPs with the highest similarity score. We also limited the analysis to articles with 2 or more authors since the goal is to analyze division of labor and credit attribution among team members. One outlier, a paper with 161 authors, was also excluded from the analysis. The final dataset comprises 1,568 PPPs from five disciplines (see Table 2 in the result section).

Results

Table 2 presents the number of PPPs found for each discipline, the average number of authors, the average number of inventors, and the average inventors/authors ratio. Note that a small number PPPs were found in some of the fields not figuring in table 2 (e.g., Biology, Professional
Fields and Earth and Space). We excluded these PPPs from the analysis because their number was too small. Engineering and Technology, perhaps unsurprisingly, is the discipline with the most PPPs (N= 522) while the number of PPPs found for other disciplines ranges between 229 in Clinical Medicine to 279 in Biomedical Research. The results show that the average number of authors varies more between disciplines than the average number of inventors. Thus, the inventors/authors ratio ranges from 47.2% in Clinical Medicine, to 81.3% in Engineering and Technology, which suggests that important disciplinary differences exists in terms of authorship practices and division of labor among members of the research teams.

We now investigate the relationship between an individual’s position in the author list and the likelihood also being listed as an inventor on the patent. If we divide the authors into three groups (first authors, middle authors, and last authors), we see that the inventors/authors ratio is smaller for middle authors than for first and last authors in all disciplines (Figure 1). We also observe that neither the first, or last authors are systematically listed as inventors on the matching patents. Moreover, last authors are most likely to be inventors than first authors in Biomedical Research, Clinical Medicine and Chemistry (although the difference seems negligible in the case of Chemistry), while in the first authors are more likely than last authors to be inventors in Physics and in Engineering and Technology.

![Figure 1. Inventors/authors ratio for first, middle and last authors](image)

As we have previously discussed in previous research (Mongeon, Smith, Joyal, & Larivière, 2016), the first author/middle author(s)/last author division of the byline does not adequately reflect the division of tasks among team members. The authors who are closer to the first and last position have typically contributed more substantially to the work than those listed further in the middle. Thus, Figure 2 displays the inventors/authors ratio as a function of the number...
of position separating authors from the first or last position. For articles with an odd number of authors, the middle author is duplicated and included in both the left and right side of the middle. For example, the third author of an article with five authors is included in both the “2 to first” and “2 to last” groups. The figure shows that the further an author is from the first and last positions, the least likely he or she is to appear as an inventor on the patent. We also see that in Chemistry, Engineering and Technology, and Physics the inventors/authors ratio tends to remain higher than in Biomedical Research and Clinical Medicine as we move further away from the first and last positions.

Note: the “middle” category includes all authors who are five positions or more (up to 14) away from the first or last position.

Figure 2. Inventors/authors ratio as a function of the number of position separating authors from the first or last position in the byline.

Discussion and conclusion

Our preliminary results display both similarities and differences between disciplines regarding the relationship between authorship and inventorship. Like Ducor (2000), we find that the first and last authors are more likely to appear in the inventors list in all discipline. This is in line with the previous finding that the first and last positions are the most important, and that middle authors have most likely made less substantial or technical contributions (Pontille, 2006).

In Biomedical Research and Clinical Medicine, the last authors are more often inventors than the first authors. Since the last author position is a senior scientist with a supervisory role and the first author is usually a junior scientist leading the experimental work (Pontille, 2006), this seems to confirm Haeussler and Sauermann’s (2013) finding that hierarchical position predicts inventorship. Interestingly, we find the opposite trend in Engineering and Technology and in Physics. This suggests either that 1) hierarchical position is a weaker predictor of inventorship in these fields, 2) that the author order in these field does not strictly follow the pattern described by Pontille (2006), or 3) that different patterns of division of labor are at play. This last hypothesis is also supported by the fact that middle authors are also more likely to be inventors in Engineering and Technology and Physics than in Biomedical Research and Clinical
Medicine. Chemistry appears to be somewhat in the middle, since the inventors/authors ratio is slightly higher for last authors compared to first authors. This ratio is also higher for middle authors in Chemistry than in Biomedical Research and Clinical Medicine, but lower than in Engineering and Technology and Physics. Further work will be needed to better understand these disciplinary differences.

Further developments of this research include the extension of the analysis to include data over a longer period. This will provide insights on the evolution over time of the authorship and inventorship practices across disciplines. The number of PPPs analyzed might also be further increased by manually identifying valid pairs for which the similarity score is below 0.40. Furthermore, the next step of the study will include contribution data when available, which will allow the comparison of the reported contribution with the information provided by the inventors list. Finally, researchers’ characteristics, such as the academic age, prominence (scientific output and impact), and gender will be included in the analysis to measure their potential effect on the patterns observed.

Acknowledgments

The author would like to thank Nees Jan van Eck from the Centre for Science and Technology Studies (CWTS) for the extraction of noun phrases from patents and publications. This research was funded by the Social Sciences and Humanities Research Council of Canada and by the Canada Research Chair on the Transformations of Scholarly Communication.

Abstract
To position library and information science in the field of reading research, and to find the direction for endeavor, as well as support of theoretical and research methods, papers published between 2010 and 2016 in 6 journals on reading research in Journal Citation Reports (JCR) are collected and analyzed by means of CiteSpaceⅢ. The important authors, core journals, the main institutions and countries, research hotspots, research fronts and knowledge base, and pivotal documents in the field of reading research are identified. It is found that people of education and educational psychology have developed abundant theoretical and empirical studies, methods for tests and experiments, standards for assessment and instruction, as well as theories and tools developed. It is suggested that people of library and information science should forwardly seek opportunities to cooperate with reading experts and practitioners of education and educational psychology, and to expand their territory not only by applying theories and methods of reading research to practice, but also by actively engaging in study so as to offer better understanding about people’s reading behavior, enrich the content in this field, and to do more personalized reading guidance.

Conference Topic
Reading guidance; reading promotion; reading research; position of library and information science in reading research; CiteSpaceⅢ

Introduction
With the development of economy, science and technology, the overall national strength of China has greatly enhanced. Both the society and the government begin to attach importance to civil quality, and reading has been regarded the essential approach to improve citizen’s quality. Library Society of China released a declaration of library service in 2008 and claims that reading promotion is the basic goal of library service (Library Society of China (2008). However, although reading promotion has become mainstream library service in China, there is a lack of reading research (Fan, 2014).

On the other hand, reading environment has changed tremendously and people’s reading behavior has been changing accordingly. Increasing amount of time is spent on electronic documents and a screen-based reading behavior is emerging. More time spent on browsing and scanning, keyword spotting, one-time reading, non-linear reading, and people are reading more selectively, while less time is spend on in-depth reading and concentrated reading. Daily reading has become digital reading. (Fan 2014; Liu, 2005; Sharmin, Spakov & Raiha, 2015; Li, Guo, Chen & Luo, 2015; Kurata, Ishita, Miyata & Minami, 2017).

In this situation, it is necessary to figure out the big picture of reading research in a whole, so as to properly position library and information science (LIS hereafter) in this field and do
something to solve problems confronting both China and the field as well. However, reading is a research topic of long history, and there are an immense number of documents in this field. So Citesepe has been used to do data mining and visualization on reading research. For example, Yu and Mu (2011) analyzed reading research in China, Liu and Hua (2012) investigated children reading research, Feng and Qiao (2013) tried to find the hot keywords in reading research, Wei (2015) studied digital reading, Wang & Yuan (2016) inspected eye movements studies of reading behavior, Wu, Li and He (2017) made a comprehensive perspective on reading research in recent 10 years with data from SSCI/A&HCI/SCI-EXPANDED and CNKI core journals.

Usually there are specialized journals in any research field, and papers published in these journals always can reveal the development, changes, hotspots and fronts of the field. Up to now no such analysis has been done on journals of reading research, so this study will take journals in JCR (Journal Citation Reports) as data source and use CiteSpace as a tool, trying to dig deeper and find out more about this field as reference for LIS.

Data and methods

There are 6 journals on reading research in JCR in 2015, which are all indexed by citation database SSCI. Table 1 shows the basic information about these journals.

As the data of Reading & Writing Quarterly appears in SSCI as late as 2010, so set time range from 2010 to 2016, and take the titles of the 6 journal as search terms and search it in “title of publication” field in Web of Science, getting 192, 162, 503, 190, 618, 143 items from each journal respectively, 1808 items in total. The retrieval date is April 6, 2017. CiteSpace III 4.0.R5 was used to analyze these data. Due to limited space, co-citation network maps will not be included, and the results will be demonstrated in tables.

Results analysis

Institutions and countries

Choose “country” for “network node”, keep the other parameters unchanged, run CiteSpace III, and a national and regional co-citation network map comes out. Sorting the results by centrality, one can get the top 10 countries, as shown in Table 2. There are 6 countries with a
centrality bigger than 0.1 with USA as the leader. USA also has the largest publications. Though the publications of England, Germany, Australia, Spain and Netherlands are not very high, they have high quality. In CiteSpace, centrality means betweenness centrality.

Influential authors

In CiteSpace III, select “Cited-Author” for “network node”, “title/abstractdescriptor /identifiers” for “Term Source”, choose “pathfinder” as the path search algorithm, set data extraction object as top 30, select the default threshold value, and choose “Burst Terms” for “Term Type”. Set “Time Scaling” for “2010-2016”, and set time partition as “1” year for each partition. Run CiteSpace III and get the author analysis map. Sorting the results by centrality, one can get the top 10 authors as listed in Table 4. There are 7 authors with a centrality bigger than 0.1. These authors are basically from fields of education and psychology. For example, Catherine McBride-Chang is a professor of developmental psychology at Chinese University.
of Hong Kong specializing in the acquisition of early literacy skills. Marilyn Jager Adams is a specialist in cognition and education, and she has developed a software using automated speech recognition to support learning to read. Charles Perfetti is the director of the Learning and Research Development Center at the University of Pittsburgh, and his research is centered on the cognitive science of language and reading processes, trying to develop a richer understanding of how language is processed in the brain.

The journals are from psychology, cognitive science, education and learning science, brain science, as well as reading studies. There are only 4 journals with a centrality bigger than 0.1, however half are journals specialized on reading, i.e., *Reading Research Quarterly*, and *Reading and Writing*. 
Research hotspots

Select “Keyword” for “network node”, keep the other parameters unchanged, run CiteSpace III, a hotspot co-citation network map composed of keywords appears. List the results by centrality and citation frequency of keywords in descending order. Top 10 keywords are listed in Table 6 and there are 6 with a centrality bigger than 0.1. Children and comprehension take the top 2 positions. Dyslexia is always one of the hot topics of brain science and educational psychology.

It’s easy to find out from the table that hotspot keywords in this field are all basic keywords in the field of reading research. From Table 1 one can see that the directions of these 6 journals are education & educational research, and psychology. This means that most scholars publish paper in these journals usually have a background of education and psychology, so they study the basic problems in reading from its’ own perspective.

<table>

Cluster Analysis on Keywords

After the hotspot co-citation network map is formed, select “find cluster” to do cluster analysis, and then choose “label clusters with title terms” to name each cluster. Set the threshold value of 50 and run cluster analysis on keywords. The value of M (modularity) is 0.4612, all the value of Silhouette are bigger than 0.5, and this means that the clustering result is quite good. Clustering results on keywords are listed in Table 7. In CiteSpace III, Silhouette is an indicator reflecting the homogeneity of members in the same cluster; the bigger the value, the higher the homogeneity, and the better the clustering results.

<table>
<thead>
<tr>
<th>Cluster ID</th>
<th>Size</th>

</tr>
<tr>
<td>#2 Bilingual Children</td>
<td>26</td>
<td>0.561</td>
<td>2010</td>
<td>reading comprehension; relationship; visual-word recognition</td>
</tr>
</tbody>
</table>

There are 3 clusters, i.e., common core, oral reading prosody and bilingual children. Common Core is a set of high-quality academic standards in mathematics and English language...
In cluster analysis, citing documents of high coverage reflect the research front, and cited documents with high centrality embody the knowledge base. In CiteSpace III, coverage means the percentage of documents in one cluster that the citing document cited. For example, if document A cites 15% of documents in cluster #1, then there will be a “0.15” in front of the title of document A, and the coverage of document A is 0.15. To understand the research front of this field, citing documents with a coverage bigger than 0.25 in cluster #0 are listed in Table 8. The document with the biggest coverage is about using smartphones to supplement classroom reading, reflecting the characteristic of mobile reading. Other documents are about guided reading, brain movies, independent reading, differentiated instruction, picturebooks, visual representations, common core, self-questioning, literature of modern family and reading in elementary school, of which some are new topic, and some are basic problems with new point of view of this time.

From Table 9 one can see the knowledge base of reading research, in which comprehension, vocabulary, strategy, acquisition, children, skill, method, developmental dyslexia are fundamental problems.

**Pivotal Documents**

In co-citation network map, the node documents with big centrality are often considered key documents that play the role of “pivotal point” in the development of domain knowledge (Chen, 2004, 2006). In CiteSpace III, select “cited reference” for “network node”, keep the other parameters unchanged, run CiteSpace III, the document co-citation network map will appear. Sort the results by descending order and list the documents with a centrality no less than 0.1, one can get the 10 pivotal documents, as showed in Table 10.

These pivotal documents are mostly published around 2005-2008, the newest appears in 2011. Perfetti is famous for his research in reading ability, and this literature review is based on his Distinguished Research Award addressed to the Society for the Scientific Study of Reading in 2006. According to lexical quality hypothesis (LQH), variation in the quality of word representations has consequences for reading skill, including comprehension. High lexical quality allows for rapid and reliable meaning retrieval, and low-quality representations lead to specific word-related problems in comprehension. In the first paper, Perfetti (2007) reviews 6 lines of research on adult readers which demonstrate some of the implications of the LQH and provide evidence that word-level knowledge has consequences for word meaning processes in comprehension.

The Simple View of Reading claims that reading comprehension is the product of two processes: word recognition and linguistic comprehension. Word recognition refers to the ability to read printed words without the aid of context, and linguistic comprehension refers to the ability to understand language. In the 2nd paper, Adlof, Catts, & Little (2006) reported their experimental study which examined the independent contribution of fluency to reading comprehension, and investigated whether a separate fluency component should be added to the Simple View of Reading. Reading and language measures were administered to 604 children in 2nd, 4th, and 8th grades. Results from both large group structural equation modeling analyses and individual profile analyses indicate that fluency does not independently contribute to reading comprehension, so the Simple View of Reading does not need to be modified to include a separate fluency component.

In the 3rd paper Share (2008) systematically critique current reading research and practice which have confined reading science to Anglocentric research agenda addressing theoretical and applied issues with limited relevance for a universal science of reading.

</tbody>
</table>
In the 4th paper, based on review of the rich cross-language database concerning phonological development, reading development, and dyslexia, Ziegler & Goswami (2005) proposed a psycholinguistic grain size theory of reading and its development, trying to integrate these cross-language data into a theoretical framework for describing reading acquisition, skilled reading, and dyslexia in different language.

The 5th paper examines the effectiveness of writing as a tool for improving students’ reading. Graham & Hebert (2011) collected 752 documents on this topic of which 95 experiments met their inclusion criteria. By meta-analysis of these true and quasi-experiments, they present evidence that writing about material read improves students’ comprehension of it; that teaching students how to write improves their reading comprehension, reading fluency, and word reading; and that increasing how much students write enhances their reading comprehension. Their findings provide empirical support for long-standing beliefs about the power of writing to facilitate reading.

In the 6th paper Kirby & Savage (2008) review the Simple View of Reading model and examine its nature, applicability and validity. After systematic review on related studies, they conclude that the model serves as an abstract framework for understand the relationship between global linguistic comprehension and word-reading abilities in reading comprehension, however it is neither a full theory of reading nor a blueprint for instruction. They indicate several areas in which the model is incomplete or in need of further empirical support, i.e., the way word decoding is conceptualized, the way reading comprehension is measured, reading comprehension strategies, the role of reading fluency, reading with illustrations and second-language reading.

Aiming at the relatively narrow definition of reading fluency, which emphasized automatic word recognition, in the 7th paper, after reviewing multiple ways of conceptualizing reading fluency, Kuhn, Schwanenflugel, and Meisinger (2010) propose a definition to expand this understanding by synthesizing several key aspects of research on reading fluency, especially automaticity and prosody, so as to develop assessments and instruction to facilitate the readers’ construction of meaning.

The 8th paper reports the work of Nagy, Berninger, & Abbot (2006). They conducted an experimental study on morphology’s contribution to literacy outcomes of upper elementary and middle-school students, with 607 students in Grades 4 through 9 in a suburban school district as participants. They use structural equation modeling to evaluate the contribution of morphological awareness, phonological memory, and phonological decoding to reading comprehension, reading vocabulary, spelling, and accuracy and rate of decoding morphologically complex words for these students. The results are quite positive, with morphological awareness making a significant unique contribution to reading comprehension, reading vocabulary, and spelling for all students, to all measures of decoding rate for the 8th/9th-grade students, and to some measures of decoding accuracy for the 4th/5th-grade and 8th/9th-grade students. Morphological awareness also made a significant contribution to reading comprehension above and beyond that of reading vocabulary for all students.

In the 9th paper Barca, Burani, Di Filippo, and Zoccolotti (2006) reported an experimental study in which they tried to understand whether Italian developmental dyslexics make use of the whole-word reading procedure. They recruited 82 Italian 6th graders as the dyslexic group and 68 participants with normal reading ability as the control group. They investigated both lexical and nonlexical reading procedures in dyslexic children through word frequency effect and the effect of contextual grapheme-to-phoneme conversion rules. Although dyslexics were slower and less accurate than controls, they were affected by word frequency, grapheme contextuality, and their interaction in a similar manner as average readers. These results show the use of lexical reading in Italian dyslexics, and reject the claim of a deficit in whole-word
processing with consequent over-reliance on the non-lexical route. This is the first demonstration of the availability and use of lexical reading in Italian dyslexics.

Reading comprehension is a complex cognitive construct, consisting of multiple component skills. However, comprehension tests are focusing mainly on word decoding skills, and they are often used interchangeably, suggesting an implicit assumption that they are all measuring the same thing. In the 10th paper Keenan, Betjemann, and Olson (2008) compare some of the most popular reading comprehension measures used in research and clinical practice in the United States. Participants are 510 children from 27 different school districts in Colorado. Measures include reading comprehension, listening comprehension, word decoding and non-word decoding. The modest inter-correlations among the tests suggested that they were measuring different skills.

These documents are basically on the fundamental problems of reading research, especially theoretical issues. There are 2 papers on the Simple View of Reading, 2 papers on assessment, others are on typical topics such as developmental dyslexia, strategy of reading instruction, etc. People in this field have been trying to understand completely on the process of reading, to build a complete model to describe the process, and to design multiple strategies to promote reading comprehension.

**Discussion**

Reading research is a field of long history, and people of education and educational psychology are the main force. They have developed abundant theoretical and empirical studies, methods for tests and experiments, standards for assessment and instruction, as well as theories and tools.

People of LIS are mainly working in reading guidance and promotion, focusing on practice other than theoretical studies. This is why there is a lack of reading research.

This is a time of new media, and there are new opportunities for people in LIS on both reading guidance and reading research. On the one hand, they should absorb the mature theories, standards, methods and tools developed by people of education and educational psychology to do more elaborate reading promotion. On the other hand, they can actively cooperate with experts and practitioners of education and educational psychology to do reading research. In this way, they can play more important role in reading research as well practice. In fact the new reading phenomenon and reading behavior in the new information environment have become the hot topic of reading research, and the visibility of reading research doing by LIS is increasing day by day (Wu, Li & He, 2017).

Reading guidance and promotion of LIS mostly aim at reading happening in people’s spare time other than school time or work time. There is no doubt that LIS is playing an important role in enriching people’s reading life and enhancing their reading ability. Based on daily practice it is also convienient for LIS profession to study people’s reading behavior so as to get deeper understanding about reading and to provide service at more professional level. By engaging more in reading research in collaboration with other fields in the practice of reading guidance and prompting, LIS profession can not only apply theories and methods of this field to practice, but also offer better understanding about people’s reading behavior and enrich the content in reading research.

For example, repeated reading method is one of the most well-known methods for improving reading fluency. It is often considered a successful fluency intervention in improving both reading fluency and reading comprehension because it gives children practice recognizing the same words in their meaningful context. (Adlof, Catts, & Little 2006). However, the time students can devote to repeated reading is limited, and the effort everyone should make on repeated reading is different. So LIS profession has opportunities to develop and launch elaborate repeated reading projects in cooperation with teachers in schools, and with experts
on reading. In these projects data could be collected and analyzed to test the effectiveness of repeated reading method, and the results may be used to design more personalized reading plan for each participants.

Conclusions

A co-citation visualization analysis has been made with CiteSpace III on the documents of 6 reading research journals in JCR, which are all in citation database SSCI, between 2010-2016. It identifies the important authors, core journals, the main institutions and countries, research hotspots, research fronts and knowledge base, and pivotal documents in the field of reading research.

It is found that people of education and educational psychology are the main force in reading research. The abundant theoretical and empirical studies, methods for tests and experiments, standards for assessment and instruction, as well as theories and tools developed by them are all available for people of LIS to do more personalized reading guidance and deeper reading research.

It is suggested that people of LIS should forwardly seek opportunities to cooperate with reading experts and practitioners of education and educational psychology, and to expand their territory in this new media time not only by applying theories and methods of reading research to practice, but also by actively engaging in study so as to offer better understanding about people’s reading behavior and enrich the content in this field.

Acknowledgments

This study is funded by the National Social Science Foundation under grant No.13BTQ024.

Path to Success: An analysis of US educated elite academics in the United States

Tolga Yuret

tyuret@gmail.com
Istanbul Technical University, Istanbul (Turkey)

Abstract

Few academics achieve to become professors in prestigious universities. These elite academics need a very strong educational background in addition to high academic ability for this achievement. We have two main objectives in analyzing the educational backgrounds of the professors. First, educational institutions are evaluated in terms of the number of the alumni who become professors. Second, professors’ path to success is analyzed and some light is shed on issues such as academic mobility. The educational backgrounds of 14,310 full professors from top 48 universities in the United States are analyzed. This study is confined to undergraduate and graduate degrees that are attained from United States. The source of educational attainment among professors is found to be concentrated. 72 percent (44 percent) of the professors get their PhD (undergraduate) degrees from 20 universities. The academic mobility is found to be very high. Only 16 percent of the professors work in the same state as they get their undergraduate degrees.

Keywords: Academic rankings; academic mobility; inbreeding; financing of education; time to graduate

Conference Topic

Country-level studies, studies on the individual level scientists

Introduction

Thousands of candidates compete for few tenure-track positions in the prestigious universities each year. Many tenure-track faculty members cannot complete the tenure process with success. Some tenured associate professors fail to become tenured full professors. At the end, few PhD holders achieve to become full professors in the prestigious universities. Therefore, it is interesting to analyze the path to this considerable success.

There are many properties of the successful academics. They have good social skills which enable them to direct laboratories and write joint papers. They expend considerable time and effort to do their scientific analysis. They have high academic ability to solve difficult scientific problems. But all these properties would not be sufficient if the academics do not get a strong academic training. Therefore, educational backgrounds of the professors have the utmost importance in the path to success.

We have two main aims in analyzing the educational backgrounds of the professors. First, educational institutions are evaluated in terms of the number of alumni who work as professors in prestigious universities. Both undergraduate and graduate degrees are considered to provide two separate ranks for the institutions. Second, the path to become a professor is analyzed. In this regard, questions such as whether public or private institutions educate more professors for each other are answered. Moreover, mobility of the professors and the degree of inbreeding are measured. Lastly, the graduation time of the professors are computed.
The educational backgrounds of 14,310 full professors who work in top 48 universities in the United States are analyzed for this study. Professors who are from 16 academic fields in natural sciences, engineering, social sciences and humanities are considered. The analysis of this study is confined to the degrees attained from United States.

The preceding paper Yuret (2017) uses the same data-set as this paper but focuses on the professors who have foreign degrees. 34.5 percent of the undergraduate degrees and 12.5 percent of the PhD degrees are found to be from foreign institutions. The source of education is found to be largely concentrated in developed countries. The ratio of foreign-educated professors are found not to vary with the ranking of the university or the public ownership of the university.

In this paper, we find that professors attain their degrees from a relatively few number of universities. 72 percent (44 percent) of the professors get their PhD (undergraduate) degrees from 20 universities. Moreover, top 17 universities in terms of the PhD alumni who become professors are also among top 20 universities in terms of the undergraduate alumni who become professors.

The concentration of source of education among elite academics has been noted by previous studies. Stock et al. (2000) analyze the economics PhD alumni and notes that only 2 out of 178 alumni work in a university that is ranked higher than the university that they graduate. Majority of the PhD graduates work in universities ranked 50 below. Therefore, it is natural that the prestigious universities have professors graduated mostly from top institutions.

Clauset et al. (2015) analyze 19000 professors from business, computer science and history. They show that 71 to 86 percent of the professors attain their PhD degrees from the quarter of the institutions. This study is different from Clauset et al. (2015) in two respects. First, this paper has fewer universities but spans more academic fields. Second, this paper computes the concentration at both undergraduate and PhD levels.

The success of the graduates have been used as a measure for the academic evaluation of the universities. For example, one of the measures that Shanghai Rankings use is the number of alumni who get Nobel Prize or Fields Medal. Laband (1985) and Amir and Knauff (2008) rank economics departments in terms of the placement of their graduates.

We compare the states in which the professors work to the states that professors get their education. There are two objectives in doing this. First, academic mobility is compared to the general labor mobility. Only 16 percent of the professors are found to work in the state that they get their undergraduate degrees. In contrast, Kodrzycki (2001) finds that 60 percent of the people who have some graduate degree works in the state that they get their undergraduate degrees. Second, the degree that some states such as California educate professors for other states such as Texas is measured. 21 percent of the professors who work in California are found to get their PhD degrees from Texas whereas only 2 percent of the professors who work in Texas are found to get their PhD degrees from California.

It has been noted that inbreeding is a problem for some countries. For example, Inanc and Tuncer (2011) find that the inbred faculty have an H index 89 percent lower than the noninbred faculty in some prestigious universities in Turkey. However, it has been noted that inbreeding is not a problem for the United States. For example, Wyer and Conrad (1984) find that inbred faculty members are as productive as other faculty members in many respects by using a survey that covers 160 universities in the United States.

The degree of inbreeding is also measured in this study. The inbreeding is found to be very small. Only 4 percent of the professors work in the university that they get their undergraduate degrees. The ratio for the PhD degrees is also found to be 4 percent. The inbreeding ratio is below 10 percent for all of the universities except for Harvard and MIT.

There is a considerable pressure for the PhD students to graduate faster because a late graduate is considered as a negative signal to the prospective employers. We find that the median PhD
graduate who succeeds to become a professor graduates much faster than the median PhD graduate.

**Data**

The educational backgrounds of the elite academics are considered both in this study and in Yuret (2017). This study analyzes the degrees attained from institutions in the United States whereas Yuret (2017) analyzes the foreign degrees. The data for both studies are collected at the same time. Naturally, there are similarities in data descriptions of both studies.

48 universities from United States that are top 100 in 2015 Shanghai rankings are considered.¹

There are 51 universities from United States that are top 100. Three of these universities are excluded because they specialize on life and/or medical sciences.²

16 academic fields are chosen by using the following three criteria.

- a-) Selected fields exist in most universities.
- b-) Selected fields are mostly organized as departments.
- c-) It is possible to attain educational backgrounds of elite academics in selected fields.

At the end, three natural sciences (chemistry, mathematics, physics), seven engineering (bio/biomedical engineering, chemical engineering, civil and environmental engineering, electrical and computer engineering & computer science, industrial engineering, materials science and engineering, mechanical & aero engineering), four social sciences (economics, political science, psychology, sociology) and two humanities (history, philosophy) fields are selected. We have some composite fields such as electrical and computer engineering & computer science because we are unable to separate them for some universities.

The undergraduate and PhD institutions from which the professors graduate and their graduation dates are collected between September 2015 and January 2016. We rely mainly on internet sources. We use the official websites of the professors, internet search engines (e.g google), undergraduate catalogs, commencement leaflets, PhD data-bases, academic trees (e.g. mathematical genealogy), internet encyclopedias (e.g. wikipedia), field specific data-bases (e.g. Inspire), social networking sites (e.g. Linkedin) and other various sites. We also use reference books (e.g. American Men & Women in Science). We send e-mails to professors if we are unable to find their educational background information from these sources. Around 1/3 of the professors replied.

After all this search, complete educational background information about 95.9 percent of the 14,310 full professors are collected. 97.2 percent of the professors have only missing graduation date information. Almost all the missing data is about undergraduate degrees. Complete information about the PhD degrees for 99.7 percent of the professors is available.

The zip codes of the universities are collected from their official web pages and wikipedia. The coordinates for the zip codes are available from <federalgovernmentzipcodes.us>. The approximate distances between the zip codes are computed by using these coordinates.

**Ranking of the educational institutions by the number of alumni who become professors**

Table 1 lays out the concentration of the education of the professors. First, universities are sorted by the number of the alumni who works as professors within each field. Then, the ratio of professors who get their education in top education providers is computed. For example, 16 percent of all chemistry professors get their undergraduate degrees from top five universities that educate most professors in chemistry.

Table 1 shows that undergraduate education is much more dispersed than graduate education. When all fields are considered, 72 percent of the professors get their PhD degrees from 20 universities whereas the rate is only 44 percent for undergraduate degrees. 35 (20) percent of the professors get their PhD (undergraduate) degrees from 5 universities and 51 (31) percent of the professors get their PhD (undergraduate) degrees from 10 universities.
The concentration of all fields is lower than the concentration within fields. For example, 51 percent of the PhD degrees are from 10 universities when all fields are considered. However, more than 51 percent of the professors are from 10 universities in all fields except for bio-engineering and psychology. This is because the universities are specialized in different fields. For example, if University X educates all the professors in Field A and University Y educates all the professors in Field B, then each university educates 50 percent of all of the professors but educates 100 percent of the professors in their respective fields.

There is a considerable concentration of PhD degrees in almost all fields. More than 40 percent of the PhD degrees are from 5 universities, more than half of the PhD degrees are from 10 universities and more than 70 percent of the degrees are from 20 universities for all fields except for psychology and bio-engineering.

There is a variation of concentration among fields. For example, 88 percent of the economics professors are from 20 universities where the ratio is 59 percent for psychology professors. Psychology degrees are less concentrated than economics degrees at the undergraduate level as well. Chemistry is the least concentrated science field and bio-engineering is the least concentrated engineering field.

In Table 2, universities are ranked in terms of the number of undergraduate alumni who work as professors. Top 20 universities are listed. The rankings are sensitive to the choices that we have made. For example, we do not control for the size of the universities. Caltech may rank higher if a size control is applied. Moreover our selection of fields depend on factors other than the importance of the field. For example, only two humanities fields are included because of the data availability. If more humanities fields could be added, Yale might have ranked higher. It is interesting to note that the academic future is mainly decided at the undergraduate level. Although Harvard tops the list in three fields, there are few Harvard graduates who become engineering professors. Likewise, a student who is an MIT graduate is very unlikely to become a humanities or social sciences professor. There are approximately eight times more engineering professors who are graduated from MIT than UCLA although more UCLA graduates become social science professors than MIT graduates.

If we added one more university to the list in Table 2, then that university would be Swarthmore which is a liberal arts college. There are 83 professors who get their undergraduate education from Swarthmore. That is, one less professor gets undergraduate education from Swarthmore compared to Michigan State. This is a considerable success considering that we do not control for the size of the universities.

Table 3 ranks the universities in terms of the PhD alumni who become professors. Top 20 universities are listed. There is a close parallel between undergraduate and graduate rankings. Top 17 universities in Table 3 are also among top 20 universities in Table 2. However, there are also differences between these two listings. For example, Stanford ranks 3rd in Table 3 but ranks 8th in Table 2. On the contrary, Cornell ranks 4th in Table 2 but ranks 10th in Table 3. Table 3 shows that there is a high degree of specialization in the universities. Berkeley tops the list although they are the leader only in natural sciences. The leader of the engineering field is MIT and the leader in both humanities and social sciences fields are Harvard. The last column in Table 3 considers the professors from eight US universities that are among top ten in the world. Table 3 shows that the rankings are sensitive to the quality of the universities. Columbia which ranks 14th educates more professors for top ten universities than Michigan which ranks 6th.

Table 3. PhD degrees of the elite academics
The rankings provided in Table 2 and 3 evaluate the success of the alumni who have graduated many years before. These rankings serve two purposes. First, the rankings of the universities do not change much through time (Daly et al. 2006). Therefore, the success of past alumni is highly correlated with the current quality of the universities. Second, reputation of the alumni of the institutions is important. An alumni of a university that has educated many professors in prestigious universities may benefit from this reputation.

Path to Success: Public ownership and rankings of the universities
Public universities provide most of the human capital necessary for the universities in many countries. United States is one of the few exceptions. Table 4 shows that 70 percent of the professors in private universities are educated in private universities whereas only half of the professors in public universities are educated in public universities. The ratios are similar for both undergraduate and graduate degrees. The fact that private institutions educate professors for public institutions may be used as an argument for increasing subsidies for private universities.

Table 5 shows that the relation between the Shanghai rank of the university that the professors get their education and Shanghai rank of the university that they currently work. It is clearly seen that the top institutions educate professors for the lower ranked institutions. For example, almost half of the professors who work in the universities that rank 11 to 25 get their PhD education from top 10 universities whereas only 14 percent of the professors who work in top 10 universities get their PhD from universities that rank 11 to 25. The dominance of the top 10 universities are weaker for the undergraduate degrees. Only a quarter of the professors who work in universities ranked 11 to 25 get their undergraduate degrees from top ten universities.

Path to Success: Mobility of the professors
Table 6 shows the mobility of the professors inbetween the states. We see that some states such as California is the human capital source of some other states such as Texas. 21 percent of the Texas professors get their PhD from California whereas only 2 percent of the California professors get their PhD degrees from Texas. The same type of human capital transfer is also true for undergraduate education but to a lesser degree. Like the PhD education, only 2 percent of the professors in California get their undergraduate degrees from Texas. However, only 12 percent of the Texas professors get their undergraduate degrees from California. Only 16 percent of the professors work in the states that they get their undergraduate degrees. This rate is much lower than the average graduate degree holder. Kodrzycki (2001) uses the National Longitudinal Survey of Youth which is a nationally representative data-set. There are 6000 observations who are 14 to 22 years old in 1979. Kodrzycki (2001) notes that only 40 percent of the sample moved to another state after college graduation when the sample is surveyed again in 1996. This is a much lower mobility than the mobility observed from our sample.

Path to Success: Mobility of the professors
Table 6 shows the mobility of the professors inbetween the states. We see that some states such as California is the human capital source of some other states such as Texas. 21 percent of the Texas professors get their PhD from California whereas only 2 percent of the California professors get their PhD degrees from Texas. The same type of human capital transfer is also true for undergraduate education but to a lesser degree. Like the PhD education, only 2 percent of the professors in California get their undergraduate degrees from Texas. However, only 12 percent of the Texas professors get their undergraduate degrees from California. Only 16 percent of the professors work in the states that they get their undergraduate degrees. This rate is much lower than the average graduate degree holder. Kodrzycki (2001) uses the National Longitudinal Survey of Youth which is a nationally representative data-set. There are 6000 observations who are 14 to 22 years old in 1979. Kodrzycki (2001) notes that only 40 percent of the sample moved to another state after college graduation when the sample is surveyed again in 1996. This is a much lower mobility than the mobility observed from our sample.
Table 7 shows how the mobility changes through time. Due to the improvements in internet and transportation technologies it is natural that the professors are more likely to travel to greater distances for their education and work. However, we see from the second column of Table 7 that the distance between undergraduate institution and the current university of the professor actually decreased by 2 miles between 1970s and 1990s. The fourth column shows that the mobility between the graduate degree and the current university of the professor just changed around 50 miles from 1970s to 1990s. The largest mobility increase is between the undergraduate and graduate degrees. The students move around 200 miles more to get their graduate degrees. The bottom line is that the professors always moved for their jobs. The distance did not matter much. However, they are more mobile for their PhD degrees recently.

**Path to Success: Inbreeding**

The degree of inbreeding is measured in Table 8. The number of professors who work in the same university that they get their undergraduate (PhD) degrees is divided to the total number of professors in the second (third) column. Table 8 shows that the ratio of professors who work in the same university that they get their degrees is 4 percent. The ratios are very similar for both undergraduate and graduate degrees. The universities which have high inbreeding from undergraduate degrees have also high inbreeding for the PhD degrees. The correlation between the two ratios is 0.89. Only universities that the ratio exceeds 10 percent is Harvard and MIT. The inbreeding rate for PhD degrees is around 7 percent for Princeton which has top PhD programs. The most
surprising result is University of Chicago which is another top university. The inbreeding rate for the undergraduate degrees is just 0.5 percent and PhD degrees is just 2.7 percent.

Path to Success: Time to Graduate
The students rush to complete their PhD degrees because the prospective employers perceives a negative signal for late graduates. We see that this perception has a statistical basis. Table 9 compares the completion rate of the professors to the average PhD holders. We see that the median elite academicians complete the PhD degree much earlier than the median PhD holder. For instance, the median engineering professor graduate in six after she gets her undergraduate degree in 1990s whereas the median engineering degree takes 2.8 years more in 1993.

Conclusion
Many academic dreams start at the early childhood. The students who have an academic tendency may want to know about their chances to be a professor at some prestigious university at an early stage. The previous studies focus on the success of PhD alumni in the academic world. We take one step backward and show the chances of undergraduate alumni to become professors. We show that undergraduate degrees attained by elite academics are more dispersed than their PhD degrees. Therefore, there is more opportunity for the graduates of lower ranked universities at the undergraduate level to become professors in a prestigious universities than the graduates of the lower ranked universities at the PhD level.
The students who aim to become professors at some prestigious university should expect to be much more mobile than their classmates. If the students dream to work in the same university that they attend then they will be disappointed to learn that only 4 percent of the professors work in the same university that they graduate. The students should listen to their advisors who tell them to finish their thesis on time. The PhD graduates who become professors in prestigious universities graduate much faster than the median PhD graduate.
The low degree of inbreeding implies that many universities employ the academics trained from other universities. The high ranking institutions provide human capital for the lower ranking institutions. Some states such as California provide human capital for other states such as Texas. Such human capital transfers between states show the brain drain dynamics within United States. Private universities provide human capital for public universities. This is an important justification for public support for private universities.

Abstract
This study explores and analyzes three types of potential knowledge in international scientometrics from weak ties, indirect reference, and the ISI-S model. To explore the flow of potential knowledge, journals dual-map overlays technology is applied. Such an approach is consistent with the weak ties, thereby broadening the perspective of research on potential knowledge.

Conference Topic
Knowledge discovery and data mining

Introduction
Potential knowledge is a concept that corresponds to mainstream knowledge, the scope of which includes undisclosed public knowledge except for mainstream knowledge (Donald R. Swanson, 2000). The study of the flow of potential knowledge is a necessary part of improving the knowledge system. Potential knowledge is not yet discovered; however, it may be subversive. The development of knowledge is also a process wherein potential knowledge and mainstream knowledge alternate. Much hidden knowledge is found in the realm of science metrology which cannot be perceived by people, because it is outside mainstream knowledge. The analysis of the type of potential knowledge and the revelation of its flow direction contribute to the development of scientific metrology.

Potential knowledge exists in many ways and is mainly derived from published and unpublished papers. The former is chiefly implied in weak ties with indirect references; the latter cannot be calculated because of its being unpublished, but it can be analyzed by the ISI-S model.
1 Data and methods

As a relatively sound knowledge system, scientific metrology is chiefly constructed by mainstream knowledge. The purpose of this research is to emphasize and reveal the value of potential knowledge via statistics and analysis of literature related to international scientific metrology in the past five years.

Using the “advanced search” function of the Thomson Reuters Web of Science TM (WOS) from the library of Wuhan University, relevant data on “TS = Scientometrics or TS = Bibliometrics or TS = Informetrics” for the years between 2012 and 2016 are collected. Subsequently, 2341 papers were found on scientific metrology as of 1st January 2016.

In this paper, we analyze these data quantitatively and qualitatively using the methods of bibliometrics, content analysis, knowledge maps, and social networks.

2 Analysis of potential knowledge in weak ties

Weak ties theory is proposed by the sociologist Grannovetter. He argues\(^1\)\(^2\) that weak ties represent a transient social contact between two actors; therefore, it is less structured and can connect different groups or subgroups and deliver messages to different parts of network. Doreian (1979:51-52) reveals the characteristics of cliques. If only relationships are considered, without the direction of the lines, and if all connections are considered as reciprocal relationships, then the results of the analysis reveal weak cliques, which represent a form of indirect relations.

According to Zipf’s Law, in the low frequency words, the graph of the network knowledge can be drawn in low frequency words, thereby indicating that small group network cliques is the key content among low frequency words, suggesting latent knowledge in weak ties in international scientific metrology. A prevailing trend states that if increasing number of researchers aim at the potential knowledge, it could become mainstream knowledge in the near future. Figure 1 is the map of low frequency key words in international scientific metrology over the past five years, in which the box represents the keyword. The larger the boxes are, the higher the frequency of the key word, and the lines between the boxes represent the relationships between them. Three large groups of high frequency words are found in the maps: 1. Quantity, Performance, Quasity, Normalization, Energy, etc.; 2. Neural regeneration, nerve repair, nerve transfer, nerve regeneration, etc.; and 3. University ranking, research competitiveness, research ranking, Google Maps, spatial scientometrics, etc. All of these groups are valuable latent knowledge in weak ties; thus, we should focus on the mainstream of future knowledge.
The analysis of conventional measurement usually focuses on hot spots, that is, high frequency words are taken as the study object. However, low frequency words often connect different groups or subgroups and deliver messages to the network. Their specific features are described as extensive, heterogeneous, and intermediary. Low frequency words within the weak ties are consistently free from networks. Given their low frequency, with few co-occurrence words and formation of network nodes, they can hardly form group factions or they can only form small scape networks. However, once the association exists, it becomes latent knowledge.

3. Analysis of latent knowledge in indirect reference associations

The journals dual-map overlays technique is a new tool to reflect the flow of knowledge, based on the coupling and co-citation analysis of journals. Bibliographic coupling, co-citation, and journals dual-map overlays can be used to explore some of the internal knowledge correlations of international scientific metrology research. They can also analyze the flow of knowledge between journals composed of citations and the citations of the 2,341 international journals of scientific metrology.

3.1 Coupling of international journals of scientific metrology

Journal coupling analysis establishes the relationships among journals by evaluating the degree of coincidence of different journals that have the same cited journals. The greater the number of documents coupled by the two journals, the more similar those two are. The co-citation of journals refers to the number of papers that have been published in two journals; and the greater the number of co-citations, the more similar the two journals. Coupling analysis of journals was conducted via VOSviewer³, developed by the Center for Science and Technology Studies at the University of Leiden, the Netherlands. The VOS Mapping method is applied to determine the coordinates of the elements in the two-dimensional space.⁴ To identify the distribution
of the most important journals, we use the density maps to visualize the journals. (In the density map, the greater the weight of the nodes, the more journals around them, and the greater the density around them.) The total cited networks and the journals dual-map overlays are obtained, and we subsequently use CiteSpace (developed by Prof. Chen) to analyze them.

Figure 2 shows a density chart of the coupling analysis of international scientific metrology research journals in the recent five years. Font size characterizes the amount of papers published in different journals such that the former is directly proportional to the latter. Network density is an important indicator of the overall level of network cohesion; the greater the network density, the more full the knowledge and information exchange. Distance between the points in two-dimensional space reflects the similarity between journals. Hence, the closer they are, the greater their similarity. Through the density map, journals can be clearly divided into a scientific metrology-based large community and several other small communities, by which we can know the tendency of achievement in international scientific metrology. Further analysis indicates that international scientific metrology represented the best in library and information science such as scientometrics, Journals of informetrics, and others, with full load of knowledge and communication. These results are consistent with the normal development track in this field, and reflect that much room for development remains for other disciplines.

3.2 Cited journals in international scientific metrology
Cited journals in international scientific metrology refer to journals that are cited in scientific econometrics studies, that is, the journals published by scholars of international scientific metrology as a reference list of articles published in the journal itself. Citation can reflect the knowledge flow from the cited journal to citing journals, and the cited journal can be considered the knowledge provider of international scientific metrology or the knowledge base. We analyzed the total citations in international scientific metrology literature, as shown in Figure 3, which is similar to
the density map. A sizeable scientific metrology-based group is also observed. As shown in Bibexcel statistics, for the top 20 journals with the achievement of scientific metrology and citing journals, all are in the realm of scientific metrology or library information science. Furthermore, many journals occur in both the citing journals and the cited journals, thereby indicating that the knowledge flow is concentrated in these journals. Such journals represent an important knowledge base of international scientific metrology.

![Figure 3 Analysis of co-citations of international scientific metrology over the past five years](image)

3.3 Potential knowledge flow in journals dual-map overlays

The development of information visualization has increased interest in issues related to knowledge tracking. Information visualization can help us illustrate the dynamic changes in the scientific paradigm as well as explain how to accommodate potential knowledge and mainstream knowledge in one visible framework. The distribution of potential knowledge flow in scientific metrology can be analyzed by the journals dual-map overlays technique in Citespace V. Journal dual-map overlays, a technique developed by Professor Chen and Leot Leydesdorff in 2013, provides journal similarity maps via computer visualization. Compared with the early journal overlay map, double graphs can provide more information and potential knowledge association, and show the knowledge flow among journals through the citation path of a paper.

Journals dual-map overlays is a novel method that shows the distribution, citation trajectory, and gravity drift of papers. The design of dual-map overlays describe citing overlay and cited overlay mapping in the same view, thereby showing an integrated citation instance and providing a clear origin and orientation at a glance. Such design also shows the possibilities in cross-subjects of both source and goal. Many overlays are added to basic dual-maps, and each layer must contain the reference record, such as records obtained from Web of Science searches. While the smallest set may contain only a single paper, no limit exists for the peak set. In the journals dual-map overlays, each reference instance is represented by an arc. Such arc originates from the source journal of the citing paper, and the end of the arc is the target journal in the cited base map. Arcs from the same set are represented with the same color to differentiate the
different sets’ cite patterns by their unique color. Base maps provided by panoramic scientific maps enable the analysis of the interaction map. As citing journals and cited journals are shown simultaneously in dual-map overlays, comparing reference behavior of different groups via source journals and target journals is possible.\textsuperscript{10}

Journals cited in international scientific metrology also reveal that knowledge flows from citing journals to cited journals. Thus, international scientific journals can be divided into citing journals and cited journals. Figure 4 is a dual-map overlays of citing journals and cited journals in international scientific metrology over the past five years. The chart on the left is a journal cluster chart based on the citing journal map, whereas that on the right is based on the cited journal map.\textsuperscript{11} Figure 4 shows that both the source journals (on the right) and target journals (on the left) have two groups. Source journals flow from molecular, biology, genetics, and nursing, to medical, neurology and movement. Conversely, target journals flow from molecular, biology, genetics, nursing, medical, psychology, and pedagogy to mathematics, cultivation, ecology, and zoology. This outcome reveals the latent knowledge flow in international scientific metrology, and is consistent with the weak ties in neurology in indirect relations. Concepts in neurology include the following: neural regeneration, nerve repair, nerve transfer, and nerve regeneration. Moreover, the consistency reflects the regularity of mining potential knowledge, thereby confirming the value of this paper.

Figure 4 Journals dual-map overlays in international scientific metrology from 2012 to 2016

4 Potential knowledge of ISI-S model
According to Merton (1973), the goal of scientific systematization is to extend the knowledge that has been identified. This systematic approach prevents the omission of any content that is not easily detected and promotes the improvement of the knowledge system. The scientific metrology model (ISI-S model) designed by Vinkler
(2002a) is a global network which considers information system and scientific knowledge as a whole, with close connections, and with dynamically changing network content and scale. The contents and rules of a single cluster are regulated by the relevant assessment process, and this model is used to explore the changes of potential knowledge in unpublished papers, thereby providing the basis for the scientific system of international scientific metrology. The ISI-S model builds six main sets of information: information in published articles, aged or neglected information, information with short-term effects, information with long-term effects, basic scientific knowledge, and scientific information. Each information set contains potential information that can complement the potential knowledge of international scientific metrology from a static perspective. The level of information set represents the hierarchical level of the following scientific system (see Figure 5): 

Figure 5 Metrological model of scientific metrology information (ISI-S model)
Note: The map is from The Evaluation of Research by Scientometric Indicators

As shown in Figure 5, each information set has a relationship with potential knowledge, such as “information to be modified or rejected in literature” in literature to be published, “information that has not been assessed or lost after assessment” in publications, and “unrelated (wrong or redundant) information and information with a hidden impact” that may be absorbed and evaluated. Other knowledge includes “information with short-term effect,” “information with long-term effect,” “aging information,” “aging knowledge,” and “wrong or superfluous knowledge” in basic scientific knowledge or scientific knowledge. They may be treated as wrong, redundant, and aged information, and will then be merged or discarded. However, such knowledge may possess hidden value to be excavated or transformed into information with significant effects in the future. Merged or discarded information
may form basic scientific knowledge over a long period. Fundamental scientific knowledge is composed of pieces of information which are effective in the long term, representing a combined, systematized, widely accepted information system of one unit (as a field or subject). The resulting information system may have a significant effect on each subject, research area, or on scientific research. Based on the ISI-S model, publications that have not been cited for a long time can be considered aging, unrelated information with latent influence. Thus, much scientific research is repetitive work that produces many publications that are unaffected or less influential. Therefore, in every information integration phase, potential influence knowledge, irrelevant knowledge, and aging knowledge exist. This potential knowledge plays an essential role for the integrity of the knowledge system by improving the knowledge from the perspective of unpublished literature.

5 Conclusion
In conclusion, many ways exist to develop and exploit the latent knowledge of international scientific metrology. In this research, we analyze the potential knowledge in weak ties, the latent knowledge in indirect reference, and the latent knowledge in the ISI-S model from published and unpublished literature. We also conclude that potential knowledge in weak ties is consistent with the target knowledge in the journals dual-map overlays of knowledge flow, thereby validating the hypothesis of this paper.

Similar to most disciplines, international scientific metrology is a relatively self-sufficient discipline that consists of mainstream knowledge in a system, thereby keeping many scholars engaged in the long term. However, as discussed, international scientific metrology contains considerable potential knowledge with the possibility of being activated as mainstream knowledge. Subsequently, such knowledge becomes basic scientific knowledge or common science, thereby promoting the development of disciplines. For example, the number of occurrences of the keyword “altometrics” during the year 2012–2016 are 0, 2, 6, 18, and 13 (as analyzed by Bibexel software). Evidently, this keyword presents itself as a kind of potential knowledge in weak ties. In fact, the prevailing trend suggests that altometrics is becoming a research hot spot in international scientific metrology.

Abstract
Understanding semantic word shifts in the scientific domains is essential for facilitating interdisciplinary communication. Using a data set of published papers in the field of Information Retrieval (IR), this paper studies the semantic shifts of words in IR based on mining the per-word topic distribution over time. From our results, different patterns of word migrating among topics are recognized, and the semantic shifts represented by the migrating process are analysed accordingly.

Conference Topic
Knowledge discovery and data mining

Introduction
Interdisciplinary communication is a crucial issue for promoting innovation and science development. Today, data are extremely rich but overwhelming (Ding & Stirling, 2016), different research areas are developing new ideas and methods constantly. During the evolution of scientific topics, different topics may view same words or phrases in different ways, e.g., “data science” in biomedical science mainly means gene codes or protein structure, and in computer science it focus more on algorithm designing, while in information science it cares more about people and society.

The phenomena of the same word appear in multiple topics are essentially semantic shifts of words during the topic evolution process. In practice, a word shifts or extends its semantics while a topic evolves, where the same word can appear in multiple topics with different contexts. In data mining and computational linguistic areas, language processing tools has been developed to recognize semantic word shifts. However, existing work studies the semantic shifts of words mainly to facilitate natural language processing in information retrieval problems, where the relationship of words with topics has been overlooked.

This paper studies semantic word shifts in different topics in a scientific domain, and using a data set in the field of information retrieval as an empirical study. A word’s semantic shifts via topic channels is herein defined by its related innovations and applications. When the same word distributed in different topics, even if it is embedded in a stable context (namely, the linguistic semantics based on the distributional hypothesis), it is usually in associate with different innovations and applications due to the change of topic themes.
Related work

Topics are essentially collections of words with semantic functions (Griffiths, Steyvers, Blei, & Tenenbaum, 2005). Defined as a change of one or more meanings of the word in time (Lehmann, 1993), the shifts of word semantics and its detection has been the focus of much research in recent years. Studies on word semantics over time can be viewed from two perspectives: synonymy detection and polysemy detection. Synonymy detection monitors the use of different words with the same meaning over time (Kenter, Wevers, Huijnen, & de Rijke, 2015). Based on a small set of input words in a certain time period, ranked lists of terms for a consecutive series of periods in time would be output. The words in the ranked lists are meant to denote the same concept as the input words. Studied more extensively, polysemy detection monitors different meanings expressed by the same word over time. A word can change semantically in a way wherein new meanings replace the old ones, or acquire additional meaning with the original meaning may still be widely used (Wijaya & Yeniterzi, 2011).

In polysemy detection, distributional semantic models (Gulordava & Baroni, 2011; Hamilton, Leskovec, & Jurafsky, 2016; Kim, Chiu, Hanaki, Hegde, & Petrov, 2014) are widely used for quantitative measurement. In these models, the similarity between words is measured by vector space models where each word is associated with its context vectors. Existing works have studied the semantic shifts of words mainly to facilitate natural language applications, for example, time-aware query expansion for document retrieval tasks in a historical corpus. In this case, words are studied alone and are not associated with topics.

Methods

Data set and topic extraction

Information retrieval (IR) is chosen as the target domain. Papers are collected from Web of Science for 1956-2014, making a total of 20,359 documents, with search based on a set of IR-related terms. Search term selection refers to the paper by Xu et al. (2015). The selected document types include article, book, book chapter and proceedings paper. The title and abstract fields are used as the text corpus for extracting topics. Before extracting topics, all terms are stemmed using the Porter2 stemming algorithm. A stop word list (Yan, Ding, Milojević, & Sugimoto, 2012) is used to filter common words. Words with only one letter or appear less than five times are removed.

The Latent Dirichlet Allocation (LDA) proposed by Blei et al. (2003) is applied for extracting topics from the corpus. LDA is a three-layer Bayesian model that is now widely used in discovering the latent topic themes in collections of documents. The LDA model represents each document with a probability distribution over topics, where each topic is represented as a probability distribution over words. For a detailed explanation of the algorithm, refer to, e.g., Blei (2012). The Gensim library (Rehurek & Sojka, 2010) is used for implementing the LDA model, where the parameters are set as the standard value proposed by Gensim. Considering the size of the dataset and the experience from previous studies (Ding, 2011), the number of topics is set at five.

Mapping word semantics via topic channels

We define the same word appears in different topics as word migration, which resemble the migration of populations in demographics as if the word is an analogue of a human population and topics are territories.
A word’s migration is examined herein based on its yearly topic distribution. The topic distribution of a word in a document is parameterized by the variational parameter $\phi$ in the LDA model (Hoffman, Bach, & Blei, 2010). The $\phi$ value indicates the likelihood of a word belonging to a topic in terms of a particular document. Each word in a document has five topic $\phi$ values corresponding to the five global topics (Table 1). After normalizing by the frequency of the word in the document, the sum of a word’s $\phi$ values is equal to 1. The same word from two different documents usually has two different sets of $\phi$ values. For a selected word, we calculate its average $\phi$ value for each topic in each year. The average $\phi$ values represent the topic probability distribution for the word in that year. As the $\phi$ values change over the years, the word migrates between topics over time.

Results and discussions

**Topic extraction**

The top ten words with the highest probabilities of the five extracted topics are presented in Table 2. Topic 1 focuses on user-oriented problems, covering online information-seeking behavior, use of digital resources such as digital library by research scholars, and user information needs, especially for health information search. The main theme of topic 2 centers on multimedia information retrieval, especially image retrieval. Topic 3 and topic 4 both study queries for structured data sets, where topic 3 mainly deals with traditional query processing for relational and object-oriented databases, and topic 4 primarily focuses on distributed query processing for spatial networks and communication networks. Topic 5 studies text retrieval for unstructured documents, which involves document indexing and terminology processing problems, such as term disambiguation, query expansion, and cross-language retrieval.

**Topic distribution**

Figure 1 presents an overview of the topic distribution status of all words. Each node is a word, and is represented by a five-dimensional vector, which is equivalent to the per-word topic distribution over the whole corpus. Words with similar topic distribution are closer to each other, and words with dissimilar topic distribution are far apart from each other, which result in the clearly distinguished five clusters corresponding to the five topics. Words that are stable in
one topic are far away from the center, such as Color and Image in Image Retrieval. Words that are distributed about evenly in multiple topics are closer to the center, such as Web, Context and Evaluation. Words that migrates between two topics are correspondingly located between these two topics, e.g., Language between Database Querying and Text Retrieval.

Figure 1. Per-word topic distribution

Semantic word shifts
Figure 2 shows the migration of the top 10 words with the highest probabilities in each topic over time. Because topics share some of the top words, there are 42 unique top words in total.
Considering the number of topics between which a word mainly migrates, words can be categorized into three groups: the non-migration, the dual-migration, and the multi-migration. Non-migration words are those that always belong to only one topic over time. In Figure 2, non-migration words include, for example, Color and Image in Image Retrieval; Document, Text and Word in Text Retrieval; Library in User Study; Network and Tree in Query Processing. Words belong to the non-migration type are core words in the topic, which reflect the research theme or main method of a topic. Dual-migration words are distinguishable in two topics. A typical example is Language in Database Querying and Text Retrieval. When in Database Querying, it is related with query language in databases. When in Text Retrieval, it is placed in the situation of cross-language retrieval. Multi-migration words are those migrates among multiple (more than two) topics, most words belong to this type. There are multiple underlying ideas represented by these words.

Considering the stability of the probabilities of a word in different topics over time, there are two types needed to be noted: the divergent words and the convergent words. Divergent words start with an approximately even probability in several topics, but the probabilities diverge in later periods for the word being assigned more apparently to one or two topics, e.g., Web starts with a probability of 0.3 distributed evenly in User Study, Database Querying and Text Retrieval. The probability in Text Retrieval then increases and separates from the other two, as web is studied more specifically under the context of text retrieval in web environments in later periods. The diverging process of a migrating word indicates the word is becoming topic specific. The topic it mainly migrates towards becomes increasingly developed, resulting in the word being more studied under the specific context of this topic.
Convergent words are obviously assigned to one topic at first, but the probabilities in the topics converge in later periods, resulting in the word being distributed evenly in multiple topics. Taking semantic as an example (Figure 2), semantic is assigned mostly to Database Querying appearing as semantic query language at first, then the word gradually migrates to Text Retrieval and Image Retrieval, and the probabilities in the above three topics converge in the 2010s. The converging process of a migrating word indicates the increasing importance of the word in the domain, for it is not only studied in a specific topic, but developed various applications covering broader range of contexts in different topics. In the case of semantic, it is not only studied as semantic query language as in the beginning, but also studied as semantic text retrieval in Text Retrieval and image semantics in Image Retrieval in later periods.

Conclusion
This paper studied the semantic word shifts of topics in the field of information retrieval. Based on the per-word topic distribution over time, different patterns of word migrating among topics are recognized. Our work contributes to a better understanding of interdisciplinary communication, and further direction could consider mining the local context shifts during the semantic shifts.

Abstract
The objective of this research-in-progress paper is to reveal word semantic change and verify whether the change conforms to the law of differentiation or the law of parallel change. This paper identifies a set of representative words in biomedical literature based on word frequency and word-topic probability distributions. It employs a skip-gram word2vec model to the identified words to measure word-level semantic changes. This paper finds no overwhelming evidence to support either the law of differentiation or the law of parallel change.

Conference Topic
Knowledge discovery and data mining; Methods and techniques

Introduction
Word semantic change is one of the several forms of historical linguistics changes that include sound change, grammatical and syntactic change, and semantic change (Xu & Kemp, 2015). Among them, semantic change is the least understood (Crowley & Bowern, 2010). A few linguistic laws have been proposed to study semantic change (Hamilton, Leskovec, & Jurafsky, 2016b; Xu & Kemp, 2015) such as the law of differentiation that dictates that synonyms tend to differentiate in meaning over time and the law of parallel change that governs that related words tend to undergo parallel changes. These laws are rooted in classic linguistic literature and, recently, two advances have made it possible to examine word semantic change and verify these laws with large empirical data. First, the availability of large-scale collections of diachronical textual data has markedly facilitated scholars’ computational investigations of language change (Frermann & Lapata, 2016). Projects such as Google Books (Lin et al., 2012) and Corpus of Historical American English (Davies, 2010) have an extensive coverage dating back to the early 1800s. Commercial databases such as Web of Science have also made an effort to index their collections to as early as the 1900s (Larivière, Archambault, & Gingras, 2008; Larivière, Gingras, & Archambault, 2009). Second, the advanced computational methods developed in the last few years for the first time have had the ability to harness large dynamic data.

A number of methods were developed and applied to understand word semantic change, including several word embedding algorithms such as positive point-wise mutual information (PPMI), singular value decomposition (SVD), and skip-gram models. Among these methods, word2vec has gained popularity in understanding word embeddedness and word semantic change. Word2vec is a distributed word representation technique from deep learning approaches (Manning, 2016). It was proposed by Mikolov and colleagues (2013) to estimate continuous vector representations of words from large corpora. It was built on previous work on neural net language models (NNLM) and the advantage of word2vec is that it significantly reduced the computational complexity. Two word2vec models were proposed, one is the continuous bag-of-words (CBOW) model that does not consider word orders and the other is...
the continuous skip-gram model that assigns different weights based on the proximity of words in a window.

The goal of this research-in-progress paper is to reveal word semantic change and verify whether empirical data support the law of differentiation or the law of parallel change by employing word2vec on a large data set of PubMed publications. The biomedical domain was selected primarily because the availability of large, publically available data sets in this domain that makes is possible to gain access to data and replicate research for transparency and sustainability.

Data

Abstracts of 18,777,129 articles published in the last 30 years (1987-2016) were downloaded from PubMed. The number of yearly publications ranges from approximately 360,000 for 1987 to more than 1,000,000 for the recent three years (2014-2016). To select a set of representative terms in the whole PubMed data set, we first identified top 500 words based on their frequencies in PubMed after a stop word list was applied. We then ran a topic model and identified, for each topic, 25 words with the highest probabilities. We merged the two lists and formed the final list of words for semantic distance calculation. Because a word can be in both the most frequent list and the highest probability list, the total number of words is 761.

Methods

In this section, we give a brief mathematical introduction to the algorithm behind the continuous skip-gram model using notations of Goldberg and Levy (2014). In this model, we consider the conditional probabilities \( p(c|w) \) given a corpus of words \( w \) and their contexts \( c \). The goal is to maximize the probability by setting the parameters \( \theta \) in \( p(c|w; \theta) \):

\[
\arg \max_{\theta} \prod_{(w,c) \in D} p(c|w; \theta)
\]

where \( D \) contains word and context pairs extracted from the corpus. \( p(c|w; \theta) \) can be parametrized using the softmax function such that \( p(c|w; \theta) = \frac{e^{v_c^T v_w}}{\sum_{c'} e^{v_{c'}^T v_w}} \) where \( v_c \) and \( v_w \) are vector representations of \( c \) and \( w \). Chiu, Crichton, Korhonen, and Pyysalo (2016) presented settings for each hyper-parameter that work best for PubMed publication data. Therefore, we used the parameter settings reported in their study. The parameters are set as follows: 10 (negative sample size), 1e-4 (sub-sampling), 5 (minimum-count), 0.05 (learning rate), 200 (vector dimension), and 30 (context window size).

We adopted the global measures by Hamilton, Leskovec, and Jurafsky (2016a). The global distance between a word in year \( t \) and year \( t+1 \) is calculated through: \( \cos(w_i^{(t)}, w_i^{(t+1)}) \), where \( w_i^{(t)} \) and \( w_i^{(t+1)} \) are word vectors of word \( w_i \) over all dimensions in \( t \) and \( t+1 \).

Results

To verify the law of differentiation and the law of parallel change, we identified a number of groups of synonymous words within the 761 words using an online thesaurus API. This API is developed based on source data from WordNet, the Carnegie Mellon Pronouncing Dictionary, and user suggestions. Because synonymous relations can be rather liberal in this API, two coders manually selected a more coherent set of synonymous words from the API’s output, resulting in 21 groups of synonymous words (87 words in total). Figure 1 shows the

1 https://words.bighugelabs.com/api.php
We inserted the average global distance of all 761 words as a benchmark (“Global Mean”).

We see in Figure 1 that synonymous words in most groups seemingly coevolve in the past 30 years. Nonetheless, when using the global mean as a benchmark, we found only two groups—group 8 (“assessment” and “evaluation”) and group 14 (“maximum”, “maximal”, and “peak”)—whose average correlation coefficient between the synonymous words is greater than the average correlation coefficient between the global mean and individual synonymous words of that group. Meanwhile, “medium” and “average” in group 5 and “genotype”, “gene”, and “dna” in group 11 have higher correlations with words in their respective groups than with the global mean, but when other synonymous words are added, as a group, words’ semantic change patterns relate more with the global mean than with each other. The results suggest that while synonymous words seem to coevolve semantically, their coevolving patterns are not significant when using the global mean as a benchmark. Thus, although the law of parallel change was identified in a few cases, this study did not find overwhelming evidence to support this law across the whole corpus.

As for the law of differentiation, among the 21 groups of synonymous words, two groups—group 9 (“experiments” and “research”) and group 17 (“therapeutic” and “curative”)—resulted in negative correlation coefficients between the synonymous words (-0.393 for group 9 and -0.392 for group 17). The majority groups, however, have strong, positive correlations between the synonymous words (average coefficient=0.65).

Conclusion
This research-in-progress paper did not find a consistent set of evidence to support the law of differentiation or the law of parallel change. PubMed is the single largest bibliographic data repository that is available to the public. We believe with the open data movement, there will be more high-quality publication data sets available to researchers. A future work in this direction will involve bringing in disciplinary perspective to gain insights on disciplinary epistemological differences invoked by word semantic changes.

Abstract
We consider the problem of extant scientific literature search and analysis systems, and suggest that term function recognition can be very advantageous for fine-grain retrieval and semantic analysis of a huge amount of scientific literature in a specific domain. We first elaborate the definition of term function (TF) in the scientific literature context, and the status and development of term function recognition (TFR) globally. Then, the computer science domain is taken as an example to design and implement a system called CS-LAS, which can provide users with several useful function modules based on TFR, such as scientific information search and browsing, domain hot spot discovery, evolution trend detection, and scholarly recommendation based on correlation analysis of functional terms.

Conference Topic
Methods and techniques; Mapping and visualization; Knowledge discovery and data mining.

Introduction
Scientists can usually understand the knowledge structure and frontier of a research domain in which they are interested by reading relevant scientific literature, which is also a requisite link in the overall process of science. However, with the rapid growth of scientific literature and the increasing popularity of interdisciplinary collaborative research, it has become increasingly difficult for researchers to keep up with relevant developments only by manpower (Spangler et al., 2014). Therefore, it is of great importance for researchers to develop computer software to automatically and rapidly solve certain problems, such as how to quickly analyse a large amount of scientific literature to comprehensively and accurately identify the domain hot spots and evolution trends of a research field via computer technologies, how to automatically find a new research method for an existing research topic, and how to discover a research topic for which an existing method is appropriate. In past decades, scholars who are from the domains of information science, bibliometrics, digital library, and information visualization have discussed these issues, as well as a series of practical literature analysis systems, such as CiteSpace (Chen, Chen, Hou, & Liang, 2009), VosViewer (Van Eck & Waltman, 2009), NEViewer (Wang, Cheng, & Lu, 2014), and BICOMB (Cui, Liu, & Zhan, 2008).

Although these systems have played a critical and positive role in solving the above mentioned issues, they are usually based on term frequency, co-word clustering, and co-citation clustering analysis. In other words, they take the absolute occurrences of terms into account from the document level, and miss the semantic information contained by the terms in the scientific literature. When a term occurs in a scientific work, however, this does not mean that it constitutes the topic of the literature. Moreover, when a paper is cited, the cited part may not be the focal point of the article. Overall, simple quantitative statistical analysis of
literature at the document level only obtains surface information of terms, and cannot represent the deep semantic information contained in the terms, which frequently leads to inaccurate analytical results.

In fact, a term usually plays a specific semantic role in a specific research, and has a particular function that we refer to as term function (TF). The purpose of this study is to recognize the term function in relation to scientific literature and, on this basis, develop a literature analysis system called CS-LAS using data from the computer science field. CS-LAS can be effectively utilized for scientific literature retrieval, navigation, bibliometric analysis, and scholarly recommendation based on term function recognition.

The organization of this paper is as follows. In section 2, we review the relevant research on scientific literature analysis systems, term function (TF), and term function recognition (TFR) in scientific text. In section 3, we depict the design idea and construction of our scientific analysis system. In section 4, we elaborate the implementation of our system, including data collection, the construction of functional term sets, the implementation of retrieval and analysis modules, the design of the user interface, and the visualization of results. In section 5, we draw conclusions from this article and identify directions for future work.

Related research

Scientific literature analysis system (SLAS)

Scientific literature analysis system, which is absolutely critical in the era of big academic data, is an information analysis system that can automatically realize semantic analysis of a massive number of scientific papers based on theory and technology from statistics, information retrieval, and bibliometrics. According to the main function of the existing systems, we divided SLAS into two categories, one based on information retrieval and the other based on bibliometrics. The system based on information retrieval which uses database technology, mainly provides users with the function of literature retrieval, domain navigation and browsing, and simple statistical analysis of scientific papers. Traditional academic databases, such as Web of Science, Scopus, PubMed, etc., belong to this category. The system based on bibliometrics, such as CiteSpace (Chen, 2009), VOSViewer (Van, 2009), and NEViewer (Wang, 2009), can be used for co-citation analysis, co-word analysis, co-occurring analysis, and powerful visualization of scientific papers to help researchers quickly obtain knowledge of a research domain.

The two types of SLAS are currently widely used due to their major advantage of realization of automatically semantic analysis of scientific articles. However, much room for improvement of these systems exists to more fully satisfy users’ academic information needs. First, the system based on information retrieved mainly ranks the results by relevance, i.e., the distance between letters and signals in text, which typically comprises a large amount of ambiguity, redundancy, or irrelevant results. For example, when one searches for papers on the theory of SVM (support vector machine), most of the results from these systems may be papers about the application of SVM in other domains. In addition, the system based on bibliometrics usually analyses scientific papers from the document perspective. Specifically, it simply counts the absolute times that the terms occur, ignoring the deep semantic meaning and role of the terms in the paper, creating substantial noise in the process of literature analysis and yielding poor results.

In this article, we assert that taking the term function into consideration can solve the above problems in the existing systems. By recognizing the term function, we can utilize it to realize semantic retrieval, optimize the results of traditional academic databases, improve the experience of navigation and browsing function, and meet the user’s academic information needs much more precisely. In addition, by using term function recognition, we can
semantically organize and store scientific papers, which can provide a reliable base for further statistical work and analysis of scientific literature.

**Term function recognition (TFR)**

The definition of term function (TF) is the semantic role and specific function that a term plays in the scientific literature, given by Cheng (2015). In different academic texts, the same term may contain different semantic meanings. For instance, the term “SVM” plays different semantic roles in Chen and Fan (2009) and Zhang, Pan, Zhang, and Jiang (2004). In the former article, SVM is the research topic; whereas, in the latter article, it is the research method. Moreover, terms may have numerous functions, other than topic or method, such as goal, technology data set, etc., that are quite commonly used. Therefore, the classification and recognition of term function have constituted a popular and difficult task for researchers to solve because it is of critical significance for the automatic semantic analysis of scientific literature.

In the extant literature, there are few works directly relevant to term function recognition (TFR). The first study on TFR was conducted by Knodo, Nanba, Takezawa, and Okumura (2009). They divided terms in the title of scientific papers into “head”, “goal”, “method”, and “other” to discuss how to master the development trend of research technology from a specific research domain. Then, different scholars proposed their own classification of term function (TF), and conducted corresponding TFR experiments (see Table 1 for more details), but they did not give an explicit definition of term function. In Cheng (2015), term function was clearly defined and a more perfect framework of term function in academic text was proposed, which divided term function into “domain-independent term function” and “domain-related term function”. In his Ph.D. thesis, “domain-independent TF” has two types: “research topic” (including main topic, general topic, and other topic) and “research method” (including main method, general method, and other method). “Domain-related TF” mainly consisted of cases in economics, tools in computer science, data sets in data science, etc. (Cheng, 2015).

Overall, TF and TFR still constitute novel issues for scholars globally. Although several effective attempts have made, the topic remains largely undeveloped. In addition, an apparent gap exists between TFR and its application, which forms the exact initiation point of the present study.

**Table 1. Classification and recognition of term function.**

**Design of literature analysis system**

Regarding the definition of term function (TF) proposed by Cheng (2015), we assumed that a scientific paper is a reflection of the process of several research topics solved by a number of research methods. On this basis, we recognize the research topic terms and research method
terms from each scientific paper to form a Topic Set, Method Set and Topic-Method Set, which can represent the main idea of the paper. It is important to note that, in this article, we only consider the main topic and main method of each academic work. In this way, we can semantically analyse scientific papers from the term perspective, which not only can provide researchers with a much more precise retrieval and navigation function, but can also more accurately detect and depict the trend and hot points of a scientific domain. In addition, by correlation analysis between the methods and topic extracted from the papers, we can realize a more intelligent and semantic scholarly recommendation system through method recommendation and topic recommendation.

The idea of literature analysis system

In order to implement a literature analysis system based on TFR, the first problem to be solved is to obtain a collection of scientific literature, and recognize and extract the main methods and main topic of each paper by utilizing the rule-based information extraction method. Secondly, we consider that the information needs of scholars are “to retrieve a research topic” or “to retrieve a research method”. To comprehensively fulfill these needs, we index, respectively, the methods and topics of each paper to provide a more fine-grained retrieval function for users, which can optimize the retrieval function of traditional academic databases. Regarding the retrieval results, the system can conduct further quantitative analysis on them, such as using the number of papers every year to depict the evolution of a topic or a method, and to detect the most commonly used methods and the hottest topic in a domain by the frequency that the methods or topic occur, etc. In addition, the system can also deliver a user-friendly interface and provide good visualization of the different results by using information visualization technologies. Finally, the system should be an interactive system, in which users can change the analysis dimensions and choose their own settings, such as time limitations, data updates, data management, etc.

Construction of literature analysis system

Considering the functions of similar existing systems and users’ needs, the system that we designed has six functional modules: 1) literature retrieval module; 2) navigation module; 3) research hot spot discovery module; 4) research trends analysis module; 5) correlation analysis module; and 6) data management module. The function framework of our literature analysis system is presented in Figure 1.

![Figure 1. Function framework of CS-LAS](image)

（1）Literature retrieval module

When searching scientific papers in traditional academic databases, it is very common for users to find results that are not what they actually wanted, a situation that is similar to the example proposed in section 2.2. In order to solve this major problem, the retrieval module of CS-LAS can index the main topic and main method extracted from each paper to provide users with a more precise retrieval function and optimize the results of traditional academic databases. The module comprises topic retrieval and method retrieval functions, which differ
according to the role of a user’s keywords in papers, and can be chosen by users with a checkbox next to the search box in the system.

(2) Navigation module
In cases in which a user may need to have a very wide scope of knowledge of a specific domain, the navigation module can be quite useful. The navigation module enables users to browse and analyse the topics discussed and methods used from the perspective of the entire domain perspective, including hot topics ranking, hot methods ranking, etc.

(3) Hot discovery module
Usually, scientists want to identify the hot topics and most common methods in a specific domain, the hottest and most reliable method for a specific topic, or the most common application areas for a specific method. The hot discovery module can fully satisfy these needs. On the one hand, the module can calculate the frequency of topics and methods, and rank them in a specific domain, and the results can show the hot rank list of different topics and methods in a specific domain. On the other hand, for a specific research topic, the frequency of corresponding method terms in the Method Set becomes the metric for hot discovery in this module, based on which we can obtain the most commonly used methods for a specific topic. In a similar manner, we can discern the hottest application area for a specific method.

(4) Trends analysis module
The main purpose of the trends analysis module in CS-LAS is to depict the evolution of methods for a specific topic or application trend of a specific research method. For a certain research topic, this module can calculate the document frequency of all methods for the topic (or all topics to which the method is applied), and obtain the time series sequences to present the trends.

(5) Correlation analysis module
In many cases, scientists would also like the system to recommend some methods that they may not be aware of that can solve the topic in which they are interested, or recommend new research topics to which methods that they are familiar with can be applied. This is why we designed the correlation analysis module for CS-LAS. By means of the collaborative filtering algorithm, this module can meet users’ needs. In the results of this module, detailed bibliographic information is also provided, and users can confirm whether or not the recommendations are appropriate for them.

(6) Data management module
The last module of CS-LAS is the data management module, which comprises three sub-modules: 1) system management; 2) spider management; and 3) extraction management. First, the system manager can modify and maintain the system through the web interface, such as modifying the path of the data files, data updates, etc. Second, the manager can set the period of data collection and the html parser by utilizing the spider management module. Finally, the extraction module allows the manager to add, delete, and modify the extraction rules.

Implications of literature analysis system
In this article, we take computer science as an example to realize a literature analysis system based on term function recognition (TFR), and name this as CS-LAS (i.e., Literature Analysis System for Computer Science). The implementation process of CS-LAS is shown in Figure 2, which can be divided into four steps: 1) the collection of raw data; 2) data processing, generating the Method Set, Topic Set and Topic-Method Set, and indexing them; 3) the implementation of retrieval and analysis modules; and 4) UI design and visualization of the results. This section will explicitly describe the issues that need to be addressed in each step.
Data collection
With the purpose of raw data collection for CS-LAS, we manually obtained the html pages of 307,455 articles published between 1994 to 2013 in the field of computer science from CNKI, which is the largest Chinese academic journal database. We then use an html parser, called Jsoup, and regular expression to parse the html pages and extract the bibliometric information of each paper, including the title in Chinese and English, publication year, author, abstract in Chinese and in English, keywords in Chinese and English, etc. Moreover, in order to adapt to the dynamic features of academic resources, the system can update data in an automatic and dynamic manner. In addition, the users can manually set the retrieval strategies and period of the data collection through the data management module, which can guarantee the accuracy and timeliness of the data set.

Construction of Topic Set and Method Set
For the construction of the Topic and Method Sets, we use extraction rules to extract functional topic terms or method terms from scientific papers that have been pre-processed. The extraction rules are generated by regular expression from the titles of the papers, which can be modified by users through the extraction module. The specific process of functional term recognition and extraction is as follows.

(1) Generation of extraction rules
Through observation of the Chinese and English titles of the academic papers, we found that there are a large number of titles written in the format of “基于 M 的 P” (an example is shown in Figure 3), which accounts for 28.9%. In the meantime, a title in this form can usually clearly express the main research topic and method of the paper, which inspired us concerning how to extract the main topic and method terms from the academic papers. In order to avoid the complexity of Chinese word segmentation and multi-expression of Chinese

Figure 2. Implementation process of CS-LAS.
terms, we decided to choose the English titles of papers, whose Chinese titles are in the format of “基于 M 的 P”, to be our experiment data set for the generation of extraction rules and functional term extraction.

After the pre-processing, including case conversion, word segmentation, de-symbolization and stemming, we represented the title of each paper as a word sequence $T = [W_1, W_2, W_3, \ldots, W_j]$. We also constructed a table of structural words $R = \{r_1, r_2, r_3, \ldots, r_j\}$ by observing the titles in the data set; every title can be treated as a word lattice, in which Chinese words like “基于” “的” “研究” and English word like “research” “on” “based” are structural words (an example shown in Figure 4). Next, we used a computer to automatically compare each word in $T$ with all words in $R$; if $W$ exists in $R$, then keep it and replace the others with “<word>”. Then, we use one “<word>” to replace all “<words>”, and can obtain the combination format of titles. Finally, we need to discern whether “<word>” in each format is a topic term or a method term manually: if “<word>” is a topic term, we replace it with “<Topi”c>”; otherwise, we replace it with “<Method>”. Table 2 shows the top eight combination formats of article titles in computer science and the corresponding extraction rules.

![Figure 3. An example for titles written in the format of “基于 M 的 P”.

(2) Term function recognition and extraction

We used regular expression based on the extraction rules to match the topic and method terms with the English title of each paper. Finally, we obtained 30,145 Topic-Method relationships, which comprise 23,221 non-repeating topic terms and 18,427 non-repeating method terms. To verify the effectiveness of the extraction experiment, we randomly selected 1,500 results to test, and the accuracy is 97.6%. By indexing the papers with their topic and method terms, respectively, CS-LAS can provide users with much more precise retrieval and a better user experience.

Implementation of retrieval and analysis module

To implement the retrieval module, on the basis of indexing papers with topic terms and method terms extracted, we utilized classical information retrieval models, such as BM25, to retrieve papers and rank the results for users. The analysis component of this system contains three aspects: 1) the detection of trends; 2) hot spot discovery; and 3) correlation analysis. CS-LAS uses a statistical analyzer written in the Java programming language and classical data mining algorithms to analyze the Method Set, Topic Set, and Topic-Method Set to complete the three tasks.

User interface and visualization

CS-LAS employs a popular web-based visualization tool, called d3.js, to present the retrieval and analysis results for users. The main interface of the system comprises three parts: 1) retrieval interface; 2) navigation interface; and 3) analysis interface. Regarding the retrieval interface, when a user enters the query into the search box, he or she can press an interactive button to choose to retrieve the “research topic” or “research method”. Figure 5 shows the result of the retrieval of a research topic, i.e., “image segmentation”. In the upper-left corner of the picture, the most common methods used for solving this topic are presented, which are represented by a dynamic word cloud. Specifically, the greater the document frequency of a research method term, the deeper the color of the term in the word cloud. When the term is clicked on, the corresponding detailed bibliometric information about that article is shown. In the upper-right corner of the picture, the distribution of documents on this research topic is shown, i.e., the number of academic works about this research topic in each year. The bottom of this picture is a dynamic presentation of the papers in the upper-right corner, which contains the title, each paper’s year of publication, and a hyperlink to detailed bibliometric information.

In the navigation interface, users can browse all topics discussed and all methods used in the computer science article set. In the meantime, the system can automatically retrieve a research topic or a research method when it is clicked on.
Figures 6 and 7 are the visualization results of hot spot detection and correlation analysis. In Figure 6, users can control the analysis time limitation to generate the overview of hot topics and hot methods in a domain. The topics and methods are cross-represented on the structure of a hierarchy tree, in which the root of the tree represents that its son node is a topic (or a method), and the nodes in the next level indicate the methods used for (or the topics solved by) its parent node. When the node (except for the root node) is clicked on, the correlation analysis will be presented in the results, as shown in Figure 7. For example, when we click on the research method “SVM”, there will be three tables in the result pages. The first table is the topics in which SVM has been used, the second table is the methods in computer science that are similar to SVM, and the last table is the topics to which SVM may be applied. Each table has three columns: 1) rank, which represents the score obtained from recommendation algorithms; 2) the name of topics (or methods); and 3) the corresponding literature.

Figure 7. Correlation analysis results of research method “SVM”.
Discussion and Conclusion

In this paper, we presented CS-LAS, a novel literature analysis system that implements semantic analysis of scientific literature from the perspective of term function recognition (TFR). CS-LAS is a tool that may be quite useful to detect hot spots and to depict evolution trends of a specific academic domain, to recognize the most popular method for a specific topic, to recommend a possible method for an existing topic, etc. It can also provide much more precise retrieval and navigation for users. In the future, we plan to construct a larger Topic-Method Set, which might facilitate a major improvement of the analysis module. In addition, the recognition of term function in academic text that we conducted by a rule-based approach constitutes the key point of this study. To improve our system, an exploration of new methods, such as machine learning and deep learning, should be performed in future work.

Abstract
This work looks in depth at several studies that have attempted to automate the process of citation importance classification based on the publications’ full text. We offer a comparison of their individual similarities, strengths and weaknesses. We analyse a range of features that have been previously used in this task. Our experimental results confirm that the number of in-text references are highly predictive of influence. Contrary to the work of Valenzuela et al. (2015) [1], we find abstract similarity one of the most predictive features. Overall, we show that many of the features previously described in literature have been either reported as not particularly predictive, cannot be reproduced based on their existing descriptions or should not be used due to their reliance on external changing evidence. Additionally, we find significant variance in the results provided by the PDF extraction tools used in the pre-processing stages of citation extraction. This has a direct and significant impact on the classification features that rely on this extraction process. Consequently, we discuss challenges and potential improvements in the classification pipeline, provide a critical review of the performance of individual features and address the importance of constructing a large-scale gold-standard reference dataset.

Conference Topic
[i] Citation and co-citation analysis [ii] The theory, method and principle of five metrics science concepts, that is, Bibliometrics, Informetrics, Scientometrics, Webometrics and Knowledgometrics. [iii] Methods and techniques.

Introduction
Citation analysis and bibliometrics are being increasingly used as a tool in assessing the impact of research. The three largest citation databases; Google Scholar, Web of Science (WoS) and Scopus all give prominence to citation counts to provide information regarding the number of times a paper has been cited. Most measures widely used to measure performance of research, such as the controversial Journal Impact Factor (JIF) [2], h-index [3] and Eigenfactor [4], rely on citation counts. All of the above methodologies suffer from the same base limitation in treating all citations equally.
It has been long established that treating all citations with equal weight is counterintuitive. Garfield, the original proponent of the JIF [2], proposed a range of 15 different reasons a paper may be cited [5]. These can include such reasons as: paying homage to pioneers, substantiating or refuting the earlier work of others, identifying methodologies used or simply giving background information regarding previous work. It can be seen from Garfield’s original list that simply counting citations cannot paint an entire picture of a papers impact.
Therefore, there is an increasing need in the automatic identification of the nature of a particular citation. Additionally, the growing availability of publication full texts is now making it possible to extend bibliometric studies further than those previously attempted with analysis of abstracts and citation networks alone. Open Access repositories such as that provided by
CORE1 [6] are allowing researchers to utilise the full text of research papers and articles in ways not possible with the meta-data offered by bibliographic databases alone. This has given rise to new areas of study including Semantometrics [7] which attest that the full text of a publication is required to effectively ascertain its impact.

In this paper, we address the problem of identifying influential citations based on publications’ full text. The rest of the paper is organised as follows. In Section 2, we introduce key studies on which our work is based. We then discuss the approach for detecting influential citation, providing a critical analysis of features previously applied in this task in Section 3, selecting a set of three key features for further analysis. We present a comparative study of the identified features in Section 4, together with the challenges inherent in this task.

Related Work

There have been several different methodologies applied to this task, Teufel (2006) [8] focuses on semantic similarity, identifying cue-phrases in the citing paper such as “we used” or “further to the work of”. Citations are classified into 11 types, which are then grouped into the higher grain categories of weak, positive and neutral sentiment. Later studies expand this and, rather than classifying only according to sentiment, attempt to classify citations as either influential or non-influential.

Hou et al. (2011) [9] first suggest the idea of using an internal citation count based on the full text of a research paper rather than just the bibliography to determine influence. They demonstrate a positive correlation between the number of times a citation occurs and its overall influence on the citing paper. Zhu et al. [10] combine these earlier approaches and suggest a range of 40 classification features including both semantic and metric features to determine influence. Most recently, [1] made significant efforts to construct a reference set which was publicly released and which this study relies heavily on. They suggest a range of 12 features, many of which show similarity with those of [10]. The features in these studies can be divided into having internal reliance or having external reliance. The former requires only the full-text of the citing paper whereas the latter relies on additional, external information being available. Furthermore, these studies identify three essential feature types. They are semantic based features, similarity based features and metrics / count based features. All of the studies under consideration use a range of different features and test them on different datasets. Consequently, getting a deeper understanding of which of the previously suggested features are most effective at this task is needed.

Methodology

- The typical workflow for classifying citation types involves the following steps:
  - Extracting the full text of the manuscript.
  - Parsing the full text to detect the document structure, such as the document metadata, references, citation markers and sections.
  - Extracting the features from the document structure, possibly with an enrichment step for features based on external evidence.
  - Applying a classifier trained using supervised machine learning approaches. In the rest of this section, we describe this workflow concentrating on the selection of features used in the citation type classification task.
Extracting the full-text and parsing

Unless a paper is available in a structure format, such as an XML, there is a requirement for converting the original PDF file into full text prior to analysis. There are numerous tools available for the conversion of PDF to text files. However, automatic text extraction from PDF is known to be problematic [11]. Some tools for inferring the document structure, such as ParsCit [12], require initial conversion to plain text. Others, such as GROBID [13], operate directly on the PDF file.

Features used by prior studies

One of the overriding aims of this work is to establish which of the previously identified classification features perform most strongly as predictors of citation importance and to use this as a baseline from which to build future work. We consider the features presented in the two most recent studies. In [10] we first see an expansion of the features into a rich range that move beyond simple counting of in-text citations;

- Count-based features
- Similarity-based features
- Context-based features
- Position-based features
- Miscellaneous features

Valenzuela et al. (2015) [1] take a similar approach to the construction of the features list. The 12 features used in this study are;

- F1 Total number of direct citations
- F2 Number of direct citations per section
- F3 Total number of indirect citations and number of indirect citations per section
- F4 Author overlap (Boolean)
- F5 Citation Is considered helpful (Boolean)
- F6 Citation appears in table or caption
- F7 1 / Number of references
- F8 Number of paper citations / all citations
- F9 Similarity between abstracts
- F10 PageRank
- F11 Number of citing papers after transitive closure
- F12 Field of cited paper.

Selection of features for experiments and comparison

We analysed the 40 features presented by Zhu et al. [10] and 12 features presented in the study of Valenzuela et al. [1] Of the 40 features, a combination of just 4 features resulted in the best performance of Zhu's model. Adding features beyond this actually lowered the performance. Out of these 4 features, we could not reliably replicate one feature (countsInPaperSecNum). Out of the 12 features of Valenzuela (Table 1) we found three features irreproducible (F3, F5 - We attempted to reproduce this feature, but failed due to Valenzuela's dictionary of cue words not being available, F12), we were unable to reliably replicate two features due to PDF extraction issues (F2, F6) and we elected not to use two features as they rely on external and
potentially changing evidence (F10, F11). Two features we tested (F7, F8) did not produce any significant correlation with the gold standard.

Of the three remaining features of Valenzuela, we found a complete overlap of two features (F1-countsInPaperWhole, F4-aux\_SelfCite) and a close match on the third (F9-simTitleCore). These three selected features correspond to the best (F1-countsInPaperWhole) feature of Zhu, the worst feature of Valenzuela (F9-simTitleCore) and a third where the opinion regarding the usefulness of this feature was divided between the two studies (F4-aux\_SelfCite). In the rest of the paper, we will provide a direct cross-comparison of these features on a single dataset:

**Number of direct citations (Integer):** This feature is labelled by [1] as 'F1 - Direct Citations' and by [12] as 'countsInPaperwhole.' Both of these studies, and the earlier study by [hou2011counting] find the total number of times a paper is cited to be a strong indicator of academic influence on the citing paper.

**Abstract Similarity (Real):** This is feature F9 in the study by [1]. Whilst [10] tested various similarity based features, none performed better than their randomly assigned baseline (equivalent to the prior distribution of the influential label in their dataset). Valenzuela et al. [1] also listed this as the weakest feature. This feature is calculated as the tf-idf cosine similarity between citing paper abstract and cited paper abstract.

**Author Overlap / Self-Citation (Boolean):** This feature is labelled F4 by [1] and as [10]. The two studies differ markedly in their opinion of the value of this feature. While [11] found little correlation between author overlap and influence, [1] listed author overlap as their third best performing feature.

**Classification**

Using the identified features, we perform a binary incidental / influential classification. WEKA 3 [14] was selected as the machine learning toolset in our study.

**Results**

**Dataset**

The dataset released by [1] contains incidental/influential human judgments on 465 citing-cited paper pairs for articles drawn from the 2013 ACL anthology, the full texts of which are publicly available. The judgment for each citation was determined by two expert human annotators and each citation was assigned a label. Both a fine-grained (4-Way) label and a binary (incidental / important) label were provided. Using the author’s binary classification, 396 citation pairs were ranked as incidental citations and 69 (14.3\%) were ranked as influential (important) citations.

It is extremely interesting to note that all studies which employed human annotators to judge citation influence [1,8,10,15] reported a broadly similar ratio of positive examples. This ranged from 10.3\% [10] through 14.3\% [1] to 17.9\% [8]. This is an important finding as it gives a clear indication that only a relatively small percentage of all citations are actually influential at all. All of the studies find that the majority of citations are perfunctory at best. Negative citations are extremely rare and this in itself further increases the difficulties in constructing a balanced reference set. Automatic identification of those influential citations is therefore both a more important and less straightforward task than may be first imagined.
To obtain a clean dataset for our experiments, we first collected the PDF files of the citing and cited papers used by Valenzuela et al. [1] from the ACL Anthology. We processed these papers using pdf2txtt [16] to extract metadata, citations, the full text and other document structure information. Any papers where the extraction was not possible or the abstract was not available were then removed. This left us with a dataset of 415 pairs with 355 citation pairs marked as incidental and 60 citation pairs (14.45%) marked as influential citations. As this corresponds to only a relatively small reduction in the number of examples from the original dataset and reflects the original ratio between incidental and influential citation classes, we consider this dataset to be sufficiently representative for our experiments. We then process the XML files using ParsCit and applied calculations to extract features for each example.

**Analysis and comparison of selected features.**

Our experiments tested a range of features and their efficacy as predictors of citation influence. We achieved the best results using the Random Forests Classifier. We tested the model using bagging with 100 iterations and a base learner, using a 10-fold cross-validation methodology. The WEKA toolset was used to generate P/R curves for each of the individual features as well as the combination of all the features (Table 1).

</tbody>
</table>

We also measured the correlation between each of the individual features and the classification given by the human annotators. Valenzuela et al. [1] present their results in terms of P/R values for each feature whereas [10] shows the Pearson correlation with their gold standard. We therefore present the results of our experiments in both formats to allow for accurate comparison. Our work confirms the earlier findings reported in [10] and [1] that the number of direct instances of a citation within a paper is a clear indicator of citation influence. We also find that author overlap, or self-citation, does have value as a classification feature. Contrary to the work of [1] we find that the similarity between abstracts is more predictive of citation influence than previously shown.

</tbody>
</table>

The correlation of this feature with the reference set (r=0.373, p < 0.01, 2-tailed) was the highest of all the features we tested. It is our contention that testing all features using P/R
values, at R0.90 masks some of the predictive value of those features when the dataset contains only a small number of instances of the influential class. Table 2 shows the precision of the random forests classifier at various recall levels. It can be seen from these results that the classifier initially performs quite well and identifies many of the influential cases, however it has difficulty identifying the last few instances which substantially decreases the classifier’s performance at R0.90. Using Mean Average Precision (MAP) or a similar metric that provides a single-figure measure of quality across recall levels would be a better choice in this case.

Results for Individual Features

Number of Direct Citations - F1: This feature is rated as the highest value in terms of predictive ability by [10] and the second highest by [1]. The latter shows P0.30 at R0.90, however our results demonstrate a slightly lower P value, P0.21 at R0.90.

Zhu et al. [10] list the equivalent ‘countsinPaper_Whole’ as the most significant feature of their classifier, with a Pearson correlation coefficient of P0.35. We find a Pearson correlation of P0.28 (significant at the 0.01 level, 2-tailed) for this feature with our dataset. The small difference in this result is likely caused by the differences in the two datasets. Our results therefore confirm that the number of times a citation appears is a strong indicator of that citation’s influence.

Author Overlap - F4: The results from the two earlier studies for this feature vary considerably. In the results for [1] this is the third ranked ‘most significant feature with P0.22 for R0.90. We find slightly less precision than [1] for this feature; P0.16 at R0.90. [10] results show little correlation with their gold standard for the similar feature aux_selfCite (Pearson 0.02). Interestingly, despite the low correlation, this feature was the fourth one selected by their model and
did indeed improve the performance of the classifier, albeit only slightly. The experiments with our dataset show a far stronger positive correlation, P0.132 (significant at the 0.01 level, 2-tailed), than that found by [10].

Abstract Similarity - F9: Whilst [10] generated many similarity-based features, they did not compare citing abstract and cited abstract. This is somewhat surprising as we consider it to be an interesting feature and one that also seems innately logical. The abstract similarity is calculated as the cosine similarity of the tf-idf scores of the two abstracts. By ensuring that the dataset only contains valid data, i.e. the abstract is available for both citing and cited paper, a direct comparison can be made for this feature with [1] who rank this as the lowest of their twelve features, P0.14 at R0.90.

Here our results are the same as [1], with P0.14 at R0.90. However, the Pearson correlation with the gold standard dataset for this feature is the highest of the three features tested in our experiments. We find a Pearson correlation of 0.373 (significant at the 0.01 level, 2-tailed). This feature was not tested by any of the other earlier studies covered in this work. Our results demonstrate that abstract similarity between citing and cited paper is more predictive of citation influence that previously shown.

The value of complex features.

It is now over a decade since Teufel [8] first attempted to automate the classification of citation function. This original study and several subsequent ones have suggested classification features ranging from the extremely simple to the extremely complex. Many of these complex features have been shown to have little predictive ability in regards to classifying citation function or importance. Some of the most basic features have been shown to offer the strongest potential
in identifying important or influential citations. Our research confirms that one of the most simplistic features, i.e. the number of times a citation appears in a paper, is highly predictive of influence. Replicating complex features is a non-trivial task unless exact details of how the values for these features were calculated or source code are provided by the original study. We believe that it is essential that the types and values of all features should be provided as part of the research dataset (as opposed to providing just source prior to feature extraction) to serve as a roadmap in replicating them. Furthermore, features that rely on external datasets, changing evidence (e.g. citations, downloads, etc.), or utilise sets of rules, that are not available to other researchers cannot be replicated by this or any other future study. There has now been a decade of research in this area and the predictive ability of many complex features is still uncertain. This is sorely detrimental to the overall value of the original studies.

Analysis of PDF extraction.

Both [1] and [10] use ParsCit - the citation parsing tool, based on Conditional Random Fields (CRF). As this is a critical pre-processing stage we conducted experiments to determine the efficacy and accuracy of this tool. GrobID [13] is a similar CRF based tool and was chosen to provide a comparison.

There are several types of errors that can be introduced during the PDF conversion process:

- PDF is a scan and would require OCR.
- Custom encoding instead of Unicode or ASCII.
- Readable XML file not created at all due to failed PDF conversion process.
- References not identified or counted correctly.
- Citations not identified or counted correctly.
- Abstract not extracted correctly or not present in cited paper.
- Title names / Author names misspelled in different parts of the paper.
- Elements being mis-tagged.

We argue that these errors unavoidably impact on the validity of any classification features that are reliant on this process. Of particular concern is the likelihood of citations being either under-counted or over-counted. The results of our experiments demonstrate that this is indeed the case in many instances. To understand the impact of this, we conducted the following experiment. Ten papers were randomly chosen from the Valenzuela dataset and the citation counts for each citation were extracted using both ParsCit and GrobID. The results of both tools were then compared to a manual check / count. [1] and [10] demonstrate that the number of times a citation appears in the body of the text is a significant indicator of influence. There is however a difference in the number of citations identified, depending on the chosen method of parsing. The reference count for five of the chosen example papers is shown in table 3.

These results show that ParsCit correctly identified the exact number of citations in only 40% of cases. GrobID was even less successful. It was exactly correct in only one case and missed a significant number of citations in many others. We argue that this demonstrates a potentially serious failing in current methodologies that rely on PDF extraction for calculation of number of citations.

Discussion

One of the major limitations of this and previous studies is the size of the publicly available, annotated, datasets. The study by [1] uses 465 citing / cited paper pairs. The study by [10] uses just 100 papers by 40 authors. Due to the unbalanced split between the incidental and influential classes, our complete dataset contained only 61 examples of the positive (influential) class. We argue that due to the relative sparsity of influential citations a much larger reference set is required. This is equally true for negative citations, which have been shown to be even rarer. Training a classifier when the dataset contains so few instances of the non-neutral classes is problematic and we will address this in future work. The construction of a gold standard dataset containing many thousands of annotated citations, rather than a few hundred, is a significant undertaking but we believe this is a vital step in improving the abilities of the classification models.

There is a noticeable difference between the datasets used by [10] and [1] which warrants further study. The [1] dataset annotation was undertaken by two independent annotators and finds significant value in using author overlap as a classification feature. However, the [10] reference set is annotated by the authors themselves and this study ranks author overlap / self-citation as being of very low importance. It may be that is demonstrates shyness or reticence on behalf of authors to regard their own, earlier, work as being a significant influence. A large-scale author-annotated reference set would be extremely helpful in ascertaining the level of this bias when compared to an anonymously-annotated dataset such as that of [8] or [1]. Finally we argue that if a citation is considered influential, this original influence remains regardless of external factors or the environment. Therefore, classification features which rely on external and potentially fluid information should be used somewhat cautiously. In future work we will address this issue in greater detail.

Conclusions

Of the features we tested we find Abstract Similarity shows the strongest positive correlation for predicting citation influence. We find Number of Direct Citations to also be highly predictive and we find Author Overlap / Self-Citation to be less predictive but still valuable as a classification feature. It is important to note that many of the features suggested by earlier studies have been shown to have little predictive ability. Additionally, despite significant efforts, we were not able to reproduce or validate several of the features used by [1] or by [10].

Furthermore, our results demonstrate that any automatic classification model that relies on PDF extraction in the pre-processing stage is unlikely to capture all of the relevant data which is fundamental to the calculation of the value of some features. We argue that this introduces a level of potential inaccuracy that has not been fully addressed. There is scope for further work surrounding the efficacy and in particular the reproducibility of some of the previously tested
classification features. Many of the earlier studies in this domain present results based on sometimes complex and irreproducible features. We contest that this is detrimental to this area of study as a whole and, whilst earlier studies have identified several effective features, having the ability to reproduce them is fundamental to further development in the area of citation classification.

Whilst it may be a relatively easy task for a human being to identify important or influential citations, building a model to automatically classify these citations with any degree of accuracy is a non-trivial task. A larger scale reference set than those used in this and previous studies is essential, particularly due to the inevitably skewed nature of any dataset of citations annotated according to influence or importance.

Abstract: Cited frequency of academic papers (APs) or academic monographs (AMs) are used to evaluate their academic influence usually. This frequency-based method does not consider detailed citation information, e.g., citation content or context, in citing paper. Citation context or content can reveal different citing motivation and behavior of authors. Citation content analysis (CCA) of APs or AMs can improve performance of their influence assessment. AMs are different from APs and they have characteristics in many ways. If we know the difference of citation content between AMs and APs, a more appropriate CCA method for AMS will be explored based on the existing CCA method of APs. Therefore, a comparison of citation content between AMs and APs is investigated in this paper. We annotated 39 academic monographs with 13, 539 citation sentences and 7, 756 academic papers with 590, 740 citation sentences respectively. Furthermore, we compared the location, mention times and length of citation content between AMs and APs and analyzed cause of the difference. The results quantitatively show that there are differences in location and length of citation between AMs and APs, while citation mention of the two is similar.

Conference Topic
Knowledge discovery and data mining

Introduction
Citation analysis includes citation bibliographic analysis and citation content analysis. Traditionally, citation analysis mainly used the bibliographic information including references of academic papers to assess academic influence of cited papers. Currently, more and more full-text of academic papers can be accessed via academic database, and it’s easy for us to obtain citation content of references in a paper. Many researchers began to analysis citation content and use it to academic influence assessment (Hu, Chen & Liu, 2013; Zhang, Ding & Milojevic, 2013; MasakiEto, 2013; Wan & Liu, 2014; Bertin, Atanassova, Larivière & Gingras, 2015; Tahamtan et al,2016). At present, citation content analysis (CCA) is mainly based on academic paper according to three aspects: syntactic, semantic and pragmatic (Small, 1982; Chang, 2013; Jeong, Song & Ding, 2014). To the best of our knowledge, this paper is the first work that analyze citation content of academic monographs. Compared with journals, updating of academic monographs has a time delay, and monographs have richer and longer contents. Besides, the lack of full text data makes it difficult to extract large-scale citations from academic monographs. So, there is no relevant research on monographs’ citation content. At the same time, APs and AMs are both important knowledge carrier. What is the difference or similarity between their citation characteristics? What is the reason for these difference or similarity? These questions haven’t been investigated in the existing

* Corresponding author, Email: zhangcz@njust.edu.cn
works. Based on this study on the difference of citation content between AMs and Aps, we would explore a fit CCA method for AMs. Therefore, a comparison of citation content between AMs and APs is investigated in this paper. 39 academic monographs (APs) and 7,756 academic papers (APs) are chose. We compare their citation content from three aspects: location, mention times and length, and find AMs has similar citation mention to APs, but location and length of citation of the two are different.

Related works

Citation content analysis of academic papers

Citation content analysis of academic papers contains three levels: syntactic, semantic and pragmatic. From the syntactic point of view, scholars mainly study the citation location, citation mention and length of citation by analysing the full text of academic papers. As early as 1976, Voos and Dagae (1976) conducted a research of the citation location. They selected four highly cited papers and found that citations at different positions had different value and purpose. Highly cited papers are more prone to appear at “Introduction” section. On that basis, Ding et al. (2013) adopted a new method, namely “count X”, and found that highly cited papers were more gathered in “Methodology” section. In general, the first 10%~15% of the full text was the densest filed where citations located, and half of citations were located in the first 30% of the full text (Halevi & Henk, 2013). In four-section (IMRC) papers, citations were more likely to locate in the section of Introduction. While inside section, citations were distributed evenly and randomly (Hu et al, 2013). Studying the position can help scholars to understand the distribution of citations in the full text. Statistics of the cited frequency of a reference can be used as the measure of its influence. By traditional methods only the number of times which the paper appears in the reference list were counted. Zhu (2013) built four different influence prediction models and observed that the times of a paper mentioned in the full text (count X) was the best standard to measure impact of the paper. Regarding to the average number of citations mentioned in a paper, the results of the early studies are low——for about 1.10 and 1.20 (Bluma C, 1983; Oppenheim & Renn, 1978). In recent years, mentioned times of general papers have risen to 1.50~1.79, and that of highly cited paper is 1.90~2.00 (Ding et al, 2013; Wan & Liu, 2014). There are few researches refer to the length and the number of words of citation sentences. A small amount of results show that the average number of words of citation is 26, and the length is mainly in the range of 0~200 characters.

In addition to the syntactic analysis, Scholars also carried out semantic research on citation content. As early as 1986, Small (1986) used the topic word in citation content to reveal the co-citation network clustering theme. Nanba and Okumura (2005) collected all the citation content of a paper, and described the main content of the paper by analyzing keywords of the citation. The researchers mainly studied the difference between the subject form by citation content and the abstract of the citation itself, and did not analyze the reason of the difference.

Pragmatic analysis mainly explored the emotion (Small, 2011), functions (Lin et al, 2014) and motivation of citations. Garfield (1964) first proposed 15 motivations of citation. Small (1982) and White (2004), respectively, explored the motivation in the field of information science and linguistics. Weinstock (1971) used the citation content to systematically summarize the motivation of citation and pointed out 15 motivations...
for scientific communication. However, these work only categorized the motivation and do not investigated its value in citation analysis.

Citation analysis of academic monographs

Scholars usually have to cite plenty of references during the writing of their monographs. Researchers carried out a series researches on the citations of monographs. Statistics of the source of citations in books indicated a complementary relationship between the three academic databases, i.e. WOS, Scopus, Google Scholar (Bar-Ilan, 2010). Torres-Salinas (2013) mapped citation patterns of book chapters in the BKCI and observed that the citation patterns of book chapters followed a Lotkaian distribution. Hammarfelt (2013) mined the interactive mode of disciplines and knowledge structure in humanities and social science filed based on the analysis of highly cited monographs. Some scholars compared academic monographs with academic papers at the same time to measure the value of academic monographs in academic exchanges. Thompson (2002) investigated the source and destination of citation in academic monographs and found that academic monographs played an important role in examining publishing models. Kousha and Thelwall (2009) analysed the same papers that were cited in different books and papers, the results indicated the book in Google Book Search could make up for the book citation shortage in ISI. On this basis, Kousha and Thelwall (2013) used the new Google Book citation automatic extraction method and compared the extractive results with BKCI, which showed there was a very high correlation between the two, even Google Book performed better in some areas. Chi (2016) analyzed the data of BKCI and observed that the referenced influence of humanities books and that of journals were quite different, while the influence of social science books and that of journals were similar.

In a word, existing works of citation content analysis at syntax level still mainly target academic papers. By using bibliographic information in academic monographs, most of citation analyses of academic monographs only focus on data source, transmission pattern and so on. There is not any woks that investigate citation content characteristics of monograph.

Methodology

In this paper, comparative analysis of citation content (CC) between AMs and ACs according to location, mention times and length of citation content respectively.

Dataset

The dataset contains 39 academic books1 from Morgan & Claypool2 and 7,756 papers from Public Library of Science (PLOS). The academic monographs are in PDF format and academic papers are available in XML format, both of them are related to two disciplines——Biology and Computer Science.

Data Annotation

We extract citation content of 39 monographs manually, and 7,756 articles automatically respectively. Meanwhile, other relevant information is annotated, such as citation context, references, and chapter numbers. In this paper, citation context includes the first and second sentence previous to citation sentence and the first and second sentence after

---

1 All of the 39 books were manually judged as academic monographs. A detailed explanation of the data scale is given in Section 5.1
2 http://www.morganclaypool.com/
citation sentence. Section means the chapter in AMs and the section in APs. A citation
refers to a sentence that contains quote marks, and the reference means the cited article
in the citation. One citation could contain more than one reference. Meaning of labels
is shown as Table 1. We obtain 13, 539 and 590, 740 citation sentences from AMs and
APs respectively.

Analysis of three aspects of CC
Using citation content and its related information from previous steps, we make statistics
about the characteristics of CC in AMs and ACs respectively.
(1) Location of CC
We get relative positions of each citation in the full text by "word_location / word_total",
and calculate "section_location / section_total" to obtain relative position of each
citation in each section.
(2) Mention of CC
Just to be clear, if an article contains 10 citation sentences and each citation contains 3
references, and there are 20 references in the reference list of this article. Then number
of citations of this article is 30, and number of reference of this article is 20.
First of all, in terms of full text, we count number of citations and references of all the
papers and monographs based on the “citation_id” and “reference_total”, and calculate
ratio of the two. After that, number of citations in each monograph and paper are counted
to calculate the ration of citation to reference. We call the ration “mention of citation
content”
In terms of chapter, number of citations are counted by each chapter, we remove
repeated reference to get the number of references and obtain the “mention of citation
content”. On this basis, we normalize each chapter and compare the mention of citation
in different chapters.
(3) Length of CC
In this article, we regard number of words as length of a sentence. In the end, we count
number of words in each citation sentence and its context respectively, and obtain the
average length of citation content and citation context. The average length of CC is taken
as standard to normalize all the average length of citation context. To discover the
difference in length of CC between monographs and papers, the Kolmogorov-Smirnov (KS) test is carried out showing that the results are highly significant (p<0.01) for all variables.

For the analysis of three characteristics in the ahead section, we organize them with tables and graphs, and compare the location, mention and length of citation content between AMs and AC.

**Comparison Results of Citation Content between AMs and APS**

*Location of citations*

*Location of citation content in full-text*

Distribution of citations in full text of 39 academic monographs is shown as figure 1. According to figure 1, we can see: distribution of citation contents in full text of academic monographs is uniform and there is no obvious concentrated field.

![Figure 1. Distribution of citation content of academic monographs](image1)

The relative location of each citation sentence of academic paper is shown as figure 2. According to figure 2, it is easy to find that citation contents are mainly distribute at both ends of papers while citation content in the middle of papers are sparser. In particular, the first 15% of full text is the densest field where citations locate.

![Figure 2. Distribution of citation content of academic papers](image2)

*Location of citation content in chapter and section*

Figure 3 displays distribution of citation content in chapter of academic monographs, where each column represents a chapter. In 39 monographs, citation content evenly
distributes among the chapter. There are no significant differences between different chapters, either.

Each column in Figure 4 represents each section of each academic paper. Distribution of citation content in section of academic papers is also uniform, but density of citations at the end of each section (after the relative position of 0.8 in the figure) is significantly sparser than the previous part.

Figure 3. Distribution of citation content in chapter of academic monographs
Figure 4. Distribution of citation content in section of academic papers

In conclusion, citation content evenly distributes in full text of monographs, but there is an obvious concentration of citation content in academic papers. Furthermore, citation sentences are evenly distributed in the different sections of both academic monographs and academic papers.

**Mention of citation content**

**Mention of citation content in full text**

Regarding 39 monographs as a whole, number of references is 8, 885 and number of citations in full text is 13, 539, mention of citation is 1.52, that is, each reference is averagely cited 1.52 times.

As for each monograph, amount of citation content, amount of references and ratio of the two is shown in Figure 5 and Figure 6 respectively. With increase of amount of references, there are many twists and turns in line of citation content. Therefore, amount of citations is not in direct proportion to number of references. But mention of citation content is more than 1 and it concentrates at 1 to 1.5 in most of academic monographs, which means at least there is a repeated citation in each academic monograph.

Figure 5. Amount of citations and references in monographs
Figure 6. Mention times of citation content of monographs

We obtain 370, 508 references and 590, 740 citations from 7, 756 academic papers, and the mention of citation content is 1.59. Figure 7 indicates that as amount of references increases, amount of citations is increase, but there are some fluctuations on the line, which also proves that the total amount of citations is not directly related to amount of references. And then we calculated ratio of the two, in 7, 756 papers, and only 28 papers’ ratio is 1, which shows that most of academic papers contain repeated citation. The ration of more than half of the papers concentrates in 1 to 1.5, and only 69 papers’ ration goes over 3, accounting for less than 1%. The overall distribution is shown in Figure 8.
Mention of citation content in section

Each spot in Figure 9 represents mention of citation content in each chapter of each academic monograph. We order them by relative chapter. It reflects that average mention of citation content in each chapter is mainly in 1.0 to 1.5. Most chapters whose mean mention of citation content beyond 2.5 are after the 0.5 chapter, which indirectly implies that highly cited references are mainly in the latter half part chapters of academic monograph.

In Table 2, the average mention of citation content is calculated per 10% of total chapters. Frequency of the first and the last section is obviously lower than others sections. And mention of citation content in different 10% chapter is irregular.

Each column in Figure 10 is frequency of citation mention times of each section of each academic paper. The most of frequency is still between 1 and 1.5.

Subsequently, we rank previous results by each 10% of total sections. The result is shown in Figure 11. If ration of citations to references reached 3, we think there are more highly cited references. So, in academic papers, a high time of citation mention is more likely to appear at the 40%-80% of total sections, that is the latter part of the paper.

Calculating average mention of citation per 10% of total sections, we could see average mention of citation in middle section is higher than the beginning and the end of the paper (see Table 3).

![Figure 7. Amount of citation content and references of academic papers](image1)

![Figure 8. Mention of citation content of academic papers](image2)

![Figure 9. Mention of citation content in relative chapter of monographs](image3)

<table>

<td>1.37</td>
<td>1.46</td>
<td>1.30</td>
<td>1.20</td>
</tr>
</tbody>
</table>

Table 2. Average mention of citation content in relative chapter of academic monographs
In general, the mention of citation content of monographs is almost similar to that of papers. But unlike the irregularity of academic monographs, the median section of paper has a higher mention of citation when compared with the beginning and ending sections.

**Length of citation content and citation context**

<table>
<thead>

<td>AM</td>
<td>26.39**</td>
<td>1.00</td>
<td>25.28</td>
<td>0.96</td>
</tr>
</tbody>
</table>

**Significant at p<0.01**

Original average length and normalized length of citation content and citation context are presented in Table 4. It is obvious that length of citation content between academic monographs and papers has significant difference (Z=-1.26E-301, p=0). Citation content in academic papers is longer than citation content of academic monographs, but average length of citation context of the two is similar.

As for citation content and citation context, average length of the sentences closes to citation content (previous_1, after_1) is slightly larger than that of the sentences far from citation content (previous_2, after_2), and the difference of length between citation content and citation context of academic papers is particularly more evident than that of the monographs.

**Discussion**

*The data scale in this investigation*

In order to investigate whether magnitude of samples have an effect on the results, we randomly select 8 academic monographs, 40 academic papers and 400 academic papers to analyze location, mention times and length with the same previous methods respectively.

Figure 12 and figure 13 indicate that location of citation in full text of 8 academic monographs is similar to 39 academic monographs, and location of citation in full text 40, 400, and 7,756 academic papers are same, too. What’s more, the sampling results of
mention times and length don’t have difference with original results (Detailed comparison is not showed due to space limitations of this paper). Therefore, the differences between data scale of AMs and APs won’t be an interference factor on the analysis results.

![Figure 12. Location of citation in full text between different scales of academic monographs](image)

**Figure 12. Location of citation in full text between different scales of academic monographs**

![Figure 13. Location of citation content between different scales of academic papers](image)

**Figure 13. Location of citation content between different scales of academic papers**

**Reason of the differences between AMs and APs**

From previous analysis, it is obvious that there are great differences between AMs and APs in location of citation content, which is closely related to the content arrangements of academic monographs and academic papers.

In general, the opening part of academic paper is introduction and literature review and contains a large number of citations. The middle of paper is a self-statement part of author which don’t need too many citations. Some authors may compare their own work with others’ research results and even move the related work to the end of paper. As for academic monographs, contents of whole book are interlinked but the authors may treat each chapter as an independent unit and cite reference evenly. So, the overall distribution of citations in academic monographs presents a more homogeneous state, however, there is an obvious concentration of citation in academic papers.

**Suggestions to citation content analysis of academic monographs**

The same distribution of citation content in different sections suggests that we have no need to consider position of citation in section when examining importance of citations. The same average time of citation mention implies method of measuring academic influence of a paper or author by total cited times can also be used in evaluation of citation in academic monographs.

Compared with academic papers, length of citation context in academic monographs is closer to the length of citation context, therefore, we are supposed to pay more attention when we make a syntactic analysis between citation context and citation content of
academic monographs. And we will explore specific reason of the difference in length of citation between academic monographs and academic papers.

**Conclusion and Future Works**

Nowadays, with the opening of full text database, more and more scholars begin to use full text of academic papers to explore citation content. On this basis, this article makes a comparative analysis of citation content in 39 academic monographs and 7,756 academic papers. The result indicates that there are obvious differences in location and length of citation between the AMs and APs, while citation mention of the two is familiar.

This paper is only a preliminary research, which still exists limitations. First of all, there is a gap between the data scale, since few full-text database of academic monographs are open to public. But our study has shown that the citation content of academic monographs has their own unique characteristics. Therefore, if full-text database was available, we can carry out a broader and deeper research on citation of academic monographs. Secondly, the AMs and APs studied in this paper are from two major disciplines. In the future, more disciplines and fields would be investigated using their monographs and papers. Finally, this article just carries out a syntactic research with some simple methods. We would extend our research from syntactic level to the semantic level, with help of the citation content and its context to explore the citation motivation and other semantic research work.

Abstract
Knowledge diffusion based on scientific collaboration is similar to disease propagation through actual contact. Inspired by the disease-spreading model in complex networks, this study classifies the states of research entities during the process of knowledge diffusion in scientific collaboration into four categories. Research entities can transform from one state to another with a certain probability, which results in the evolution rules of knowledge diffusion in scientific collaboration networks. The knowledge diffusion model of differential dynamics in scientific collaboration of non-uniformity networks is formed, and the relationship between the degree distribution and evolution of knowledge diffusion is further discussed, to reveal the dynamic mechanics of knowledge diffusion in scientific collaboration networks. Finally, an empirical analysis is conducted on knowledge diffusion in an institutional scientific collaboration network by taking the graphene field as an example. The results show that the state evolution of research entities in the knowledge diffusion process of scientific collaboration networks is affected not only by the evolution states of adjacent research entities with whom they have certain collaboration relationships, but also by the structural attributes and degree distributions of scientific collaboration networks. The evolution of knowledge diffusion in scientific collaboration entities with different degrees also shows different trends.

Conference Topic
Knowledge discovery and data mining

Introduction
Knowledge plays a vital role in economic growth, which is generally acknowledged by endogenous growth economists (Kline & Rosenberg, 1986; Lucas, 1988; Romer, 1990). The power of knowledge depends on whether the knowledge is diffused and on the diffusion depth and breadth, in addition to the value of the knowledge (Bacon, 1908). When knowledge is diffused, information and experiences gained by both sides would increase linearly; if the knowledge is further diffused with constant feedback and extension of the problems concerned, the information and experience would even increase geometrically (Quinn, Anderson, & Finkelstein, 1908). The knowledge societies are characterized by the proliferation of knowledge-intensive communities, specialized in knowledge production and reproduction, knowledge acquisition and exchange, and the use of information technologies (David & Foray, 2002; Yan, 2016). The production and creation of knowledge are not dependent on a single isolated entity; instead, knowledge is diffused, exchanged, and circulated among various entities (Crane, 1972). The competitiveness and the potential competitiveness of institutions are embodied in the acquisition and mastery of knowledge and innovative capacity (Drucker, 1999). Effective diffusion of knowledge can better promote their competitiveness and research level, and make optimal use of knowledge. Knowledge diffusion is the link between knowledge acquisition and knowledge application. It has become an important subject of common concern to realize more effective diffusion and management.
of knowledge (Cronin, 1982; Rogers, 2003; Chen & Hicks, 2004; Lambiotte & Panzarasa, 2009).

Many efforts have been made to improve the understanding of knowledge diffusion in various networks. According to the connection strength of network members, Granovetter (1973) proposed a weak ties theory of social networks, emphasizing the significance of "connection" between network members in knowledge and information diffusion. Cowan and Jonard (2004) and Kim and Park (2009) compared knowledge diffusion in regular, random, and small-world networks, and found that the small-world network is the most efficient structure to diffuse knowledge. Tang, Xi, and Ma (2006), and Lin and Li (2010) argued that the scale-free structure is more effective for knowledge diffusion.

Within the context of the growing complexity of research, collaboration has been considered one of the most crucial and common phenomena in the science community (Persson, Glänzel & Danell, 2004; Wuchty, Jones, & Uzzi, 2007; Adams, 2013; Chung, Kwon, & Lee, 2016). The process of scientific collaboration is also accompanied by the diffusing, sharing, and exchanging of both explicit and tacit knowledge among scientific research entities (Singh, 2005). Collective knowledge production and diffusion processes in science and technology have captured the attention of sociology of knowledge scholars throughout history (Mannheim, 1968; Kuhn, 1970; Scheler, 1980).

A scientific collaboration network, especially the co-authorship network formed by scientists in a deliberate and cautious way, is a structured form of knowledge exchanging and sharing among collaborators. The autonomous and self-organizing nature of scientific practices in knowledge creation and diffusion determines that the scientific collaboration network is the most appropriate mode of knowledge transmission and diffusion (Autant-Bernard, Mairesse & Massard, 2007; Ozel, 2010; Yang, Hu, & Liu, 2015).

Knowledge diffusion based on scientific collaboration is similar to disease propagation. In the process of scientific collaboration, knowledge exchange and diffusion can take place by the social collaboration connection among research entities including individuals, institutions, regions, countries, and so forth, while disease is usually propagated among organisms through air, food, contact, matrix, blood, and so forth (Anderson & May, 1991). From the perspective of information theory, both knowledge diffusion and disease propagation are composed of four elements that are the same in essence: information, information source, information channel, and information sink (Shannon, 1942).

The modeling of knowledge diffusion in scientific collaboration networks can help visualize the knowledge diffusion process through scientific collaboration, reveal the dynamics mechanism of knowledge diffusion in scientific collaboration networks, and realize more effective management and regulation of knowledge diffusion.

**Literature Review**

Studies on evolution mechanisms and the law of dynamics of knowledge diffusion are conducted from the perspective of model building, the current quantity of which is relatively small, with a majority of the research being qualitative. Usually, well-developed models from such fields as epidemiology, complexity science, and sociology are referenced. The knowledge diffusion process is accompanied by the generation and evolution of the knowledge diffusion network, and the construction of the knowledge diffusion model requires a tangible or intangible carrier network for knowledge diffusion. Currently, most scholars regard co-authorship (Eslami, Ebadi, & Schiffauerova, 2013) and literature citation relationships (Tsay, 2015; Zhu & Yan, 2015) as the paths to knowledge diffusion, and explore abstract representations of the knowledge diffusion process. The present knowledge diffusion models include the citation path model (Lu & Liu, 2013; Yu, Lu, Liu, & Zhou, 2014; Yan, 2014), epidemiological model (Bettencourt, Cinron-Arias, Kaiser, & Castillo-Chávez, 2006;
Epidemiological models focus on the transmission of different traits among certain populations; such traits can be transmitted diseases, knowledge, behaviors, or innovative ideas (Yan, 2014). An entity can be classified into one of the basic classes in epidemiological models: the susceptible class (S), the exposed class (E), the infected class (I), the skeptical class (Z), and the recovered class (R) (Hethcote, 2000). In the initial period of the diffusion of a good idea most of the population will be in the susceptible class (S), with a few entities in the exposed class (E)—having been in contact with the idea while not diffused it—and a small number of infected (I) manifesting it. In addition, there may be competing and mutually exclusive ideas (e.g., where susceptibles are turned off from the idea and become skeptics or idea stiflers, represented by the class Z). Furthermore, entities may recover or become immune (R), and not manifest the idea again (Bettencourt, Cinron-Arias, Kaiser, & Castillo-Chávez, 2006). Scholars can choose these classes based on their specific research questions.

In consideration of the similarity between knowledge diffusion based on scientific collaboration and disease propagation via actual contact, and inspired by the disease-spreading model in complex networks, the paper classifies research entities in the process of knowledge diffusion in scientific collaboration into potential knowledge recipients, potential knowledge diffusion entities, knowledge diffusion entities, and knowledge immunes. The four classifications of research entities can transform from one to another with a certain probability ($\alpha$, $\beta$, $\omega$, and $\gamma$, respectively). Then the evolution rules of knowledge diffusion in scientific collaboration networks are made. Furthermore, the knowledge diffusion model of differential dynamics in scientific collaboration of non-uniformity networks is formed, and then the relationship between the degree distributions and evolution of knowledge diffusion is further discussed, to reveal the dynamic mechanics of knowledge diffusion in scientific collaboration networks. Finally, an empirical analysis is conducted on knowledge diffusion in an institutional scientific collaboration network by taking the graphene field as an example.

**Theoretical Model**

*Description of knowledge diffusion process in scientific collaboration networks*

Many studies of the behavior dynamics mechanism of propagation and diffusion are based on the classical SIR epidemic model (Liu & Zhang, 2013; Su, Huang, & Zhao, 2015; Woo & Chen, 2016), in which diffusion states are defined to be the susceptible state (S), infective state (I), and recovered/immune state (R). During the actual evolution process of knowledge diffusion in scientific collaboration, however, there are two special phenomena: (1) When receiving certain knowledge, a research entity tends not to spread the knowledge immediately. Instead, there exists a certain period of time in which it digests the knowledge. After the research entity absorbs and converts the knowledge into intrinsic knowledge, it will spread the knowledge to others. (2) Under the influence of internal factors (such as the transition of research direction, demand, and interests) and external factors (such as the macro-control of the government), a research entity may not diffuse knowledge anymore. However, this kind of immunity is temporary for some research entities, because they will accept and diffuse the knowledge again in the future. Therefore, this paper argues that the SEIRS epidemic model, which has a certain latent state (E) and feedback mechanism (R to S), is more consistent with the nature of the knowledge diffusion process in scientific collaboration, and is more suitable
to function as the basic model of differential dynamics for knowledge diffusion in scientific collaboration networks.

**States of research entities in the knowledge diffusion process of scientific collaboration networks**

For the knowledge exchange and diffusion process among research entities, we define that research entities in different states of knowledge diffusion in scientific collaboration networks fall into four categories: potential knowledge recipients (S), potential knowledge diffusion entities (E), knowledge diffusion entities (I), and knowledge immunes (R).

1. Potential knowledge recipients (S): research entities who have not known the knowledge or have known but not acquired it yet.
2. Potential knowledge diffusion entities (E): research entities who have acquired the knowledge but not diffused it yet.
3. Knowledge diffusion entities (I): research entities who have mastered the knowledge and are diffusing it to the potential knowledge recipients.
4. Knowledge immunes (R): research entities who have acquired the knowledge but are immune to it now. They have lost interest in the knowledge and will not continue to diffuse it.

**Process of knowledge diffusion in scientific collaboration networks**

In the initial phase, there are only small numbers of knowledge diffusion entities in the network, while others are potential knowledge recipients. The number of potential knowledge diffusion entities and knowledge immunes is zero. As time goes on, knowledge begins to be diffused in the following ways:

1. When knowledge diffusion entities transmit knowledge to potential knowledge recipients, the recipients begin to accept it with a certain probability (α) and become potential knowledge diffusion entities.
2. If potential knowledge diffusion entities are interested in the knowledge, they will continue to diffuse it with a certain probability (β) and become new knowledge diffusion entities.
3. Knowledge diffusion entities lose interest in the knowledge with certain probability (ω) and turn into knowledge immunes.
4. Knowledge immunes become knowledge recipients again with a certain probability (γ) and take in the knowledge to which they have been immune.

**Evolution rules of knowledge diffusion in scientific collaboration networks**

At a certain time in the knowledge diffusion process in scientific collaboration networks, which could be marked as \( t \), a research entity can only be in one of the four states mentioned above. At the time node \( t \), we can define the proportion of scientific collaboration entities that are in a certain knowledge diffusion state in the whole system as follows.

1. \( s(t) \): the proportion of potential knowledge recipients to all research entities in different states of knowledge diffusion at time \( t \).
2. \( e(t) \): the proportion of potential knowledge diffusion entities to all research entities in different states of knowledge diffusion at time \( t \).
3. \( i(t) \): the proportion of knowledge diffusion entities to all research entities in different states of knowledge diffusion at time \( t \).
4. \( r(t) \): the proportion of knowledge immunes to all research entities in different states of knowledge diffusion at time \( t \).

Here, \( s(t)+e(t)+i(t)+r(t)=1 \).

According to the above description of the knowledge diffusion process in scientific collaboration networks, a schematic paradigm of the dynamic state evolution rules of research entities in knowledge diffusion is presented as follows (Figure 1).
Figure 1. State transformational rules of research entities’ knowledge diffusion of scientific collaboration.

When potential knowledge recipients cooperate with knowledge diffusion entities in the process of scientific collaboration, they could become potential knowledge diffusion entities with probability $\alpha$; potential knowledge diffusion entities become knowledge diffusion entities with probability $\beta$; knowledge diffusion entities turn into knowledge immunes with probability $\omega$; and knowledge immunes generate feedback with probability $\gamma$, and become potential knowledge recipients.

Modeling derivation of knowledge diffusion in scientific collaboration networks

A scientific collaboration network is a kind of complex networks with obvious scale-free features. Its degree distribution accords with the power-law distribution. The connections between nodes are unevenly distributed, which means that only a minority of nodes in the network have many links, while most nodes have few links (Barabási & Albert, 1999). Research entities of different degrees play different roles in the process of knowledge diffusion. According to the evolution rule of knowledge diffusion mentioned above, the knowledge diffusion model of differential dynamics in scientific collaboration of non-uniformity networks is formed by applying the mean field theory on the basis of the classical disease-spreading equation of SEIRS. The derivation process is deduced as follows.

In accordance with the evolution rule shown in Figure 1, considering the non-uniformity distribution characteristics of nodes, the system dynamics equations for each point $(k)$ can be established from the perspective of mean field theory as follows:

\[
\begin{cases}
\frac{ds_k(t)}{dt} = -\alpha k N(k)s_k(t)\theta_k(t) + \gamma r_k(t) \\
\frac{de_k(t)}{dt} = \alpha k N(k)s_k(t)\theta_k(t) - \beta e_k(t) \\
\frac{di_k(t)}{dt} = \beta e_k(t) - \omega i_k(t) \\
\frac{dr_k(t)}{dt} = \omega i_k(t) - \gamma r_k(t)
\end{cases}
\] (1)

In the equation set above, $t$ is the time step; $k$ is the node degree of research entities; $N(k)$ stands for the number of research entities with degree $k$; $s_k(t)$, $e_k(t)$, $i_k(t)$, and $r_k(t)$ indicate the proportion of research entities with degree $k$ at time $t$, and their knowledge diffusion states are $S$, $E$, $I$, and $R$, respectively; and $\theta_k(t)$ represents the probability that a random edge will connect with any knowledge diffusion entity at time $t$ (namely, the infection probability for a research entity through a linked edge with other entities).

For a scientific collaboration network in which node degrees are correlative, $\theta_k(t)$ can be expressed as (Xia, Liu, Chen, & Yuan, 2008):

\[
\theta_k(t) = \sum_{k'} P(k' | k)i_{k'}(t)
\] (2)

where $P(k' | k)$ stands for the probability that an edge will stretch from a node with degree $k$ to a node with degree $k'$.

If the node degrees are not correlative, then
\[
\theta_k(t) = \sum_{k'} P(k' \mid k) i_{k'}(t) = \sum_{k'} \frac{k'P(k')i_{k'}(t)}{<k>}
\]

where \(<k>\) is the average degree of the scientific collaboration network; \(P(k')\) indicates the probability that the research entity with degree \(k'\) will collaborate with an entity whose degree is \(k\); and \(i_{k'}(t)\) represents the proportion of research entities with degree \(k'\) whose knowledge diffusion state is \(I\) at time \(t\).

By putting Formula 2 and Formula 3 into Equation Set 1, respectively, the knowledge diffusion models of differential dynamics in scientific collaboration networks with both correlated and uncorrelated node degrees will be formed, eventually, which are represented respectively as follows.

(1) The knowledge diffusion model of differential dynamics in scientific collaboration networks whose node degrees are correlative:

\[
\begin{align*}
\frac{ds_{s}(t)}{dt} &= -\alpha k N(k) s_{s}(t) \sum_{k'} P(k' \mid k) i_{k'}(t) + \gamma r_{s}(t) \\
\frac{de_{s}(t)}{dt} &= \alpha k N(k) s_{s}(t) \sum_{k'} P(k' \mid k) i_{k'}(t) - \beta e_{s}(t) \\
\frac{di_{s}(t)}{dt} &= \beta e_{s}(t) - \omega i_{s}(t) \\
\frac{dr_{s}(t)}{dt} &= \omega i_{s}(t) - \gamma r_{s}(t)
\end{align*}
\]

(2) The knowledge diffusion model of differential dynamics in scientific collaboration networks whose node degrees are uncorrelated:

\[
\begin{align*}
\frac{ds_{s}(t)}{dt} &= -\alpha k N(k) s_{s}(t) \sum_{k'} \frac{k'P(k')i_{k'}(t)}{<k>} + \gamma r_{s}(t) \\
\frac{de_{s}(t)}{dt} &= \alpha k N(k) s_{s}(t) \sum_{k'} \frac{k'P(k')i_{k'}(t)}{<k>} - \beta e_{s}(t) \\
\frac{di_{s}(t)}{dt} &= \beta e_{s}(t) - \omega i_{s}(t) \\
\frac{dr_{s}(t)}{dt} &= \omega i_{s}(t) - \gamma r_{s}(t)
\end{align*}
\]

**Empirical Research**

Graphene has drawn worldwide research attention because of its unique structure and the excellent characteristics of electricity, mechanics, optics, chemistry, and thermodynamics, becoming one of the hottest research subjects in the fields of physics, chemistry, and material science (Ma, Wan, & Feng, 2012). Scientific collaboration in the field is very common and frequent, and the transmission and communication of knowledge are very active. Carbon nanotubes are allotropes of carbon with a cylindrical nanostructure and one-dimensional quantum materials with a special structure. Graphene and carbon nanotubes are complementary in structure and capability, and there are also marked resemblances between them in research methodology (Baughman, Zakhidov, & De Heer, 2002). Studies of them present an overlapping, mutually permeating, and inseparable trend. Therefore, the knowledge point "carbon nanotubes" in the field of graphene is selected as the research object to form and verify the knowledge diffusion model of differential dynamics that simulates the knowledge diffusing process of carbon nanotubes through the institutional scientific collaboration network of graphene, and the research results are further analyzed and explained. Because the knowledge point "carbon nanotubes" in the field of graphene emerged
in 1993, the research period of this model is set from 1993 to 2012.

Data collection

According to the following rules, the data was retrieved from the Web of Science (Table 1).

Table 1. Rules of data retrieval.

<table>
<thead>
<tr>
<th>Retrieval strategy</th>
<th>TS=(graphen* or &quot;single layer graphit*&quot; or &quot;monolayer graphit*&quot;)</th>

</tr>
</tbody>
</table>

By applying the above retrieval rules, 23,458 primary pieces of literature were obtained. Then the data was imported into the Thomson Data Analyzer (TDA) and data cleaning was conducted. The institutional scientific collaboration network matrices of graphene and institutional knowledge diffusion network matrices over the years were ultimately formed. Considering the updating of the network database, the data was collected on June 7, 2014 to maintain data consistency.

Degree correlation of scientific collaboration networks

The Pearson correlation score between the node degree k and the average degree of its adjacent nodes is -0.402. A significant correlation is not observed between them. Therefore, we ultimately select Model 5 as the theoretical model of this study.

State evolution of knowledge diffusion entities

In this paper, we define research entities in the state of knowledge diffusion entities at a certain time as the institutions that publish papers containing the knowledge point "carbon nanotubes" in the graphene field at that time. The total number of members in the institutional scientific collaboration network is 2,595. The quantity and proportion of knowledge diffusion entities from 1993 to 2012 are shown in Table 2.

Table 2. Quantity and proportion of knowledge diffusion entities during 1993–2012.

</tr>
</tbody>
</table>
It can be seen from the table that the proportion of institutions in the state of knowledge diffusion entities (in other words, institutions that are diffusing knowledge), is growing continually (from 0.1156% to 37.3025%). The growth rate is slow from 1993 to 2006, and gradually speeds up after 2006. In 1995 and 1999, though, the proportion declines. The knowledge diffusion of carbon nanotubes is in the embryonic stage from 1993 to 2006, and enters its development stage from 2007 to 2012.

Model construction and validation

In the original state (i.e., in 1993), there were three knowledge diffusion entities of carbon nanotubes in the network (i.e., Massachusetts Institute of Technology; University of California, Los Angeles; and Drexel University). The others were all potential knowledge recipients. The numbers of both potential knowledge diffusion entities and knowledge immunes were zero.

Parameter determination

According to the distributing characteristics of the theoretical and practical data values (between zero and one), the Kolmogorov–Smirnov statistic and Likelihood function are employed in this paper for parameter estimation. On the basis of Model 5, we simulate the theoretical model using MATLAB, adjust parameters ($\alpha$, $\beta$, $\omega$, and $\gamma$) with a step length of 0.1, and calculate K-S statistic and MLE (L) between the output values of the model with different parameters and actual values from 1993 to 2009, respectively, to determine the optimal parameters of the fitting model. The set of parameters that result in the minimum values for both K-S and L is the optimal parameter set for the fitting model at the 0.05 significance level (Table 3).

Table 3. Optimal parameter set of fitting model and its K-S and L values.

Model building

Evolution curves of the theoretical and actual proportions of knowledge diffusion entities in the optimal fitting model are shown in Figure 2.

Figure 2. Evolution curves of theoretical and actual proportions of knowledge diffusion entities with the optimal fitting parameters.

Therefore, the knowledge diffusion model of differential dynamics simulating the knowledge diffusion of carbon nanotubes through the institutional scientific collaboration network of graphene can be described as follows.
The model illustrates that the state evolution of research entities in the knowledge diffusion process of scientific collaboration networks is affected not only by the evolution states of adjacent research entities with whom they have certain collaboration relationships in knowledge diffusion, but also by the structural attributes and degree distributions of scientific collaboration networks. The state change of institutions with different node degrees (k) is influenced by factors such as their own degrees, the number of nodes (N(k)), and the connection probability of states.

Model verification

In accordance with Model 6, the proportions of institutions that are diffusing knowledge from 2010 to 2012 are predicted by the iteration of time steps (Table 4).

### Table 4. Predicted value of the proportion of knowledge diffusion entities from 2010 to 2012.

<table>
<thead>
<tr>
<th>Year</th>
<th>Predicted value</th>
<th>Actual value</th>
<th>Deviation</th>
</tr>
</thead>
<tbody>
<tr>
<td>2010</td>
<td>0.217252</td>
<td>0.222351</td>
<td>-2.293%</td>
</tr>
<tr>
<td>2011</td>
<td>0.300011</td>
<td>0.304432</td>
<td>-1.452%</td>
</tr>
<tr>
<td>2012</td>
<td>0.377568</td>
<td>0.373025</td>
<td>1.218%</td>
</tr>
</tbody>
</table>

The table shows that the deviations between the theoretical value and actual value of the proportion of knowledge diffusion entities predicted from 2010 to 2012 are -2.293%, -1.452%, and 1.218%, respectively. This is an insignificant discrepancy, and the closeness between the values illustrates the validity of the model.

### Results

**Evolution analysis of knowledge diffusion in scientific collaboration networks**

From 1993 to 2012, the state evolution of research entities diffusing the knowledge of carbon nanotubes in the institutional scientific collaboration network of graphene is shown in Figure 3.

![Figure 3. Evolution curves of research entities in different knowledge diffusion states in the scientific collaboration network.](image-url)
From the perspective of the overall evolution trend of knowledge diffusion, the proportion of potential knowledge recipients in the institutional scientific collaboration network shows an incessant drop with the passage of time. However, the proportion of knowledge diffusion entities and knowledge immunes rises constantly. Moreover, the proportion of potential knowledge diffusion entities shows only a slight growth trend. From the perspective of evolution tempo (changing speed of proportion) of knowledge diffusion, the proportion of potential knowledge recipients, knowledge diffusion entities, and knowledge immunes changes slowly at first and then speeds up rapidly, while the change of proportion of potential knowledge diffusion entities has shown a slight growth tendency. From the perspective of evolution acceleration (change rate of velocity) of knowledge diffusion, the change rate of potential knowledge recipients ranks first, followed by that of knowledge diffusion entities and knowledge immunes, and that of potential knowledge diffusion entities ranks last.

In addition, it can be judged from the evolution trend of state proportion of knowledge diffusion entities that the knowledge diffusion of carbon nanotubes in the institutional scientific collaboration network of graphene is in its developing stage, having not reached the saturation point. The diffusion scale of the knowledge will continue to expand as time goes on.

Relationship between node degree distribution and knowledge diffusion evolution in scientific collaboration networks

To reveal the impact of node degrees on knowledge diffusion, the relationship between node degree distribution and knowledge diffusion evolution in scientific collaboration networks is further analyzed and explained.

(1) Node degrees and potential knowledge recipients in scientific collaboration networks
The evolution of the proportion of nodes with variable degrees k in the state of potential knowledge recipients is shown in Figure 4.

![Figure 4. Evolution curves of proportion of nodes with variable degrees k in the state of potential knowledge recipients.](image)

We can see from the above evolution curves that, overall, the proportion of potential knowledge recipients shows a downward trend, with the descending rates slowing down gradually. The proportion of scientific research entities with degree k=2 remains at a low level. Simultaneously, the proportion of potential knowledge recipients at the nodes with larger degrees is higher.

(2) Node degrees and potential knowledge diffusion entities in scientific collaboration networks
The evolution of the proportion of nodes with variable degrees k in the state of potential
knowledge diffusion entities is shown in Figure 5.

![Figure 5](image)

**Figure 5. Evolution curves of proportion of nodes with variable degrees k in the state of potential knowledge diffusion entities.**

As shown in Figure 8, generally speaking, the proportion of potential knowledge diffusion entities is in decline, and the declining rates slow down by degrees. The proportion in research entities with degree k=2, however, is rising slowly, and the proportion with degree k=1 rises rapidly first, followed by a sharp drop, and finally becomes steady.

(3) Node degrees and knowledge diffusion entities in scientific collaboration networks

The evolution of the proportion of nodes with variable degrees k in the state of knowledge diffusion entities is illustrated in Figure 6.

![Figure 6](image)

**Figure 6. Evolution curves of proportion of nodes with variable degrees k in the state of knowledge diffusion entities.**

As shown in Figure 9, the overall trend of the proportion of knowledge diffusion entities rises rapidly at first and then descends slowly. The proportion in research entities with degree k=2, however, shows a gradual falling trend. Regarding scientific research entities with node degree k before reaching the highest proportion of the knowledge diffusion entities, the larger the degree is, the lower the proportion will be; after the highest proportion of the knowledge diffusion entities, the larger the degree is, the higher the proportion will be.

(4) Node degrees and knowledge immunes in scientific collaboration networks

The evolution of the proportion of nodes with variable degrees k in the state of knowledge immunes is shown in Figure 7.
Generally, the proportion of knowledge immunes with variable degrees rises gradually. Simultaneously, the larger the degree is, the lower the proportion of knowledge immunes will be.

Additionally, in light of the assumption of the model that knowledge diffuses with the help of scientific collaboration, the node with degree $k=0$ will not engage in the knowledge diffusion process because it does not participate in scientific collaboration. Therefore, it will remain in the state of potential knowledge diffusion entities. Once there is scientific collaboration, the node degree will change and be further involved in the recurrent state of knowledge diffusion.

**Discussion**

Inspired by the disease-spreading model in complex networks, the paper builds the knowledge diffusion model of differential dynamics in scientific collaboration of non-uniformity networks, and conducts an empirical analysis on the model. The research has shown that:

1. The hypothesis that knowledge can be diffused with the aid of scientific collaboration is justified, and the knowledge diffusion model constructed in this paper is rational and reasonable.
2. The state evolution of research entities in the knowledge diffusion process of scientific collaboration networks is affected not only by the evolution states of adjacent research entities with whom they have certain collaboration relationships, but also by the structural attributes and degree distributions of scientific collaboration networks. For institutions with different node degrees, the change of states is jointly influenced by their own degrees, the number of nodes, and the connection probability of states.
3. When the state transition probability meets the conditions that $\alpha=0.3$, $\beta=1$, $\omega=0.1$, and $\gamma=0.1$, the knowledge diffusion model of differential dynamics can almost accurately simulate the knowledge diffusion process of carbon nanotubes in the institutional scientific collaboration network of graphene.
4. In the evolution process of knowledge diffusion in the scientific collaboration network, the proportion of potential knowledge recipients declines constantly, but the proportion of knowledge diffusion entities and knowledge immunes increases continuously. Meanwhile, the proportion of potential knowledge diffusion entities shows only a slight growth trend.
5. The knowledge diffusion evolution of scientific collaboration entities with different degrees also shows different trends.

Based on the previous research results, policy makers can regulate the structure, degree distributions, and transition probability of states in scientific collaboration networks through various means to achieve different evolution effects of knowledge diffusion, and can control
the knowledge diffusion process in scientific collaboration by promoting or inhibiting it. For example, they could expand the cooperation breadth of research institutions to further promote the absorption and mastery of knowledge and accelerate diffusion of knowledge with measures such as providing platforms for academic communication, consummating incentive mechanisms for scientific research innovation, etc.

Abstract
There were 11398 journals were included in Journal Citation Report from Web of Science in 2015, including about 44.47 percent of journals included by multiple disciplines, which indicates interdisciplinary is a common phenomenon. The number of cross-journals among different disciplines reveals the role of journals in the interdisciplinary, which can be used to analysis interdisciplinary. This paper proposes a Cross-Discipline Vector Space Model for quantitative analysis of the degree of interdisciplinary. Through calculating the relevance among discipline, we obtain the pattern of interdisciplinary, which could provide scientific advice to promote the development of disciplines and scientific research.

Keywords: Web of Science Categories, Cross-Discipline, Vector Space Model, Scientometrics.

Scientometrics, Webometrics and Knowledgometrics: The research about data science and metrology; Journals, databases and electronic publications; Methods and techniques; Knowledge discovery and data mining

Introduction
With the development of scientific research activities, scientists engaged in the activities of scientific research from single field to broader fields. The inner cross-discipline also influences the scientific research activities. The development of discipline emerges in two trends. One is the overall subject gradually divided into a finer professional field, the other one is the discipline overlapping forming a new discipline, which is due to the progress of science and technology and the demand for society to solve practice requirement, different discipline fields become more and more close. For example, Artificial Intelligent is a brand-new discipline field applying computer technology and biological neural network technology comprehensively. Therefore, how to quantify the degree of correlation between disciplines becomes more and more important. Revealing the development of cross-discipline will provide reference for the advancement of scientific research in the future.

Cross-Discipline is a comprehensive scientific activity which is born to meet the needs of social development and the development of discipline itself. Cross-discipline is the prerequisite for formatting interdisciplinary, and the interdisciplinary is the result of Cross-discipline(Xu, Yi & Guo, 2015, PORTER& RAFOLS,2009). Cross-Discipline is the new growth point of science and the new frontier of science. Scientific achievements are often originated in interdisciplinary field. Interdisciplinary sciences is a comprehensive and systematic knowledge system which is formed in the intersection of the external disciplines and the inter discipline of natural sciences, social sciences, humanities and other disciplines(Li, Zong&Xu,2013). The continuous development of interdisciplinary sciences has greatly promoted the progress of science. Therefore, Cross-Discipline research reflects the trend of science development. With the rapid development of discipline in science field and the strengthening of university cooperation, disciplines have broken the previous barriers and the disciplinary integration has gradually produced brand new disciplines.

The studies of Cross-Discipline are mainly divided into the following research methods: Researchers used Citation Analysis Methods to explore the characteristics of knowledge diffuse among different disciplines(Qiu,Cao,2012). Researchers used Cross-Analysis to analysis literatures based on target literature, references and cited literature(Huang,
According to the practical research experience of Cross-Discipline, Weiying Jin used the method of literature and system theory to recognize Cross-Discipline (Jing, 2005). Xiaoling Sun used cross-field authors to map the evolution of scientific fields (Sun, Ding & Lin, 2016).

In this paper, we use the statistical method to analyze 11398 core journals which were included in SCIE and SSCI. In order to ind out the degree of correlation about Cross-Discipline and reveal the associated rules about Cross-Discipline, we proposed a Cross-Discipline Vector Space Model method to analyze the number of core journals crossed by disciplines. The degree of correlation between Cross-Discipline have a further influence on discipline research and national development strategy.

Materials and methods

Dataset

In this paper, we use ISI (Institute for Scientific Information) database platform of WOS (Web of Science) to study Cross-Discipline. Web of Science is the products based on Web platform by Thomson Reuters Company, and is the largest comprehensive academic information resource which covered the largest number of disciplines in the world. Web of Science includes 11398 high-quality core journals in 2015, which are the most influential journals and have been reviewed by peers around the world. We used these core journals included in the database for research. Web of Science divides all disciplines into 234 categories, and every year Web of Science will publish an edition of journal classification from 1997 to 2015. We use the latest discipline division of 2015 for analysis.

By logging into WOS database, and entering JCR (Journal Citation Reports) module, you can download all the journal information included by 234 categories in 2015.

Research Methods

SCI/SSCI journals are not always classified into a single JCR category, some journals are grouped into multiple JCR categories, which are called “Multi-assigned Journal” (Li & Chen, 2015). In this paper, we firstly use the statistical methods to compare the discipline of Multi-assigned Journal in 234 disciplines, and then use the Cross-Discipline Vector Space Model to calculate the degree of interdiscipline based on the number of Multi-assigned Journal in different disciplines. The Vector Space Model is the concept of continuous correlation sequence proposed by (Salton, Wong & Yang, 1975). The correlation measure method is widely used in information retrieval, but it rarely applied in discipline relevance measurement, so we select Vector Space Model to measure the degree of correlation between disciplines.

Results

Core journals included by disciplines

In scientific fields, We take the percentage the number of interdisciplinary journals in a discipline take up in all the core journals as the indicator to measure the interdisciplinary (Cheng & Liu, 2005). Figure 1 shows the Cross-Discipline percentage distribution of 234 disciplines.
Figure 1 shows that there are 46 disciplines whose percentage of multi-assigned journals is between 80% and 90%. While there are only 1 discipline whose percentage of multi-assigned journals is between 0% and 10%. Overall, most disciplines have more than 50% (a total of 178 disciplines, 76.1% of all disciplines) of multi-assigned journals, which is in a higher range.

From the data in Figure 1, it can be concluded that Cross-Discipline is a common phenomenon. Compared with the situation of Cross-Discipline in previous decade, Nowadays, the interdisciplinary integration of the disciplines on the basis of the original moves further forward, and the degree of cross-range is more far-reaching and more extensive span. It can be concluded that discipline development will enter a new era in the future, the barriers between disciplines will no longer exist and how to grasp the degree of interdisciplinary with an accurately method will be related to the development of scientific research activity and academic research.

The Cross-Discipline situation based on the core journals
Web of Science divided 234 disciplines and contain a total of 11398 journals. There are large number of Multi-assigned journals exist in 234 disciplines. The detail is showed in Figure 2. As we can see from Figure 2, the number of interdisciplinary journals with one Multi-assigned Journals are 6298, that is, there are 6298 journals that were only included in self-disciplines in Web of Science. There are 5100 journals belong to Multi-assigned journals, accounting for a total of 44.74%. The number of Multi-assigned journals was so large, which indicates that there is a large degree of Cross-Discipline between the disciplines. Specially, there are 8 journals included by 6 disciplines at the same time, the name of which are: 1. JOURNAL OF CHEMOMETRICS 2. ADVANCED MATERIALS 3. EUROPEAN JOURNAL OF CANCER CARE 4. CHEMOMETRICS AND INTELLIGENT LABORATORY SYSTEMS 5. Disability and Health Journal 6. NANO LETTERS 7. Small 8. ADVANCED FUNCTIONAL MATERIALS. There are two core journals belong to materials among eight kinds of journals, two core journals belong to nanotechnology, two core journals belong to medical and health science, one core journal in the field of chemistry.
and one core journal of computer science. It is found that there is large similarity between materials science and nanotechnology in the eight journals by analyzing the similarity of the disciplines later in this paper. The two disciplines not only have a large degree of Cross-Discipline between themselves, but also have Cross-Discipline with other disciplines. Meanwhile, there are 6298 core journals only included by one discipline, which have more pertinence and researchers will more convenient to get relative information by query those journals for research question of specific areas.

![Figure 2. The distribution of journals based on the number of interdisciplinary subjects](image)

**Cross-Discipline analysis between disciplines**

For further study, we process data of each Cross-Discipline in details. Figure 3 shows the result of Cross-Discipline situations.

![Figure 3. The discipline distribution based on the number of interdisciplinary subjects](image)

We found that the number of subjects in 234 categories without interdisciplinary subjects was zero. In other words, a journal that does not have a single subject belongs to itself. Meanwhile, from the distribution of Figure...
3 we can find that a total of 96 disciplines cross with four disciplines, and there are 202 disciplines have Cross-Discipline with at least three disciplines, accounting for 86.3% of the total number of disciplines. It is shown that discipline has not only intersected with one or two disciplines, but mostly intersects with more than three disciplines. The interdisciplinary phenomenon shows that there are close relationships between disciplines. By comparison, only 32 disciplines have fewer than three interdisciplinary disciplines. We could see that the disciplines have completely broken the academic barriers (Zhu, 2003), exploring the Cross-Discipline among disciplines will be a shortcut to advance the convergence of disciplines in the future.

At this point, we have demonstrated that there are very close relationships between disciplines and the Cross-Discipline has reached a certain height. How to quantify the degree of interdisciplinary will be related to the further development of disciplines.

Cross-Discipline Vector

In order to measure the correlation between disciplines, we propose a Cross-Discipline Vector Space Model for quantitative analysis of the degree of interdisciplinary. The motivation of core journals included in a discipline is the importance for the development of the discipline, regardless if the journal is the core journal for other disciplines or not. All the core journals included in the same discipline have equivalent contribution to the discipline, and they have the same property for the discipline. Based on the above viewpoint, we propose the Cross-Discipline Vector Space Model and calculate the similarity between disciplines. Because of the Vector Space Model can perfectly represent the data relevance and has been widely used to calculate the similarity between data in information retrieval, we use the Vector Space Model to calculate the similarity and based on the values of spatial Vector to determine the degree of Cross-Discipline.

Vector definition

We build model to explore the relevance of disciplines based on 234 disciplines. The basic vector of discipline research is constituted by the number of Multi-assigned journals between this discipline and other disciplines. In order to measure the degree of Cross-Discipline between A and B, we use C discipline as a bridge. We use the number of Multi-assigned journals between A and C as an index, and the number of Multi-assigned journals between B and C as another index, then the relevance between A discipline and B discipline is calculated using these two indexes as input for Cross-Discipline Vector Space Model. The construction of the vector is shown in the Table 1.

The discipline in this paper is represented as a Vector with 234 dimensions, and the value of each dimension stands for the number of common core journals included by this discipline and other disciplines at the same time, and the corresponding discipline of every dimension is the same for all the disciplines. For example, in Table 1, ECONOMICS discipline is represented as a vector of 234 dimensions, and each dimension stands for a discipline of 234 disciplines. The dimension value is the number of core journals that intersected with other disciplines. If there are no common core journals between disciplines, the value of the dimension will be zero.
The calculation of vector relevance.

We use the cosine of the angle between the spatial vectors to calculate similarity between Cross-Discipline Vectors. The calculation method is shown as formula (1):

$$\text{Cosine}(x,y) = \frac{\sum_{j=1}^{t} c_{xj} c_{yj}}{\sqrt{\sum_{j=1}^{t} (c_{xj})^2} \sqrt{\sum_{j=1}^{t} (c_{yj})^2}}$$

(1)

where $x, y$ are two disciplines, $X, Y$ are discipline vectors, $c_{xj}$ is the number of Multi-assigned journals between $x$ discipline and $j$ discipline, $t$ is the number of disciplines, which is 234 there. $j$ is the number of disciplines which have included same journals with $x$ (including $x$ itself). The result is a positive number which is in the range $[0,1]$, and the result is 1 when the two Vectors are exactly equal. The larger the similarity between the vectors is, the higher the value of cosine method will be. In this paper, we can get the similarities with 234 disciplines based on the Multi-assigned journals, and we choose the disciplines with the values of similarity larger than 0.5 to show in Table 2.

</table>
From the perspective of journals, we analyze the similarities among 234 disciplines of Web of Science. The study found that there are 46 pairs of disciplines with similarity larger than 0.50 in
234 disciplines, and 8 pairs of disciplines with similarity larger than 0.7. The similarities between disciplines are shown in Table 2; The 8 pairs of disciplines are HEALTH POLICY & SERVICES and HEALTH CARE SCIENCES & SERVICES, EDUCATION SPECIAL and REHABILITATION, MEDICAL ETHICS and ETHICS and so on. The highest degree of similarity between disciplines is HEALTH POLICY & SERVICES and HEALTH CARE SCIENCES & SERVICES, the similarity of which is 0.78. From this result, we could see that these pairs of disciplines have very similar research topics compared to other disciplines, and these disciplines have completed a large degree of Cross-Discipline. There are total 82 disciplines with similarities that are more than 0.50, accounting for 35.04% of all discipline, indicating that the current development of disciplines show a rapidly cross trend, and nearly half of the literature and knowledge are interrelated. Plenty of same core journals are included in different disciplines, which indicate Cross-Discipline is a common phenomenon. Specially, we find that there are higher degrees of similarity among multiple disciplines. Such as NANOSCIENCE & NANOTECHNOLOGY, MATERIALS SCIENCE MULTIDISCIPLINARY and PHYSICS APPLIED. The similarity between NANOSCIENCE & NANOTECHNOLOGY and MATERIALS SCIENCE MULTIDISCIPLINARY is 0.73, and the similarity between NANOSCIENCE & NANOTECHNOLOGY and PHYSICS APPLIED is 0.69, the similarity between PHYSICS APPLIED and MATERIALS SCIENCE MULTIDISCIPLINARY is 0.64. In all disciplines, these three disciplines rank in the top 20 by similarity, indicating that the Cross-Discipline existence is not limited to two disciplines, but is forming a Cross-Discipline cluster over time, and the interdisciplinary phenomenon between discipline clusters indicate that disciplinary development has entered the stage of discipline cluster, and the Cross-Discipline as discipline clusters is evolving. In all disciplines of Cross-Discipline, there are 12 pairs of medical disciplines with similarity larger than 0.50, accounting for 26.08% of all 46 pairs, indicating that medical disciplines have better Cross-Discipline among all disciplines in recent years and medical discipline is hot topic today. Strengthening the construction of medical disciplines could not only promote the progress of medical technology, but also promote the development of interdisciplinary fields and provide reference for accelerating the Cross-Discipline of other disciplines. In order to intuitively show the similarity of disciplines, we use Gephi to draw a network map shown in Figure 4. Different colors indicate different communities. We could see that not only MATERIALS SCIENCE MULTIDISCIPLINARY and PHYSICS APPLIED have large Cross-Discipline phenomenon, but also ENGINEERING ELECTRICAL & ELECTRINIC, PSYCHOLOGY have large similarity with other disciplines. There is a complex Cross-Discipline between disciplines. We divide this network into several parts to analysis. Due to the space limitation, we just analyze the ENGINEERING ELECTRICAL & ELECTRINIC discipline. The size of the node indicates the status of the discipline in the network and the thickness of the connection indicates the degree of similarity, the greater the degree of similarity, the thicker the connection will be. We could intuitively observe that ENGINEERING ELECTRICAL ELECTRONIC, COMPUTER SCIENCE INFORMATION SYSTEMS, COMPUTER SCIENCE THEROY & METHODS and other disciplines have obvious connections between each other.
Figure 4. Cross-Discipline network in 2015. (The threshold is set to 0.2)

Figure 5. A part of Cross-Discipline network in 2015 (The threshold is set to 0.2)
Through the Figure 5, the size of the node indicates the status of the discipline in the network and the thickness of the connection indicates the degree of similarity, the greater the degree of similarity, the thicker the connection will be. We could intuitively observe that ENGINEERING ELECTRICAL ELECTRONIC, COMPUTER SCIENCE INFORMATION SYSTEMS, COMPUTER SCIENCE THEROY & METHODS and other disciplines have obvious connections between each other.

**Discipline overall vector**

We used all of the journals included in 234 disciplines as the overall discipline, and calculate the similarity between the overall discipline and other disciplines. Similarly, we use the Vector Space Model to calculate the degree of Cross-Discipline, the discipline overall vectors are shown in Table 3.

</table>

Among the 234 disciplines of Web of Science, the discipline which has the largest similarity with all other disciplines is BIOCHEMISTRY & MOLECULAR BIOLOGY and the values of similarity are 0.27. The top 10 disciplines ranked by similarity mostly belong to nature science indicating that nature science played a basic role in supporting other discipline development. In addition, there are totally 89 disciplines whose discipline overall vector similarity are less than 0.1, accounting for 38.0% of all disciplines. And there are totally 145 disciplines whose discipline overall vector similarity are more than 0.1, accounting for 62.0% of all disciplines. It could be concluded that most disciplines are closely related to the development of the whole disciplines. The improvement of the whole disciplines not only improves the progress of the whole discipline, but also improves the development of each discipline.

**Conclusions**

With the rapid development of science, the phenomenon of independent study has gradually disappeared and more and more disciplines begin to converge. Different disciplines through Cross-Discipline with other disciplines could promote the development of the discipline itself and also promote the development of other disciplines. There is a trend that Cross-Discipline
becomes more and more common and disciplines are merging. Interdisciplinary often lead to the birth of new scientific achievements and subsequently accelerate the development of disciplines.

In order to measure the similarity between disciplines, we propose a Cross-Discipline Vector Space Model method based on the 234 disciplines of Web of Science. We find that a large degree of Cross-Discipline exists in different disciplines and the degree of similarity between discipline groups also reaches a high level. Through the research of the high degree of Cross-Discipline between disciplines, the high degree of Cross-Discipline between disciplines and discipline groups, and the high degree of Cross-Discipline between disciplines and the entire set of disciplines, we can conclude that disciplines have accomplish a large degree of Cross-Discipline merging.

We used the Vector Space Model to calculate the similarity between disciplines, and used the degree of Cross-Discipline values to determine the correlations. The larger the value is, the closer the connection is. The advantage of the quantitative evaluation method is more scientific to judge the development status of Cross-Discipline between disciplines, and could provide scientific suggestions for determine the trend of disciplines development and disciplinary activities in the future.

Disciplinary barriers are the main causes of impeding the integration of disciplines. Therefore, colleges and institutes have to break through the barriers when they want to cultivate comprehensive talents. Breaking through the existing talent training model will perfect the program of cultivating. The integration of these disciplines will provide some referential significance for promoting the level of scientific research and technology into the leader group in the world. For example: we could divide MATERIALS SCIENCE MULTIDISCIPLINARY, PHYSICS APPLIED and NANOSCIENCE & NANO TECHNOLOGY into a large discipline for promoting the development of MATERIALS SCIENCE MULTIDISCIPLINARY, which will be more conductive to the development of the whole discipline. At the same time, we should pay more attention to the Cross-Discipline between different disciplines and can not only confine ourselves to a specific field, and it will be easy to break through discipline barriers and achieve success. The development of Cross-Discipline is an inevitable trend. Strengthening the development of universities and research institutions and promoting disciplines merging will provide a referential significance for constructing a list of world-class universities and improving the speed of scientific research.

In addition, the trend of Cross-Discipline is still in the stage of continuous development, Disciplines in different fields are merging and interactive at all time. We attempt to measure the Cross-Discipline phenomenon in the top journals and magazines to find out the development direction of all scientific fields, and predict the development trend and opportunity in the future. It is important for researchers to know how to grasp the scientific development trend and guide us towards a more effective scientific research. We attempt to measure the degree of Cross-Discipline and transform the relevance of disciplines into information for researchers, in order to bring more scientific research values.

Abstract
Assessing the interdisciplinarity of a given body of research is an important work in bibliometric studies. Since the nature and concept of interdisciplinary is ambiguous and uncertain, various indicators have been created to capture interdisciplinarity. However, few studies have examined the consistency of these indicators. In this context, this paper aims to systematically explore and compare to what extent these interdisciplinarity measures are consistent, and observe which attributes of interdisciplinarity they aim to indicate. We examine these interdisciplinarity measures on WoS categories. Based on the Pearson’s correlation coefficient, we find most measures in the different conceptual groups do not show high correlations. However, although measures in the same group are expected to be strongly related, some measures that are supposed to indicate the same attribute of interdisciplinarity are rather dissimilar. Furthermore, distribution figures provide an insight of the discriminatory power of the measures. Hence, we can identify measures with poor discriminatory power. In addition, we selected five WoS categories to carry out an in-depth analysis. These analyses are, to some extent, consistent with the Pearson’s correlation coefficients. Our results provide some evidence that these measures indicate different attributes of interdisciplinarity, perhaps more than presumed.

Conference Topic
Indicators, Science policy and research assessment, Citation and co-citation analysis

Introduction
Works that aim to quantitatively assess interdisciplinarity tend to bemoan the measurement situation, for there are no consensus on the definition and operationalization of interdisciplinary research. Since the concept of interdisciplinarity is ambiguous and not well delineated, yet several indicators purport to measure it or aspects of it, it is important to empirical examine the potential consistency of such measures in order to be able to more thoroughly analyse the meaning and validity of these constructs. However, while numerous indicators have been created to measure interdisciplinarity, empirical comparisons of interdisciplinarity measures are generally overlooked. In this context, this paper aims to systematically explore and compare to what extent that these interdisciplinarity measures are consistent, and observe which attributes of interdisciplinarity they aim to indicate.

Previous explorations of ways to measure interdisciplinarity can be carried out from various aspects, for instance analyzing publications, researchers, and terminologies. While we constrain our review to indicators based on bibliometric data such as publications, references, and citations, there remains a variety of other approaches to measuring interdisciplinarity. This study is organized as follows. We first provide some related work on the conceptual and analytical frameworks of interdisciplinarity. Then, we summary previous measures of interdisciplinarity. Next section briefly introduces the data in this work. The following section reports the results of our analysis. Discussion and conclusions is in the last section.

Analytical framework of interdisciplinarity
Regarding the conceptual and analytical framework of interdisciplinarity measures, Rafols and Meyer (2010) develop the conceptual framework of interdisciplinarity by exploring the concepts of “diversity” and “coherence” in a bibliometric context. Diversity aims to “describe the heterogeneity of a bibliometric set” (Rafols & Meyer, 2010, p.263), and coherence include
indices that “are constructed to measure the intensity of similarity relations within a bibliometric set” (Rafols & Meyer, 2010, p.263). The assumption is that a cluster of publications with a high degree of interdisciplinarity, should contain a considerable number of within cluster citations spanning distant predefined journal subject categories. Compared to multidisciplinary, interdisciplinarity is seen as a more advanced stage of the relationship between disciplines in which integration of theories, methods, techniques and data is attained. As illustrated in Figure 1, interdisciplinarity is associated with high degree of diversity and coherence.

![Figure 1. Conceptual framework of IDR (Source: Rafols et al., 2012)](image)

In addition, Rafols et al. (2012) supplements the analyses of interdisciplinarity with a further concept of “intermediation”. Intermediation depicts a situation where a large proportion of publications in a set is in an “intermediate” position as depicted in Figure 1. This is another perspective of exploring interdisciplinarity, which stresses the position of a set of publications in a citation network. Whereas, the combination of diversity and coherence is more focused on the internal distinct components and their relations within a given publication set. As mentioned by Rafols and Meyer (2010), their conceptual framework is constructed from the perspective of a knowledge integration process.

**Overview of interdisciplinarity measures**

This section introduces 16 bibliometric-based measures typically operationalised as one-dimensional (non-composite) indicators of interdisciplinarity. In order to present these measures systematically, they are embedded into Rafols and colleagues’ conceptual framework of interdisciplinarity. Another point should be elucidated before introducing these measures, the issue of unit of analyses. This work examines the interdisciplinarity of WoS categories, which we will introduce in the next section. Outgoing (references) and incoming citations (citations) can both be used to analyse the interdisciplinarity of a publication set. However, “there does not seem to be clear evidence that one is preferable to the other” (Levitt et al., 2011, p.1121), while others stress that citations and references have different implications (e.g. Porter & Chubin, 1985). To simplify, we limit this study to the references in publications, i.e. outgoing citations. Besides this, it should be noted that not all bibliometric-based indicators are included in the present work. This is because not all indicators are suitable for measuring interdisciplinarity of WoS categories.

---

1 Notice, these measures were all developed using the Web of Science database.
Diversity

As mentioned above, diversity includes measures that “describe the heterogeneity of a bibliometric set” (Rafols & Meyer, 2010, p.263). We first introduce measures depending on the WoS journal classification system. WoS allows journals to have multiple categories, and thus researchers can use this characteristic to assess interdisciplinarity. Morillo et al. (2001, 2003) propose several measures to describe the interdisciplinarity based on the WoS classification system. Table 1 summarizes some of their measures.

It is obvious that the arbitrary construction of the WoS classification system seriously influences the measurement of diversity. Therefore, some researchers are focused on measuring the proportion of references to outside categories (PRO). It presumes that the higher proportion of references to journals in other categories, the larger the expectation that the journal contains publication with interdisciplinarity research. Nevertheless, PRO is still a rather simple indicator that lacks considerations on the distribution of references over categories, the number of outside categories, similarity between each pair of categories, etc. Thus, relatively complex measures have been continuously proposed to improve the measurement of diversity. For instance, some researchers prefer to adopt a probability perspective, such as Simpson’s diversity (Simpson, 1949), Shannon’s entropy (e.g. Stirling, 2007; Leydesdorff & Rafols, 2011; Silve et al., 2013) and Brillouin’s index (Steele & Stier, 2000, see also Brillouin, 1956; Chang & Huang, 2012). Economic measures have also been used as indicators of interdisciplinarity. For instance, the Gini coefficient, which is perceived as a measure of income inequality, is used to evaluate the degree of unevenness in citation or reference distributions of subject categories (i.e. Leydesdorff & Rafols, 2011). Besides Gini coefficients, other indicators have also been adopted and proposed to measure the concentration of publications in a research field, for instance, Pratt index (Pratt, 1977, see also Morillo et al., 2001) and Specialization measurement (Porter et al., 2007; 2008), as shown in Table 1. Note that these three concentration-related measures are inversely related with interdisciplinarity.

The diversity measures introduced so far focus on the distribution of citations over different categories, but they are criticized for not considering the similarity of pairs of such categories. Rao (1982) and Stirling (2007) respectively proposed that similarity should be taken into account when assessing diversity. Here we need to introduce some mathematical notions here. Let $c_{ik}$ denote the number of references from WoS subject category $i$ to $k$, and $t_i$ denote the total number of reference for category $i$, then we have $t_i = \sum_{k=1}^{n} c_{ik}$. The percentage of references from category $i$ to $k$ can be expressed as $p_{ik} = \frac{c_{ik}}{t_i}$. Then the general diversity formula is as follows,

$$\Delta = \sum_{i \neq j} (d_{ij})^\alpha (p_{ik}p_{jk})^\beta,$$

in which, $d_{ij}$ shows the difference between the category $i$ and $j$. Other traditional indices can be derived by setting the value of parameters $\alpha$ and $\beta$. For example, when we define delta “as the variant for $\alpha = 1, \beta = 1$, [we get] the simplest form incorporating variety, balance and similarity” (Rafols & Meyer, 2010, p. 267). This is known as the Rao-Stirling index:

$$\text{Rao – Stirling index} = \sum_{i \neq j} d_{ij}p_{ij}p_{ij}.$$

The Rao-Stirling measure has been widely used to measure diversity and thus been used as an indicator for interdisciplinarity (e.g. Porter et al., 2007; Porter & Rafols, 2009; Wang et al., 2015). Note that there are several ways to construct the matrix of dissimilarity. While Salton’s cosine similarity (Salton & McGill, 1983) is frequently applied, it has several transformations. Hence, different results can be expected (e.g., Schneider & Borlund, 2007a; 2007b). Here, we discuss two transformations of the cosine formula to calculate similarity. Suppose we aim to attain a symmetric similarity matrix of WoS categories $[s_{ij}]$ by using their citation relations. The first step is to construct a matrix of citation relations between categories $[c_{ij}]$. Note that
[s_{ij}] is a symmetric matrix, but [c_{ij}] is asymmetric. We use \( c_{ij} \) to denote the number of citations from publications in \( i \) to publications in \( j \).

The first way of using Salton’s cosine index can be illustrated as two subject categories are considered to be strongly related if they commonly cite the same subject categories. Hence, the similarity of two subject categories \( i \) and \( j \) is given by

\[
S_c(i,j) = \frac{\Sigma_k c_{ik} c_{jk}}{\sqrt{(\Sigma_k c_{ik}^2)(\Sigma_k c_{jk}^2)}}
\]

Another way of using the cosine formula (also called the Ochiai index) is that

\[
S_O(i,j) = \frac{c_{ij} + c_{ji}}{\sqrt{(\Sigma_k c_{ik} + \Sigma_k c_{ki})(\Sigma_k c_{kj} + \Sigma_k c{kj})}}, \quad i \neq j
\]

Here, \( c_{ij} + c_{ji} \) is equal to the total number of citations between subject category \( i \) and \( j \). Note that \( S_O(i,i) \) is set as 1. (More details, see Zhang et al., 2016).

In addition, several strategies can transform a similarity matrix into a dissimilarity matrix. The mainstream solution is to use \( 1 - [s_{ij}] \) to attain a distance matrix \([d_{ij}]\). There are also studies using \( 1/[s_{ij}] \) to construct a distance matrix (e.g. Jensen & Lutkouskaya, 2014). This work will examine both strategies of constructing a dissimilarity matrix.

Besides this, it should be noted that Rao-Stirling diversity can be used at various levels. To be more specific, one could measure Rao-Stirling diversity for each publication in a category and then calculate the mean value as the interdisciplinarity of this category. On the other hand, one could also view this category as a whole, calculating the proportion of references in all publications over different categories. In this work, we examine Rao-Stirling index at both levels. Table 1 summarizes different transformations of the Rao-Stirling index, where rs_p is based on the references of individual publications, and rs_r is based on the references of all publications in a dataset.

Recently, Zhang et al. (2016) claim that the Rao-Stirling measure has a low discriminatory power, since the interdisciplinarity results obtained by Rao-Stirling measure are quite similar. Instead, they promote the Hill type measure \( ^2D^2 \) to overcome these limitations. The formula of \( ^2D^2 \) is shown in Table 1.

### Coherence

We now move to another conceptual group of measures, namely coherence, which is used to capture the intensity of a group of publications. Note that, according to the studies by Rafols and colleagues (Rafols & Meyer, 2010; Rafols, 2014), diversity and coherence should be used in conjunction to assess interdisciplinarity. However, in the light of our summary of previous studies, coherence tends to be ignored when measuring interdisciplinarity. Many studies use merely diversity to indicate interdisciplinarity (e.g. Porter & Rafols, 2009). The reason might be that coherence has often been conceived as an inherent attribute within the dataset under study. For instance, if research topics are identified using a certain clustering algorithm, they would be expected to be coherent.

As mentioned, the present study will measure the interdisciplinarity of WoS categories. In the present study, we make a strong assumption that publications in the same WoS category are expected to display strong coherence\(^2\). Hence, we will only test one coherence measure, which is shown in Table 1. However, it is worth noticing that some studies claim that this coherence measure is suitable for quantifying the degree interdisciplinarity (more details, see Soo & Kampis, 2012; Wang, 2016).

\(^2\) This is most likely not true, for all publications or categories, given the well-known core and scatter phenomena in literatures.
Intermediation

As discussed above, Rafols et al. (2012) supplement their analyses of interdisciplinarity with the concept of “intermediation”. However, measures of intermediation designed for interdisciplinary purposes are few. One frequently used index is the “betweenness centrality” measure, which is originally proposed by Freeman (1977) and later introduced by Leydesdorff (2007) to measure the interdisciplinarity of journals. Two other measures of intermediation are introduced by Rafols et al. (2012). The first is a clustering coefficient, which “identifies the proportion of observed links between journals over the possible maximum number of links” (de Nooy et al., 2005, p.149; see also Rafols et al., 2012, p. 1268). The second measure of intermediation proposed by Rafols and colleagues is “the average similarity of a given journals to all other journals” (Rafols et al., 2012, p. 1268).

Data

This paper aims to systematically explore and compare to what extent these interdisciplinarity measures are consistent, and further observe which attributes of interdisciplinarity they aim to indicate. As a case, we examine the interdisciplinarity of WoS subject categories using the measures that we have introduced in the previous section. As data we use a publication set consisting of all publications of the document type article published in 2010 from the in-house WoS database. Our study uses publications and their references to investigate interdisciplinarity. The validity and effectiveness of using this type of data source might be questioned in some research fields, especially in the fields where journals are not the main scientific communication medium. We therefore exclude journals from the Arts & Humanities Citation Index resulting in a total of 224 WoS categories included in the analysis.

One issue worth highlighting. The WoS classification system is a coarse classification of science; however, some measures might be problematic when working at the high aggregation levels of science. For instance, measures of intermediation like “betweenness centrality” are sensitive to the level of aggregation, and it should probably be applied at levels lower than WoS categories (Rafols et al., 2012). Besides this, it would be more reasonable to measure coherence when evaluating the interdisciplinarity of an institution. Since publications of an academic institution might be diverse, but they do not closely connect with each other.

Hence, examining these measures at various levels of aggregation seems necessary. However, due to space constrains, the present work will only examine the measures that we introduced in the previous section and are relevant to measuring the interdisciplinarity of WoS categories. Future studies will expand these analyses to different units of analysis and at different levels.

Results

This section presents the results of our analysis. We will first provide the results regarding the relations of the interdisciplinarity measures, then report the distribution over categories of each measure, and finally provide an in-depth analysis with five categories.

Relations between indicators of interdisciplinarity

Pearson’s correlation is used to analyse the linear correlations between the measures of interdisciplinarity. From the previous discussion, we know that these measures can be roughly classified into six groups according to the attribute of interdisciplinarity they aim to quantify, see Tables 1. Table 2 provides Pearson’s correlation coefficients, and the results for each group is framed in black.

First, it can be seen that the measures in the first group to some extent are highly correlated with each other, except p_in_so. As mentioned, p_in_so is defined as the percentage of journals that are classified in another category inside a research area. In this paper, we adopt the strategy provided by CWTS, which assigns WoS categories into 35 research areas. Hence, p_in_so seems to constrain the diversity of journals of a category into a given research field. Thus, it is not surprising for it to have a weak correlation with other measures in its group and even hold a negative correlation with p_out_so. The first four measures in the second group, i.e. entropy, Brillouin, Simpson and PRO, are highly correlated, especially Shannon entropy and Brillouin index. This is in line with our expectation, since Brillouin’s index is mathematically related to Shannon’s entropy (Steele & Stier, 2000). The third group is designed to capture the degree of centralized tendency of publications in the same category. Therefore, we expect them to have a negative or weak relation with other measures of interdisciplinarity. However, Pratt index
differs from our expectation, for it shows a negative relation with the Gini coefficient and Specialization. Pratt index seems to quantify the dispersion degree of publications in a category, and should probably therefore be assigned to the first group.

Measures in the fourth group complement previous measures by considering distance. As shown in Table 1, using different similarity measures, namely $S_c$ and $S_o$, lead to comparatively weakly related Rao-Stirling results. On the other hand, and not surprisingly, Rao-Stirling measures using the same similarity measure at the level of individual publications and categories are strongly linearly associated with each other. In short, $rs_p$ and $rs_r$ with the same similarity matrix are highly correlated. However, the comparative correlation profile of the Hill type measure differs with all other Rao-Stirling measures. While it applies the same cosine function as $rs_p$ [1-$S_o$] and $rs_r$ [1-$S_o$], their correlations are weak.

Coherence has relatively weak correlations with all other measures, except the Rao-Stirling [$S_c$] version. This seems reasonable as the coherence measure is conceptually different, and strong coherence may not imply a high degree of interdisciplinarity. Finally, the left three measures focus on intermediation. Intermediation differs from coherence, since a high intermediation of a WoS category may suggest that the category has a high degree of interdisciplinarity, as shown in Figure 1. Our results show that these three measures are weakly correlated with all other measures.

In addition, we also examine to what extent measures in the different groups quantify different attributes of interdisciplinarity. To provide more insight to this issue, a cluster solution is produced using a Ward’s cluster algorithm. As shown in the dendrogram in Figure 2, measures below the line are perceived to describe the diversity attribute, whereas the others mainly include measures regarding intermediation; i.e. the latter reflects the proportion of publications of a category in “intermediate positions”, and the centralized tendency of publications within a category.

Our results indicate that these measures, so far in the literature, have been operationalized (and perhaps interpreted) rather differently when used as indicators of interdisciplinarity. On the other hand, some measures are clustered into the group that seems unintuitive. For instance, the Hill-type index aims to capture the attribute of diversity, but it presents a significant difference with other diversity measures.

Discriminatory power is one criteria for evaluating the effectiveness of indicators. As mentioned in Rafols and Meyer (2010), “since we do not have benchmarks for diversity or coherence from other areas of science, we cannot investigate whether this field is particularly
diverse or coherent” (p. 275). In other words, it is challenging to quantitatively determine if an indicator of interdisciplinarity is actually “valid”. However, distribution figures can implicitly provide the impression of degrees of interdisciplinarity in the entire science system. In other words, we can estimate the number of WoS categories with presumably high or low degrees of interdisciplinarity according to measure applied, and then heuristically assess if the results are in line with our expectation. Distributions of WoS categories over “interdisciplinarity” are provided in Figure 3. For each graph, x-axis shows the degree of “interdisciplinarity” and y-axis shows the number of categories.

As shown, the interdisciplinarity values of Simpson, Gini, Rao-Stirling index with $S_o$, Hill type measure, clustering coefficient, and average similarity are comparatively concentrated in a certain range. Hence, these indicators might be problematic in their discriminatory power. Taking the average similarity measure as an example, while it shows a normal distribution in Figure 3, its values actually range between zero and 0.3. Thus, we conclude this measure shows an unsatisfied discriminatory power. The remaining measures to some extent follow Gaussian distribution. Nevertheless, some are highly right-skewed like PRO and Pratt, and others are highly left-skewed like $p_{in \_so}$, $rs_p$ with $1/S_o$, and betweenness centrality.

![Figure 3. Distribution of interdisciplinarity indicators](image)

In-depth analysis for several WoS subject categories

A specific examination of the degree of interdisciplinarity of the WoS categories based on the various measures provide a more direct impression regarding the effectiveness of these measures. However, because of limited space, here we only examine five WoS categories in-depth; these are NANOSCIENCE & NANOTECHNOLOGY (NANO) and BIOCHEMISTRY & MOLECULAR BIOLOGY (BIOM), which previous studies often consider to be highly interdisciplinary, LAW and MATHEMATICS (MATH), which are supposed to show a low degree
of interdisciplinary, and INFORMATION SCIENCE & LIBRARY SCIENCE (LIS). LIS is chosen because readers of this paper might be familiar with this field.

Table 3 presents the interdisciplinarity ranks of these five subject categories obtained using the measures that we have introduced previously. Instead of reporting the interdisciplinarity values obtained from the measures, we list the rank number attained after sorting all 224 categories according to their interdisciplinarity scores in a non-decreasing order. It should be mentioned that Gini, Pratt, and Speciation are inversely related with interdisciplinarity.

Obviously, the results obtained using these measures are quite different. As explained previous, measures in the first group is based on the WoS journal classification system. Hence, they reflect to what extent journals in a category are “diverse”, or can be assigned into multiple categories. The second group generally focuses upon references outside the journal subject categories or over various categories. Shannon entropy, Brillouin index and Simpson diversity show similar results, whereas PRO show some differences compared to the other three. The next group describes the centralized tendency of publications within a category. Interestingly, the results of the three measure are rather dissimilar. This is consistent with our Pearson’s correlation result, as shown in Table 2. This may suggest that our classification of these measures are deficient, or that they conceptually measures more diverse constructs than hitherto presumed. The fourth group contains several transformations of the Rao-Stirling index, and they are expected to be consistent in their empirical results. However, the results are not in line with the expectations. Using varying dissimilarity (or distance) matrices and working at different unit levels lead to rather divergent results. Finally, results from the intermediation measures are also quite varied. Meanwhile, note that the clustering coefficient and average similarity measures have poor discriminatory power of interdisciplinarity scores; hence, their ranks are not so useful in this context.

In short, these measures seemingly provide very different results when it comes to degree of interdisciplinarity for categories. This we consider strong evidence for the claim that interdisciplinarity cannot be sufficiently captured by one measure as a one-dimensional non-composite indicator.

Discussion and Conclusions

This paper aims to systematically explore and compare to what extent 16 interdisciplinarity measures are consistent, and to examine which attributes of interdisciplinarity they aim to indicate. We examine these interdisciplinarity measures in relation WoS categories. Based on the Pearson’s correlation coefficient, we find that most measures in the various groups do not have strong correlations. However, although measures in the same groups are expected to be strongly related, some measures that supposedly indicate the same attribute of interdisciplinarity turn out to be rather dissimilar. Furthermore, distribution figures provide an insight into the discriminatory power of the measures. Hence, we can identify measures with poor discriminatory power, for instance, measures of cluster coefficients and average similarity. These measures may not appropriate to be used. However, this may also cause by the choice of our dataset. In addition, we selected five WoS categories to carry out an in-depth analysis of the consistency. These results are to some extent consistent with the findings based on the Pearson’s correlation coefficients. Our results provide evidence for the claim that these measures indicate different attributes of interdisciplinarity, they are much more diverse than usually perceived.

Conducting such a study is challenging. Several issues are worth further discussion. First, we embed these interdisciplinarity measures into the analytical framework of Rafols and colleagues, since the framework can help us better understand various perspectives of interdisciplinarity. However, it does imply that this framework is not problematic. It is still open to discussion whether interdisciplinarity should be described using one or several attributes and thus measures. Our work provide some evidence that different measures of interdisciplinarity are not consistent, and they may actually capture different dimensions of interdisciplinarity. However, the question of which attributes are essential for depicting the nature of interdisciplinarity is still not answered.

Second, measures purporting to indicate the same attribute should be consistent. More specifically, we discuss several ways of using the Rao-Stirling measure, and they are expected to be consistent. However, the results are not in line with such expectations. It should be noted that using different dissimilarity (or distance) matrices and working at different levels of units would lead to different scores. Unfortunately, this issue is always overlooked in previous studies.

The main limitation of this work is that we have only examined the degree of interdisciplinarity for WoS categories. It may be that this is not an appropriate level for studying interdisciplinary research. Besides this, measures regarding coherence and intermediation do not perform well when examining the interdisciplinarity of WoS categories. Hence, further studies will be carried out at the disaggregate level of for example research institutions. In addition, our grouping of the measures maybe not be sufficiently appropriate. For instance, Shannon entropy, Brillouin index, and Gini coefficient probably should be assigned to the same group, for they all quantify unevenness in a dataset. Further studies should re-think and improve this grouping.

Abstract

In scientific funding applications, scientists usually pursue interdisciplinary applications that lead to interdisciplinary knowledge flow. This paper utilizes the co-occurrences of disciplinary application codes (DACs) to construct an interdisciplinary knowledge flow network. Based on 193517 sponsored projects of the National Natural Science Foundation of China (NSFC), we study the interdisciplinary flow of knowledge. Results show that the interdisciplinary knowledge flow network is a small-world network. The distribution of knowledge flowability follows the 80/20 law. Two main knowledge flow paths across scientific departments exist, showing the heterogeneity of knowledge distributions across scientific disciplines. Furthermore, it is also found that individual disciplinary diversity in the interdisciplinary knowledge flow can significantly positively influences the number of sponsored projects and the total sponsored money. The findings can give implications to the policy interventions in research practices.

Conference Topic
Science policy (on different levels), Studies on the level of individual scientists, Co-occurrence analysis, Social network analysis

Introduction

In scientific communities, knowledge flows across various scientific disciplines to solve emerging complex problems (Siedlok, Hibbert, & Sillince, 2015). Science is indeed becoming more interdisciplinary (Porter & Rafols, 2009) and scientists themselves need interdisciplinary knowledge and seek a variety of knowledge from other individuals through interdisciplinary collaborations (Carayol & Thi, 2005). In scientific funding, scientists sometimes pursue interdisciplinary scientific funding applications to succeed in academic competitions. Generally, interdisciplinary scientists are more competitive in applications. They do interdisciplinary research and have abilities to integrate knowledge flexibly. The relationship between scientific disciplines is strongly influenced by national funding foundations (Lyall, Bruce, Marsden, & Meagher, 2013). Interdisciplinary research needs financial support from different disciplines (van Rijnsoever & Hessels, 2011), and many scientific foundations, including the National Natural Science Foundation of China (NSFC), encourage interdisciplinary collaborations to accelerate innovation (Benner & Sandström, 2000). Understanding the rules of interdisciplinary knowledge flow of scientific funding is important to help create research policies and evaluate studies for scientists (Porter, Cohen, Roessner, & Perreault, 2007).
Knowledge flow across various scientific disciplines normally starts from knowledge chains generated by the interactions between scientists, and becomes a knowledge flow network with the extension of the flow boundary. With the collision of knowledge and emergence of new knowledge, a knowledge field will gradually form across various scientific disciplines to accelerate innovation (van Harmelen et al., 2012). This paper investigates the evolution of the structure of an interdisciplinary knowledge flow network over different periods. Furthermore, in knowledge flow, besides the heterogeneity of knowledge distributions in different geographical locations (Gertler & Wolfe, 2006; Wu, 2012), the distributions of knowledge flowability in different scientific disciplines are also heterogeneous. The diversity and heterogeneity in science and technology is regarded as a main factor to promote innovation (Stirling, 2007). Therefore, using the dataset of scientific funding, the present paper also studies the heterogeneity of knowledge distribution in different scientific disciplines.

In previous studies, datasets used to empirically study knowledge flow across different disciplines are mainly bibliometric (Wagner et al., 2011), including citations, co-occurrences, and co-authors. In citations, cited studies have their own scientific disciplines, which can be used to calculate the disciplinary diversity by Citations Outside Category (COC) (Porter & Chubin, 1985), Brillouin’s Index (Steele, 2000), and Network Coherence (Rafols & Meyer, 2010). Interdisciplinary knowledge flow is also studied at the journal-journal citation level (Leydesdorff, Rafols, & Chen, 2013). Compared with citations, co-occurrences mainly refer to the relation among subjects or keywords. In this aspect, the basic method is co-words analysis (Gautam & Yanagiya, 2012). Using this method, some meaningful words with high frequencies are drawn out and mapped to scientific disciplines. Similar to co-occurrences, co-author relationships are generated through the collaboration among scientists. With various disciplinary background, scientists need to exchange and create knowledge together. In previous studies, researchers use literature or patents dataset to study interdisciplinary knowledge flow (Chang, Lai, & Chang, 2009; Hu, 2009).

In this paper, we intend to explore the knowledge flow in interdisciplinary research using scientific funding dataset. The relationship between scientific disciplines, especially the creation of interdisciplinary knowledge, is strongly influenced by national funding agencies (Lowe & Phillipson, 2009; Lyall et al., 2013). We propose a new measure to quantify interdisciplinary knowledge flowability. In one hand, knowledge flowability considers the cognitive distance among disciplines based on the disciplinary application codes (DAC) tree used by NSFC (Benner & Waldfogel, 2008). In the other hand, the calculation of knowledge flowability also considers the co-occurrence of scientist’s interdisciplinary applications, which represent their initial motivation of knowledge flow among their corresponding scientific disciplines. Knowledge flowability is used to weight the edges of interdisciplinary knowledge network and investigated through the analysis of the interdisciplinary knowledge network.

Furthermore, with the development of modern science and technology, Interdisciplinary research play more and more important role. Scientists themselves need interdisciplinary knowledge and also seek a variety of knowledge from other individuals through interdisciplinary collaborations (Carayol & Thi, 2005). In the application of scientific funding, they also pursue interdisciplinary applications to be successful in academic competitions. Scientific interdisciplinarity, i.e. the diversity of individual scientific disciplines, might also be
an important factor to affect individual sponsored funding. However, to the best of our knowledge, it is still unclear how scientific interdisciplinarity affects the individual sponsored funding. Therefore, in this paper, we will also try to understand the impact of scientific interdisciplinarity on the performance of scientists to be sponsored. Using the regression methods, it is found that the diversity of knowledge in terms of scientific disciplines significantly influence the number of sponsored projects and the total sponsored money at the individual scientists’ level.

**Dataset**

We collect the raw dataset from 1999 to 2013 from the ISIS system, which is an Internet-based Science Information System of NSFC (National Natural Science Foundation of China), including 193,517 records in total. Each record contains project ID, the title, project leader’s name, the amount of sponsored money, approval year, disciplinary application code, etc. Disciplinary application code, called DAC in short, indicates which discipline a project belongs to. Individuals are thus required to select the suitable DAC, which represents the specializations in their own disciplines, when they apply for scientific funding. The set of DACs has a tree structure, in which the top nodes are scientific departments, the children nodes of scientific departments are research areas, the children nodes of research area are research fields, and the children nodes of research fields are research directions. Each DAC is divided into four parts and is used to map a NSFC sponsored project into its corresponding scientific department, research area, research field and research direction, respectively. For example, the DAC of a project is A010101, which indicates that the scientific department of the project belongs to “Mathematical and Physical Science”, its scientific area is “Mathematical Theory of Numbers”, and its scientific direction is “Analytic Theory of Number”. In the NSFC, there are eight scientific departments from A to H, 86 first-level DACs, 981 second-level DACs and 1679 third-level DACs.

**Calculation of knowledge flowability**

In order to investigate knowledge flowability among scientific disciplines, the formulation of the calculation is proposed in the following.

Firstly, we calculate \( CS_{ij} \) to confirm the existence of knowledge flow between two disciplines and if it exists, to measure how frequent it is. Let \( P_i \) denote the set of scientists who have applied projects using \( DAC_i \) as the main application code. Similarly, let \( P_j \) denote the set of scientists who have applied projects using \( DAC_j \) as the main application code. \( CS_{ij} \) is the occurrence frequency of scientists between \( DAC_i \) and \( DAC_j \), which can be formulated as follows:

\[
CS_{ij} = |P_i \cap P_j|
\]

(1)

where \(|.|\) indicates the size of a set.

If \( CS_{ij} > 0 \), it means there are scientists who are overlapped in discipline \( i \) and \( j \). These scientists may have the ability to apply interdisciplinary knowledge. Scientists who do interdisciplinary research make the initial engine of knowledge integration and utilization
across different disciplines (Klein, 2008). Therefore, $CS_{ij} > 0$ somehow indicates there exists potential knowledge flow between discipline $i$ and $j$. The bigger $CS_{ij}$ is, the more frequent the potential knowledge flow is. Otherwise, if $CS_{ij} = 0$, interdisciplinary relation between $i$ and $j$ does not exist in the disciplines of science funding.

The name ambiguity have to be solved in any studies that use author name information in bibliometric analysis (Wagner, Horlings, Whetsell, Mattsson, & Nordqvist, 2015). In this paper, we did not use bibliometric data, and in our sponsored project dataset, attributes related to each sponsored scientists is his/ her name and affiliation. However, in the real world, the ambiguity of names hampers us to identify a person merely by his/ her name. A way of disambiguation is to simultaneously use the name and the affiliation or co-authorship. Therefore, we combine the names and affiliations of sponsored project leaders to uniquely identify each person in this paper (Wu & Ding, 2013).

Secondly, we calculate $W_{ij}$ that denotes the interdisciplinary score between discipline $i$ and $j$. Each DAC is divided into four parts, and is changed into a DAC set that includes four codes, i.e., the code of scientific departments, the code of research areas, the code of research fields and the code of research directions. Let $C_i$ and $C_j$ denote the DAC sets of $DAC_i$ and $DAC_j$, respectively. $W_{ij}$ is calculated as below,

$$W_{ij} = \begin{cases} 0, & C_i = C_j \\ 1, & |C_i \cap C_j| + 1, & C_i \neq C_j \end{cases}$$

(2)

where $|.|$ indicates the size of a set.

Based on this formulation, the set of values of $W_{ij}$ is $\{0, 1, 1/2, 1/3, 1/4\}$. Accordingly, interdisciplinary scores can be classified into five types: $W_{ij} = 0$ is superior-subordinate; $W_{ij} = 1$ is cross-scientific-departments; $W_{ij} = 1/2$ is cross-research-areas; $W_{ij} = 1/3$ is cross-research-fields; $W_{ij} = 1/4$ is cross-research-directions.

Thirdly, we integrate the above two calculations to calculate $FL_{ij}$. $W_{ij}$ is interdisciplinary score between two disciplines, measuring the cognitive distance based on the hierarchical structure of the disciplinary code tree. $CS_{ij}$ is the co-occurrence frequency of scientists between two disciplines, measuring the potential knowledge flow in disciplines of scientific funding. Let $FL_{ij}$ denote knowledge flowability between discipline $i$ and $j$. Therefore, we have

$$FL_{ij} = CS_{ij} \times W_{ij} = \begin{cases} 0, & C_i = C_j \\ \frac{|P_i \cap P_j|}{|C_i \cap C_j| + 1}, & C_i \neq C_j \end{cases}$$

(3)

where $|.|$ indicates the size of a set.

Based on the above calculation, we construct an interdisciplinary knowledge flow network. In the network, nodes are DACs and each node represents one discipline. If the value of knowledge flowability between two nodes is above zero, the edge between them is formed and the weight of the edge is $FL$. In order to investigate the evolution of network, we construct four sub-networks of four periods. Accordingly, the whole sample data is classified.
into four parts according to the approval years. The first is from 1999 to 2001 with a total of 199 records, the second is from 2002 to 2005 with a total of 3071 records, the third is from 2006 to 2009 with a total of 3459 records, and the forth is from 2010 to 2013 with a total of 5899 records.

Investigation of knowledge flow across disciplines
Evolution of knowledge flowability
To investigate the evolution of interdisciplinary knowledge flow network, we calculate ratios of DACs used in interdisciplinary applications for each period and the results are as follows. As shown in Figure 1, in the first period, the ratio of DACs involved in the interdisciplinary application is only 10.6 percent, while in the latest period, it has risen to 81.8 %. There are an increasing number of disciplines (nodes) involved in the interdisciplinary knowledge flow network.

Next, the changes of knowledge flowability are also investigated. In the result of Analysis of Variance (ANOV) shown in Figure 2, the value of Sig. is zero, indicating that the between-group (between different time periods) differences are significant. The changes of standard deviations and means of knowledge flowability among the first three periods are obvious, but from the third period to the last period, they are much more subtle.
In order to observe the changes of knowledge flowability in details, we analyze the types of interdisciplinary knowledge flow in each time period. There are four types of interdisciplinary knowledge flow in each time period: cross-research-departments, cross-research-areas, cross-research-fields, and cross-research-directions. We plot the ratios of all the four types in Figure 3. As the figure shows, no matter in which time period, the type of the cross-research-departments contributes the highest ratios in the whole. In addition, we can find that the ratios of the type of the cross-research-fields and the cross-research-directions are becoming bigger. It means that researches cross-research-fields and the cross-research-directions are more and more popular over years.

**Evolution of interdisciplinary knowledge flow network structure**

Structural characteristics in each time period reveal the evolution of knowledge flow network. In order to draw out these structural characteristics, some network indicators are calculated. Those indicators include the number of nodes, average degree, average weight, the density of network, average clustering coefficient and average path length, etc. These indicators are separated into three types. The first type is macro network indicators, including the number of nodes and density. The number of nodes reflects network scale. The more nodes the interdisciplinary knowledge flow network has, the wider the network boundary is. Density describes the aggregation of nodes. The network becomes more concentrated as the density grows greater. The second type of indicators shows the characteristics of one node or one edge from a micro view. They are average degree and average weight. The former one indicates the width of connection and the latter one explains the depth of connection. The last type of indicators illustrates which type the network belongs to. We can determine whether a network belongs to a random network, regular network or small world network through the comparison of average clustering coefficient and average path length. Comparatively, the average path length of random network is shortest and its average clustering coefficient is comparatively lowest, while the average path length of a regular network is longest and its average clustering coefficient is highest. The small world network has the average path length and average clustering coefficient between random network and regular network (Watts & Strogatz, 1998).

</tbody>
</table>

The structural characteristics of knowledge flow network in each time period are shown in the Table 3. With the increase of nodes, the density declines from 0.005 to 0.002. It indicates all the networks are loose. Meanwhile, with the expansion of the network size, there is no significant increase or decrease of the network cohesion indicated by the average clustering coefficient. The average degree can represent the width of connections between disciplines, and the average weight represents the depth. Overall, the width of connections between two disciplines in the network continues to increase, but the depth fluctuates around 0.7. In brief, the addition of nodes cannot deepen disciplinary connections.

At last, we analyze the type of network by comparing average clustering coefficients (CC) and average path lengths (PL) with those (CCR,PLR) of random networks generated with the same nodes(n) and the same mean links per node (k value). We use the following formula to estimate CCR and PLR: CCR~k/n, PLR~lnn/lnk (Uzzi, Amaral, & Reed-Tsochas, 2007). Typically, there are two ways to compare small-world networks to a random network. One is that PL>PLR and CC>>CCR (Uzzi et al., 2007; Watts & Strogatz, 1998). The other is a more quantitative definition of these relationships. We set $\gamma=CC/CCR$ and $\lambda=PL/PLR$. Then, we have the following equation: $S=\gamma/\lambda$. If the equation satisfies the condition: $S>>1$, the small-world exists (Davis, Yoo, & Baker, 2003; Uzzi et al., 2007). In this paper, all networks satisfy the condition of $S>>1$. Thus, we can judge that the interdisciplinary knowledge flow network is a small-world network. It means some disciplines are related to each other much more closely and the possibility of interdisciplinary collaboration and innovation due to interdisciplinary knowledge flow is considerably high.

**Heterogeneity of knowledge flowability**

Knowledge flow is heterogeneous among different disciplines. Knowledge flow among some disciplines is rather easier, because: firstly, these disciplines are somehow related; secondly, several basic disciplines whose knowledge is more inclusive and have wide influences on other disciplines; thirdly, some disciplines develop rapidly and need to absorb knowledge from others. In this part, we will explore the heterogeneity of knowledge flow across scientific departments.

In order to verify the heterogeneity of knowledge flow across scientific departments, we test the between-group differences with Analysis of Variance (ANOVA). Here, the grouping
variable is scientific departments. As shown in Figure 6, the value of Sig. is zero, which indicates that there are very highly significant differences of knowledge flowability among different scientific departments. In addition, we plot standard deviations (Std.Devs) and means of knowledge flowability in each department. Except for department D (Earth sciences), all the means are centered on 1 and all Std.Devs locate in [1, 2]. It reveals that the knowledge flowability between two disciplines in department D (Earth sciences) is more concentrated inside the scientific department than others.

<td>.000</td>
</tr>
</tbody>
</table>

**Figure 4.** Comparison of knowledge flowability across scientific departments

To further compare knowledge flowability among different departments, we analyze the types of interdisciplinary knowledge flow in each department according to interdisciplinary types. There are three interdisciplinary types in one department: cross-research-areas, cross-research-fields, cross-research-directions. The ratios of all these three types in department A to H are shown in Figure 7. The type of the cross-research-areas contributes the most to the whole knowledge flow. It's worth to note that it happens in departments H, G, F, D, C, B, but not in A and E where the main interdisciplinary type is cross-research-fields rather than cross-research-areas. This means that the proportions of these three interdisciplinary types are much more balanced in scientific department A and E.

![Graph showing interdisciplinary knowledge flow types](image)

**Figure 5.** Types of interdisciplinary knowledge flow in each department
After the above comparisons, it can be confirmed that there exists the heterogeneity of knowledge flow across scientific departments. The knowledge flow differs dramatically in different scientific departments.

**Distribution of knowledge flowability**

According to the distribution of knowledge flowability, the heterogeneity of knowledge flow can be investigated directly. Therefore, we draw out the curves of knowledge flowability distributions from 1999 to 2013, as shown in Figure 8. There are four colors in the figure and one color represents one time period, respectively. The horizontal axis is the value of knowledge flowability between two disciplines, and the vertical axis is the frequency. It is found that apart from the first one whose range is only three years, the remaining three curves are very similar in shapes. The similarities appear significantly in two respects. First, there are three peaks in every period and the peaks locate in the same horizontal position. Second, besides peaks, the curves are extremely close to the horizontal axis to hold long tails (we cut off parts of the tails in the figure).

![Figure 8. Distribution of knowledge flowability](image)

Based on the above observation, we wonder if there exist some profound laws to follow or not. To further explore the potential law, some parts of knowledge flowability, whose value is 1/3, 1/2 or 1, are picked out and summed up in ratios. Knowledge flowability with these three values counts almost 80% of the total. In general, the distribution of knowledge flowability obeys the law of 80/20.

**Investigation of knowledge flow across scientists**

In order to investigate the knowledge flow across scientists in scientific funding, this section uses negative binomial regression and ordinary least squares regression to investigate the impact of individual disciplines diversity on the number of sponsored projects ($NumProj$ is...
the dependent variable in Model 1 and Model 2) and the sponsored money (SponMoney is the dependent variable in Model 3 and Model 4), respectively. In the regressions, we also control the total number of sponsored projects in the scientific department that the sponsored scientist belongs to (DeptNumProjs), the scientist’s experience that is the total years from his/her first sponsored project in NSFC (Experience), the prestige of the institution that the sponsored scientist works in (Prestige), the total number of projects that the institution of the sponsored scientist has sponsored (InsNumProjs). The main predictors are the diversity of disciplines (Diversity), which is first calculated according to Formula 2 for all the pairs of the DACs of his/her sponsored projects and then average the values of each pair of DACs.

</tbody>
</table>

* p< 0.05, ** p< 0.01, ***p< 0.001

Through the regressions, it is found that Diversity and Diversity squared in the knowledge flow across scientists both positively affect the scientists’ innovation performance in term of NumProj and SponMoney, respectively. This main finding is interesting to indicate that a good level of interdisciplinary knowledge flow is very important for a scientist to be successfully sponsored by scientific funding.

Conclusions

One of the most important characteristics of modern science is interdisciplinary (Porter & Rafols, 2009). About 46.8% of the 5500 existing disciplines are interdisciplinary and new inter-disciplines are emerging as well (Research, 2005). Under this situation, the NSFC encourage interdisciplinary applications through a series of policies such as disciplines union funding support. By the end of 2013, more than 59% applicants have ever changed disciplinary application code during application (Wu et al., 2015). The disciplinary application code plays a key role in the selection of review experts during the peer review. It is necessary to understand the relationships among disciplines to to well guide the funding applications.

This paper investigates the interdisciplinary knowledge flow across disciplines and scientists based on disciplinary application codes of scientific funding. The interdisciplinary
knowledge flow network is made up of disciplines as nodes and their relationships as links. The nodes of disciplines correspond to disciplinary application codes. The links among disciplines represent the co-occurrences of disciplinary application codes (DACs). Through analyzing knowledge flow networks among scientific disciplines and investigating the impact of scientific interdisciplinarity on the performance of scientists, the findings have some implications from a scientific policy perspective, and can also give some suggestions to the policy interventions in research practices.

Therefore, this paper studies the interdisciplinary knowledge flow across disciplines and scientists, and gives some suggestions to policy makers of scientific research. Nevertheless, our research is not without limitations. Although we have solved the ambiguity of applicant names, the ambiguity also exists among DACs in the dataset because it cannot be completely solved and the discipline classification scheme has not been perfected with the development of interdisciplinary trend in science and technology (Huutoniemi, 2012). In the future work, the impact of network effects on the total sponsored money and the number of sponsored projects in a certain scientific discipline can be studied as well.

The association between university research indicators and success rates in the European Framework Programmes

Abstract

In this study, we investigate which university research indicators (size, citation impact, industry collaboration and reputation) are associated with success in the European Framework Programmes for Research and Innovation (the Seventh Framework Programme and Horizon 2020). Based on a unique dataset involving all applicants to and project participants in EU projects, we have calculated success rates for all universities in the world that have applied for EU funding in the period 2007-2015. Linked to results from the Shanghai Ranking and to publication indicators from the Leiden Ranking, we demonstrate how such university research indicators are correlated with success rates in various EU programmes. Our analysis shows that highly cited papers have the highest correlation with success rates.

Conference Topic
Indicators; Science policy and research assessment; University policy and institutional rankings

Introduction

There are large differences in how institutions perform in university rankings. The most influential rankings allegedly reflect various aspects of university performance, such as the reputation or research quality of an institution; to a lesser degree the teaching quality. Similarly, there are large differences across universities in their success when applying for external funding. Although there are several limitations attached to university rankings, one would expect that there is a certain correlation between the two measures: The higher ranked institutions (by high quality research or high international reputation) would have higher success rates in terms of obtaining research funding. In this study, we attempt to investigate to what extent the institutions’ reputation and publication and citation patterns as reflected in university rankings are associated with their success rates in the European Union’s Framework Programmes for Research and Innovation (EU FPs). There is little evidence about this correlation, because the data that is available – and the studies using these data – have relied upon participation data in FPs, and not on application data, thereby not taking the ratio between number of submitted proposals and number of granted projects (i.e. success rates) into account.

Some scholars have studied patterns and determinants of R&D collaborations using datasets on participation in EU FPs (e.g. Roediger-Schluga & Barber 2008; Paier & Scherngell 2011; Enger & Castellaci 2016). In a recent study by Lepori et al. (2015), it was demonstrated that in a sample of 2,235 European higher education institutions, the level of participation in EU FP funded projects was strongly associated with organizational characteristics, particularly with size and reputation. The finding is in accordance with studies that have shown that acquisition of research funds also at the individual level is more strongly correlated with the reputation of the research applicant than with the judgement of the proposal quality in the selection process (cf. Hamann, 2016). With respect to R&D collaboration, Lepori et al. (2015, p. 2153) argue that: “higher-reputed researchers and organizations will be sought to a greater extent as research
partners and, therefore, move to the center of the network”, but such an assumption – at the university level – does not take into account that the highly reputed institutions may be at the centre, i.e. participating in many collaborative projects, also because they simply submit many proposals, reflecting their large institutional size. Piro, Scordato & Aksnes (2016) investigated all EU FP consortia in EUs Seventh Framework Programme and Horizon 2020, involving participation from six European countries and concluded that a strong determinant for success in FPs was previous participation in FP projects and a large network of European partners from past and ongoing projects, indicating that institutions that are already central in the European research network will become even more central as they are attractive partners to engage with for other institutions, thus strengthening the ‘Matthew effect’ of FP participation.

Research questions
The aim of this study is to examine the correlation between universities’ success rates in EU’s Seventh Framework Programme (FP7) and Horizon 2020 (H2020) and their size (measured as publication volume), research impact (measured as citation impact), industry orientation (measured by co-authored publications with industrial partners) or with reputation (measured as position in global university rankings). The research questions of our paper have the universities’ success rate in EU FPs at their centre, i.e. the ratio between an institution’s number of submitted proposals and its number of funded projects. We examine whether this measure is differently associated with the four university research indicators described above. The study is carried out in two steps. First, we make a correlation analysis of the relationship between success rates and university indicators. Second, we carry out fine-tuned analyses, where the following four correlations are investigated:

Across thematic areas in the FPs (1). The structure of FP7 and H2020 is different, with different organizing of thematic areas/pillars, emphasis of action instruments, demands for technology readiness levels (TRLs), demands for inclusion of industry and end-users in consortia, varying degrees of basic and applied research, etc. Altogether, considering a university’s total success rate for an entire FP may not be very useful as a university may be highly successful within the thematic area closest to the main research areas of the university, while may still be participating in proposals to a range of more distant topics that in sum may exceed the volume of the former. In some thematic areas of the FPs, academic qualifications and merits may play a larger role in the review process, compared to other areas where the actions are more aimed at private for profit companies, thus making the universities’ role less crucial.

University as coordinator vs. ordinary partner (2). The coordinator is the driver of the project, and in a consortium where the number of participants may vary from 2-3 to more than a hundred, it seems plausible that the reputation or impact of the coordinating university will be more important than those of the other universities involved in the consortium. In other consortia, which may be coordinated by e.g. private companies, it is an open question whether the inclusion of a highly reputed university among the partners will strengthen the proposal’s prospects for funding. Alternatively, the review process may be so holistic in its consortia assessments that no special attention is given to the coordinating institution - rather the consortia is being judged based on the totality of all involved partners.

The European Research Council (ERC) vs. collaborative programmes (3). One distinction that can be made between different elements of the FPs is that the ERC in contrast to other instruments is less focused on research collaboration. Decisions on ERC funding are made based on criteria related to scientific excellence only. This criterion is applied for assessing both the proposed research and the Principal Investigator. The main purpose of ERC is to support
investigator driven, frontier research, across all fields. ERC belongs (now) formally to the first pillar of the H2020 programme promoting ‘Scientific Excellence’ alongside e.g. EU’s mobility programme Marie Skłodowska-Curie actions (MSCA) and the programme Future and Emerging Technologies (FET), aimed at initiating radical new technology through unexplored collaborations between advanced multidisciplinary science and cutting-edge engineering. In the review of the applications to the ERC, the panels have used three criterions: 1) scientific quality of the applicant, 2) quality of the research project proposed by the applicant, 3) assessment of the scientific environment at the institution where the applicant’s research would be conducted. In later calls, only the first two criterions have been used. Such criterions are different from other programmes, and may therefore lead to different importance of universities’ citation impact and reputation in the review process. For the other programmes under H2020, the general rule is that experts are to assess proposals on the basis of three criteria: excellence, impact, and quality and efficiency of the implementation (Langfeldt & Scordato, 2016).

Geographical origin: European vs. non-European countries (4). It is fully possible that e.g. citation indicators are more associated with overall success rates compared to results from university rankings in some programmes, while the opposite may be the case in some thematic areas or for universities from some specific geographical areas. For example: the citation impact may be important in explaining differences among European universities, while rank position in a global university ranking may be more associated with differences in success rates between universities from Asia and South-America. The geographic dimension is important because many of the most successful universities in the world, according to our selected indicators, are from the United States (in particular), Canada and Asian countries. These countries seldom contribute as coordinators and their total participation in the FPs is limited compared to European institutions, thus making their centrality in the FP networks less pronounced.

Methods and data sources
This study draws upon three main data sources: 1) data about EU FP proposals and applications from the European Commission’s data warehouse ECORDA, 2) data from the Leiden Ranking produced by Centre for Science and Technology Studies (CWTS) at Leiden University, and 3) data from the Academic Ranking of World Universities (ARWU) from the Shanghai Jiao Tong University, commonly referred to as the Shanghai Ranking. Three of our university indicators are taken from the Leiden Ranking: Number of fractionalized publications (PUBS), share of publications co-authored with industry (INDUSTRY), and percentage of the world’s ten per cent most cited publications (TOP10%) (see Waltman et al. 2012). The fourth indicator is the universities’ mean rank position in the Shanghai Ranking (ARWU).

ECORDA data
The main data source in this study is ECORDA data, covering FP7 and the early phase of H2020. We have used the November 2015 edition, which means that our FP7 data are complete, whereas the analysis of H2020 is restricted to the early results of that framework programme. In ECORDA, the institutional affiliations of applicants are not standardized. It is therefore not possible to use the data for calculating success rates without going through the process of standardizing the institutional names. The novelty of our study is the build-up of a completely new database for participation in both EU proposals and projects. At Nordic Institute for Studies in Innovation, Research and Education (NIFU), all institutional addresses in EU’s application and project databases of FP7 and H2020 have been standardized (approximately 1.1 million institution names). To the best of our knowledge, such a standardized data file including both applicants and grant recipients does not exist anywhere else. This has enabled us to extract data
about all institutions’ total volume of applications and projects, thereby making it possible to

In targeting universities for the present study, we excluded all university hospitals, and left out
continuing education, training centres, etc., thus focusing the analysis on ‘pure’ universities and
university colleges. All institutions in ECORDA with a research and/or teaching activity has
been investigated in detail to ensure that only universities are brought into the analyses. Based
on the number of applications and project participations, we calculate each university’s success
rate in each FP programme separately, and overall for FP7 and H2020 combined.

Number of publications from the Leiden Ranking (PUBS)
The Leiden Ranking includes data on the publication volumes of the world’s largest
universities. Lepori et al. (2015) investigated whether the number of participations in FPs is
expected to increase with the research capacity of the organization. They postulated that
organizations with more research capacity have more research teams (possibly also covering
more research topics), and therefore engage in more collaborations. Size of an institution may
also determine whether or not the institution has developed an administrative capacity that may
facilitate participation in FP applications and projects, which is often seen as crucial for
researchers (Piro, Scordato & Aksnes, 2016). Since we do not have institutional data for the
universities – we use the number of scientific publications (PUBS) as a size indicator. All
universities in the Leiden Ranking have been given a value representing their mean number of
fractionalized scientific publications during the years 2011-2014 (the Leiden Ranking does not
provide numbers further back in time).

Top 10% publications from the Leiden Ranking (TOP10%)
In the Leiden Ranking, there are two main citation indicators: mean normalized citation score
(MNCS) and percentage of highly cited papers, i.e. top 10 per cent publications (TOP10%).
The latter indicator measures the proportion of a university’s publications that, compared with
other publications in the same field and from the same year, belong to the ten per cent most
frequently cited in the whole world. Since MNCS and TOP10% are strongly correlated we
chose TOP10% as this reflects the proportion of a university’s publications with very high
impact, compared to MNCS which provides an average of all research at a university, from
uncited works to extremely cited works. We refer to Waltman et al. (2012) for a more detailed
discussion of the MNCS and TOP10% indicator.

Share of co-authored publications with industry from the Leiden Ranking (INDUSTRY)
The Leiden Ranking provides the proportion of a university’s publications that have been co-
authored with one or more industrial partners (INDUSTRY). We use this as a proxy for how
business/industry oriented a university is.

University ranking data from the Shanghai Ranking (ARWU)
The relevance and quality of university rankings are highly disputable (Piro & Sivertsen, 2016),
but they are well-known and may be used to investigate the ‘quality’ of the institutions the
applications are affiliated with. Despite the various limitations of the university rankings’
indicators and methods underlying them (Docampo and Cram 2015; Safón 2013), few would
disagree that the universities ranked at the top in these rankings are prestigious and leading
institutions. We may claim that the rankings are able to identify the best universities of the
world, but fail in discriminating between ‘regular’ universities. Here, we compare the
universities based on their ranking in the Shanghai Ranking (ARWU), providing the
universities with a mean value of their rank position in the years 2003-2014. A large portion of
the universities’ ARWU scores are derived from their publication output and a citation indicator (cf. PUBS and TOP10%). Nevertheless, it is important to note that the methodology is very different. ARWU measures whole counts of publications, while we measure fractionalized publications; ARWU measures highly cited researchers (based on individuals featuring on Thomson Reuters’ list of highly cited researchers), while we measure highly cited publications.

Programmes studied in EU FPs

Although some of the FP7 programmes are possible to compare with H2020 programmes, others are not. Therefore, the only consistent way of comparing success rates is to do so for all programmes separately. We have restricted our study to seven main programmes of the FPs: (1) The European Research Council (ERC) and (2) Marie Curie Actions (MCA in FP7)/Marie Skłodowska-Curie Actions (MSCA in H2020) are comparable across FP7 and H2020 and therefore features as four distinct programmes. (3) Cooperation (FP7): Energy; Environment (incl. Climate Change); Food, Agriculture & Biotechnology; Health; Information and Communication Technologies; Joint Technology Initiatives; Nanosciences, Nanotechnologies; Materials and new Production Technologies; Security; Socio-economic Sciences & Humanities; Space; Transport (incl. Aeronautics). (4) Societal Challenges (H2020): Climate action, environment, resource efficiency and raw materials; Europe in a changing world – inclusive, innovative and reflective Societies; Food security, sustainable agriculture and forestry, marine and maritime and inland water research; Secure societies – Protecting freedom and security of Europe and its citizens; Secure, clean and efficient energy; Smart, green and integrated transport; Health, demographic change and wellbeing. (5) Industrial Leadership (H2020): Access to risk finance; Advanced manufacturing processing; Advanced materials, Biotechnology; Cross-theme; Nanotechnologies, advanced materials and production; Space; Information and communication technologies. (6) Science with and for Society (H2020): Develop the governance for the advancement of responsible research and innovation; Integrate society in science and innovation; Make scientific and technological careers attractive for young people; Promote gender equality in research and innovation. (7) Future and Emerging Technologies (H2020), which is one of four programmes under the Excellence pillar of H2020 (alongside ERC, MSCA and Research infrastructures – the latter not part of our analysis).

Study Sample

In ECORDA we have identified 4,957 higher education institutions from a total of 174 countries. Of these 697 are included in the Leiden Ranking and 482 in ARWU. Combined there are 718 universities from 49 countries that are included in one, or both, of these rankings. With more than 200 universities in total, the United States and China are highly dominating the list of universities. 270 universities are from EU member states, 32 from other European countries, 191 from North America, 20 from Latin- and South America, 168 from Asia, 28 from Australia/New Zealand, and 9 from Africa. The universities are analysed separately and in groups. For each university research indicator, we have grouped the universities in deciles by their position on the respective indicator, so that each university (in most cases) will be assigned to different categories for different indicators. In ARWU the universities are grouped in ten groups of 41-52 universities, whereas the universities in the Leiden-based indicators are grouped in nine groups of 69-76 universities. In analyses where the results are split by geographical regions, we distinguish between EU28 and associated countries to H2020 (as of January 1st 2017 includes universities from Israel, Norway, Serbia, Switzerland, Tunisia and Turkey) and the rest of the world.
Results

Table 1 shows the key values for the (deciles of) university groups by four university indicators: Mean position in the Shanghai Ranking (ARWU), mean number of fractionalized publications in the Leiden Ranking (PUBS), mean shares of publications co-authored with industry (INDUSTRY) and mean share of top 10 per cent publications in the Leiden Ranking (TOP10%). These numbers are based on overall performance in both FP7 and H2020 and do not distinguish between programmes, thematic areas and so forth. A few inconspicuous findings emerge. First, in all university groups we find universities with a success rate of zero, i.e. they have not taken part in any proposals that have been granted funding. Most of these ‘unexpected cases’ originates from the US university system, but it is important to note that their contributions to proposals is not low – in some cases US universities have participated in more than 200 proposals, resulting in no funding. Second, due to the large US contribution to the first university categories (1), it appears that the top-tiers for all three indicators are found in university groups 2 and 3, having a larger European contribution of universities. Third, the activity measures (applications and projects) of EU FP involvement, is clearly diminishing from university groups 2 and 3 and onwards, which is hardly surprising as the universities are getting smaller the closer we are approaching university group 10. Fourth, mean success rates of universities by groups do not follow a similarly easily detectible pattern. Based on ARWU, the lowest success rates are indeed found among the highest ranked universities, while the mid-ranked universities (groups 5 and 6) have the highest success rates (15 and 16 per cent respectively).

In the indicator PUBS, success rate is lowest in the expected university group (10), and highest in the third and sixth university group, while for a university stratification based on TOP10% the highest success rate is in the second highest ranked group of universities.

**Correlations**

Again, without distinguishing between different types of programmes, thematic areas and so on, a correlation analysis (Pearson’s r) found no significant correlations between the university indicators and success rates. The only exception was a weak correlation between INDUSTRY and success rates.

**Correlations is significant at the 0.01 level (2-tailed). * Correlation is significant at the 0.05 level (2-tailed).**
However, when splitting the results by European vs. non-European countries, the results change markedly (Table 2). Outside Europe, the correlations are weak and appear random: high shares of TOP10% are even negatively associated with success rates, while for high ARWU rank it is the opposite. We will therefore only pursue results for European countries in upcoming tables and figures. The correlations are split in Table 3 by a sample of nine main thematic areas/sub-programmes, and shown separately for coordinators and partners. In the Cooperation programme of FP7, all four indicators are significantly correlated to coordinators’ success rates, most notably the TOP10% indicator. 308 universities in the Leiden Ranking had coordinated an application submitted to the Cooperation programme. This programme does not have any direct equivalent in H2020, rather, the sub-programmes of the Cooperation programmes are now found in the pillars Industrial Leadership (e.g. ICT) and Societal Challenges (e.g. Health).

** Correlation is significant at the 0.01 level (2-tailed). * Correlation is significant at the 0.05 level (2-tailed). (1) Regression estimate significant at the 0.05 level (2-tailed), (2) Regression estimate significant at the 0.01 level (2-tailed) and (3) Regression estimate significant at the 0.005 level (2-tailed).

In H2020’s Industrial Leadership only INDUSTRY is correlated with success rates, while it is foremost TOP10% and PUBS that are correlated in the Societal Challenges program. In the Marie Curie mobility programmes, there is very little evidence of university indicators being correlated with success rates, while the only significant correlation found in the program Science with and for Society, is a negative correlation between ARWU and success rate, clearly indicating that this programme is not targeting the most prestigious universities.

Due to the correlations between our university research indicators, we also performed an OLS regression analysis to determine whether their significant correlations with success rates still
held. In Table 3, the significance levels of the regression estimates are indicated by (1) significant at the 0.05 level, (2) significant at the 0.01 level and (3) significant at the 0.005 level. As expected, the most consistent set of associations between university research indicators and success rates is found for ERC. It is also evident that TOP10% and ARWU are more strongly correlated to success rates than PUBS and INDUSTRY. The programme Future and Emerging Technologies (FET) under the Excellence pillar of H2020 is a special case, as it has become the programme with the lowest success rate in H2020 due to the large volume of submitted proposals. FET consortia are typically much smaller than consortia in Industrial Leadership and Societal Challenges, and it is only coordinators’ TOP10% and INDUSTRY values that are correlated to success rates. The main tendency in Table 3 is that the university indicators for coordinating universities are more related to success rates than for universities in a partner role, and that TOP10% is clearly more associated with success rates across the programmes than the other indicators.

**Prediction analysis**

The results so far have been based on correlation analyses where each university is treated as a separate unit. We now look at the ten university groups that were constructed for each university indicator. Based on mean success rates within each group we use a simple prediction test of how many correctly predicted rank values each university group has for the indicators. In a selection of ten groups, if a university group with e.g. the third highest ARWU score also has the third highest success rate, then the ARWU score is 100 per cent correct predicted for this group.

</table>

If the university group with the lowest ARWU scores (that is, group 10) has the highest success rate, then the ARWU rank of this group completely fails to predict the success rate. The
prediction value of each indicator is then the sum of all university groups’ deviations from a correctly predicted success rate rank. The first observation, cf. correlations in Table 4, is the very low predictive power of university groups for partners’ success rates. It is practically non-existing in many programmes. The main result is that when universities are coordinating applications, the university group values correspond with success rates. ERC, FP7 Cooperation and H2020 Societal Challenges may all be characterized as programmes with good overall association between university research indicators and success rates. In the FET program it is striking how the TOP10% indicator is correlated to success rates. In other programmes such as Marie Curie and Science with and for Society there is no evidence at all for such associations. TOP10% values of coordinators generally stand out as most linked to success rates.

We illustrate these findings by analysing the coordinating universities in FP7 Cooperation (Figure 1). We find that for all four indicators, except INDUSTRY, the success rates are highest in university groups 1 (i.e. the groups consisting of universities with the highest indicator values). For the indicator PUBS, there is a clear tendency towards declining success rates as we move from group 1 to group 10, but from the third group and onwards, it levels out. For ARWU values, there are no systematic patterns at all. However, when we study TOP10%, there is a systematic decline from university group 1 to university group 10. The success rate of the university group with the lowest TOP10% values is less than 20 per cent of what the universities with the highest shares of highly cited papers have.

**Discussion and conclusions**

The findings of our study implicate that analysing publication, citation and reputation indicators in relation to success rates in the European Framework Programmes (EU FPs) do make sense, i.e. the indicators that we have used are associated with success rates in plausible manners, indicating that these associations are not random or due to statistical noise. Our analysis
demonstrates that universities’ success rates in EU FPs are less size- and reputation dependent than what might be expected, and more related to citation impact.

Previous studies have shown that the large, prestigious universities dominate EU FP participation. This study provides new insight into characterizing European research as ‘elite-driven’. The basis for the analysis is the yet unexplored possibility that large and prestigious universities are more involved in EU FPs simply because they are either highly research intensive and/or has a size allowing them to engage in more proposals. Our standardization of ECORDA has, for the first time, enabled comparative analysis of success rates for all universities in the world. The study thus adds knowledge about these universities’ relative strong contribution to EU FP participations. The analysis point at the following results for the four dimensions studied in this paper:

**University as coordinator vs. partner (1):** The success rates for universities differ and depend on whether they have coordinated or contributed as partner in a proposal. The university research indicators related to the coordinating university’s size, industrial collaboration, citation impact and global reputation appear to be most important for success rates. An explanation may be that the coordinator characteristics are given more weight in the review process of proposals than partners’ characteristics in some programmes. In other programmes, it is the consortia itself that is reviewed based on the partners’ complementarity in fulfilling the aims of the project. Here, we may postulate that ‘strong’ universities attract stronger partners to their consortia, thus making the characteristics of the coordinating university associated with the partners’ characteristics.

**Across thematic programmes (2):** The correlations of university research indicators and success rates differ between the EU FP programmes, e.g. the TOP10% indicator stands out as the ‘ERC indicator’, the INDUSTRY indicator as the ‘Industrial Leadership indicator’, ARWU’s negative association in the Science with and for society programme illustrates how this program is lesser oriented towards research excellence than other EU programmes. These findings are not surprising as the indicators may have varying relevance across programmes and instruments. For example, the Marie Sklodowska Curie actions aims at targeting young researchers, stimulating mobility and cooperation, and build effective cooperation between science and society; aspects that are unlikely to be reflected through the selected indicators. The university research indicator that is most strongly associated with success rates in EU FPs is the share of highly cited papers, that is, papers that belong to the ten per cent most frequently cited publications. This indicator is strongly correlated to the mean citation rate of publications, but not so with a university’s total number of publications, its share of co-authored publications with industry or with its position in ARWU. It is not foremost large or highly ranked universities that obtain high success rates in the FPs, rather it is the highly cited universities.

**European vs. non-European countries (3):** One possible mechanism behind the often very low success rates of the large non-European universities may be that they are peripheral actors in the EU FP network. Piro, Scordato & Aksnes (2016) defined ‘centrality’ as the sum of unique partners an institution had been working with in funded EU-projects, and found a strong relationship between centrality and success rates (also between the number of project participations and success rates, clearly providing support to the ‘Matthew effect’ in EU FPs). Universities that are on the inside of the EU FP networks benefit from their institutional reputation, their know-how on how to write proposals and their networks that they can draw upon. The importance of strengthening one’s degree of centrality in the European research network, has even been highlighted by the European Commission (2015a, p.112) as an
important driver towards success, recommending that institutions should make efforts in increasing their networks. However, the landscape of FP partners seems fixed. The growth in FP funding over time has not been followed by a corresponding increase in the number of units that receive funding (European Commission, 2015b). Our results certainly do not support any claims that bringing e.g. highly prestigious US universities into a consortium is beneficial for the prospects of funding. In fact, bringing in a prestigious university into a consortium only seems a proper strategy when the university is already a key player in FP research. Although it is possible for partners from outside of the EU to coordinate projects, such coordination is almost non-existing, and our results have clearly demonstrated that the university research indicators are almost exclusively associated with success rates for universities in a coordinating role, hence the lack of significant correlations for universities from outside of Europe.

**ERC vs. collaborative programmes (4):** There are large differences in various EU programmes in how university research indicators are related to success rates. The most distinct finding was between ERC other thematic areas. As expected, university indicators measuring scientific excellence was more accentuated in ERC, but a startling discovery was how the split-up of FP7’s Cooperation program to new programmes in H2020 led to much smaller associations between these indicators and success rates. Furthermore, industry collaboration became more evident as a factor in understanding success rates. We believe this must be seen in light of the reorientation in H2020 towards commercialization and societal impact.

Abstract
This article analyses the flow of scientific information across several domains. The point of departure was the collection of data on the characteristics of European projects on energy savings funded under the Seventh Framework Programme. After bibliometric identifiers were created for the respective scientific papers indexed in the Web of Science, the impact of these papers was analysed using altmetric indicators. A multiple linear regression model was developed to relate the variables from each information source in an attempt to detect the ones that contribute to the social impact of scientific production. The preliminary results show that the publishing journal, type of paper and international collaboration are the most significant factors in that regard.

Conference Topic
Altmetrics

Introduction
Until only a few years ago, the predominant model for the production and assessment of academic knowledge revolved around the dissemination of research results in the form of published papers and patents. Against that backdrop, scientometrics and bibliometrics provided the tools of choice for analysing scientific productivity and studying the impact of research within the academic community (Callon et al., 1995). In addition, the analysis of research projects has proven to be a valuable approach to locate data on the lines of research proposed and accepted and acquire insight into significant aspects of research underway (Plaza, 2001).

While scientometrics and bibliometrics are consolidated disciplines for studying scientific output and impact, the traditional model of scientific dissemination has been revolutionised by the institution of the Web 2.0 and the furtherance of inter-individual communication and collaboration. Fora, blogs and social networks such as Facebook or Twitter that have proven to be so popular among the public at large have also influenced the members of the scientific community, giving rise to a so-called 'academic social network'. The proliferation of informal communication vehicles poses a new challenge for the analysis of scientific activity (Mohammadi and Thelwall, 2013) that calls for new approaches to the issue. One might consist in supplementing traditional scientometric studies with the formulation of altmetric indicators that constitute a measure of public interest in R&D+I in a particular area.

Given the existence of the various avenues for scientific communication, the present study tracked the flow of scientific knowledge, from the R&D projects themselves to the publication of the findings in scientific journals and the possible impact in social networks. A dual aim was pursued. The production of new knowledge was explored by analysing its
various stages, and a model was developed to identify the factors that contribute to the social impact of scientific projects and papers.

The specific field chosen for the analysis was ‘energy savings’, regarded as a key factor in countries’ economic development, with a heavy social and environmental impact that cuts across a host of industries. It is also a sector under constant development due to the intense technological innovation involved. One of the aspects that arouses greatest interest and that has been crucial for the development of national and international R&D+I policies such as implemented by the European Union is the relationships among energy efficiency, sustainability and the use of renewable resources. The OECD has also sought to heighten awareness of the importance of sustainable development in a number of programmes geared to improving study and promotion of the conceit, particularly in the area of sustainable and so-called ‘green’ growth (OECD, 2011; OECD, 2012).

Sources and methodology

Three sources of information were used in the study.

European projects-CORDIS: the calls for projects under the European Union’s Framework Programme have become one of the main avenues for scientific and technological activity and funding for the region’s institutions. FP7 introduced a change in approach to international cooperation, placing greater emphasis on R&D activities with third countries to rise to global challenges. The CORDIS database (http://cordis.europa.eu/projects/home_es.html) was used as a source of information on energy savings research channelled through FP7 projects. The following information was retrieved for each project: reference, start and finish date, abstract, lead institution, participating institutions, participating countries, total funding, funding obtained.

Papers-Web of Science: the analysis of information flows entailed studying the scientific papers stemming from the projects analysed. The database used was the international and multi-disciplinary Web of Science, which lists the scientific output deemed to be of highest quality and prestige. Information was retrieved from the Core Collection, which includes the SCI, SSCI and A&HCI databases. Papers on energy savings projects were identified by searching funding-related fields (FO=funding agency; FG=grant number; FT=funding text) for the projects analysed under those tags. The data collected were cleansed and the main activity indicators were found (number of papers, language, paper type, journal, specialisation (subject area), collaboration (number of authors, institutions and countries), impact (citations) and visibility (publishing journal quartile).

Social networks-ALTMETRICS.com: with the main bibliometric indicators in hand, altmetric indicators were identified through papers’ DOIs. A script developed by the Carlos III University of Madrid's Metric Information Studies Laboratory was deployed to obtain information from the ALTMETRICS.com platform on: posts, Twitter, Wikipedia, communication media, Google and Facebook and Mendeley, CiteUlike and Connotea readers.

The data collected in the initial stage furnished sufficiently descriptive information to characterise the results of each of the aforementioned sources.

The second stage consisted in inter-relating all the information obtained to develop a multiple linear regression model with which to determine links among the indicators analysed and detect possible relationships among certain project characteristics, the respective papers and social impact. To be able to run statistical tests, the model had to deliver a quantitative variable. Although the Altmetric.com ‘score’ could have been used, it was ruled out because its calculation is based on academic rather than social impact variables, such as the number of
academic social network (such as Mendeley or CiteULike) readers and the weights assigned to the variables are somewhat arbitrary.

Factor analysis techniques were consequently applied to obtain a single, more representative variable to quantify the social impact of research. Based on the contribution of each altmetric indicator to this new fictitious variable, a system of weights was established to formulate a synthetic indicator, following OECD (2008) recommendations, to be applied to scientific papers.

Defined as ‘score2’, this synthetic variable was used to build a multiple linear regression model, into which the variables and factors given in Table 1 were entered. In light of the colinearity between some of the possible variables (number of authors and institutions; number of countries and international collaboration), a selection was made to narrow redundancies and develop a sounder model.

The formula for the initial regression model was:

\[
\text{score2} \sim \text{project_cost} + \text{SO} + \text{DT} + \text{WC} + \text{numaut} + \text{Colab} + \text{best\_quartile}
\]

The preliminary results for the two stages are discussed in the section below.

Preliminary results

Stage 1

The descriptive information for the first stage is summarised in Figure 1.

The findings showed that scientific papers were generated by two-thirds of the projects analysed, to the exclusion of 88. Project papers were highly concentrated, with just 11 projects (4% of the total) accounting for 560 articles (33% of the total). Whilst the vast majority of the papers had a DOI, only 22% had any impact on social networks.

Figure 2 shows the projects grouped by subject area and the number of papers stemming from each (size of nodes), as well as the presence or absence of altmetric indicators.

Stage 2

Factor analysis yielded a first variable that explained 73% of the variability. Percentage weights were assigned to each altmetric indicator based on their contribution to this new fictitious variable (Table 2). The synthetic indicator denoting the social impact of papers was calculated on the grounds of those weights.

As the analysis of variance of the initial model only yielded three variables with a p-value of under 0.05, journal (‘SO’), paper type (‘DT’) and international collaboration (‘Colab.’), these were the variables selected to build a simpler model, the ANOVA for which is given in Table 3.

One prominent characteristic of the final model, its negative y-intercept (-3), inferred that the a priori likelihood of a paper generating social impact is very low. With international collaboration, however, the slope on the social impact prediction curve rose by a factor of +3, varying as well with paper type. Papers in the form of articles or proceedings were penalised by a factor of -5, whereas reviews were flattered by a factor of +13. The publishing journal was the most influential variable. The model showed that most journals (507) affected the slope positively, although a few (4) had an adverse effect and yet others (7) were neutral. On average, journals contributed with a value of 38.7 to the model’s standardised regression coefficient, beta. The ten journals with the highest beneficial effect were: Science; Earth System Science Data; Nature Genetics; Nature; Trends in Genetics; Genome Biology; Microbial Cell Factories; BMC Genomics; Nature Communications; Biotechnology for Biofuels.

In addition, due the score variable2 does not met the normality assumption, non parametric tests were calculated in order to get effect size and p-value of each variable (table 4). For ‘Colab’ variable, Mann-Whitney U test was used, because is a dicotomical variable (yes/no), but in the case of ‘DT’ and ‘SO’ variables were necessary to use Kruskal-Wallis test, and according to Tomczak & Tomczak (2014), $E^2$ was calculated so as to know the effect of these
variables, which does not show many differences with ANOVA test, due to the bigger effect size is in ‘SO’ variable and is low in ‘Colab’ and ‘DT’ variables.

Conclusions
In light of the importance of energy savings on the scientific as well as the social, economic and environmental scales, research is in order to determine how scientific and technological activity is being conducted and identify the aspects of greatest significance for academics and citizens. Scientometric techniques constitute a promising approach to this issue. This study identified the key characteristics of energy savings projects funded under the Seventh Framework Programme and analysed the flow of knowledge from project to publication in scientific journals and from there to social networks.

The preliminary findings show that papers have been published in WoS-listed journals around two-thirds of the projects. Although that figure may seem low, many of the projects underway in 2013-2014 are presently being written up. The high concentration of papers in a short number of projects is striking, however. Altmetric indicators show that the number of papers mentioned in social networks (22 %) is still low and apparently unrelated to productivity; i.e., the projects with the largest number of papers are not necessarily the ones cited in social networks.

The study’s major contribution is indisputably the development of a multiple linear regression model to detect relationships among variables that help understand the social impact of papers. The initial findings show that the likelihood of mention in social networks is low and favoured most by three factors: publishing journal, paper type and international collaboration. The next stage in the research underway will be to analyse these findings in greater depth.

Acknowledgements
This study was conducted under the project entitled ‘Detection of new research and innovation fronts in energy efficiency. Analysis of knowledge flows in the scientific domain, industry and society’ (ref.: CSO2014-51916-C2-1-R), funded by Spain’s Ministry of the Economy and Competition.

Assessing the Interdependencies between Scientific Disciplinary Profiles at the Country Level: a Pseudo-Likelihood Approach

Cinzia Daraio, Francesco Fabbri, Giulia Gavazzi, Maria Grazia Izzo, Luca Leuzzi, Giammarco Quaglia and Giancarlo Ruocco

Abstract
The investigation of the dynamics of national disciplinary profiles is at the forefront in quantitative investigations of science. There is an increasing number of papers that analyse the disciplinary specialization at the country level. We contribute to this literature by proposing a new approach to investigate the complex interactions among scientific disciplinary profiles. The approach is based on recent pseudo-likelihood techniques introduced in the framework of machine learning and complex systems. We infer, in a Bayesian framework, the network topology and the related interdependencies among national disciplinary profiles. We provide an illustration on data extracted from the Scopus database which relate to the national scientific production of most productive world countries for the 27 Scopus subject categories.

Conference Topic
Country-level studies, Methods and techniques

Introduction and Method
The dynamics of national research systems is a topical issue in quantitative science and technology research. The number of works on this issue has seen a considerable increase from the King (2004)’s work until the most recent years. Country-level studies of the evolution of disciplinary profiles include Glänzel (2000); Glänzel & Schlemmer (2007); Glänzel et al. (2006, 2008); Hu & Rousseau (2009); Tian et al. (2008); Wong (2013); Wong et al. (2012); Yang et al. (2012); Radosavic & Yoruk (2014); Bongioanni et al. (2014, 2015), Shen et al. (2016) and Li (2017). In particular, Shen et al. (2016) extend the Input-output model of the economist Leontief to investigate the interrelations between the scientific subfields of physics. We consider research systems as complex systems. Once the analogy is well defined the mathematical tools developed for complex systems can be exploited for studying research systems. Science is considered a complex system also according to the sociological perspective (see e.g. Shi et al. 2015) based on the actor network theory (Latour, 2005). Networks are general models, which can represent the relationships within or between given systems. The structure and function of complex networks is widely studied in the statistical mechanics: see e.g. the classical reviews by Albert and Barabasi (2002) and Newman (2003) and the recent book by Barabasi (2016). Network approaches are widely applied in scholarly evaluation. West and Vilhena (2014) provide a clear introduction to the topic, which has become a “cornerstone of bibliometric research” since the seminal work of Price (1965). The most studied networks include paper-level citation networks (in which nodes are the papers and the links are the citations between the papers) and co-authorship networks (in which nodes are the authors and the links represent the frequency a pair of authors has coauthored). West and Vilhena (2014, p.
conclude their overview stating that: “Network-based measures are more complicated than non-network measures, but the richness gained with such a measure is worth the extra effort.” The prediction of future links or the reconstruction of missing links from an incomplete network is a related interesting stream of literature (see Guns, 2014). In this paper we adopt a different level of analysis. In our modelling, nodes are the disciplinary profiles (or the scientific production in a given research area) of countries and the links represent the interdependencies existing between them. In addition, we consider these links as unknown parameters. We infer these unknown parameters by applying recently introduced tools to solve inverse problems in graphical models with wide applications to complex systems. The approach that we propose in the present paper is based on the similarities between statistical physics models for complex systems and research systems. See Table 1.

We exploit these analogies (Table 1) to model the interdependencies within the world research system as interactions. *Interaction* in physics is considered as a direct - and reciprocal - effect of one entity on one or more entities. The nature and the strength of this effect can be measured by applying tools developed by the statistical physics of complex systems. The concept of interaction in physics can find its correspondence in the one of *interdependency or interrelations* for research systems. The latter means the existence of a mutual *influence* among countries scientific activity: all countries are to some degree affected by the research activity of all other countries. This influence can be considered discipline by discipline or on the basis of the overall scientific production (disciplinary profile).

The term interrelation here encompasses all the channels of contact, exchange and so on, between two countries, which effect the convergence of the disciplinary profiles of the two countries. The interaction parameters of the *generalized multicomponent spin model* adopted here are thus effective parameters embedding several effects. Given the Hamiltonian related to this model (see Table 1), a positive interaction between two countries actually would lead to convergence of their disciplinary profiles in order to satisfy the principle of minimum energy. However, since the Hamiltonian represents a disordered many-body system with pairwise interactions, competition can arise between them giving rise to so-called *frustration*, that is a spin blocked between two opposite profiles, which is not able to choose the profile to follow grounding on the principle of minimum energy. The underlying hypothesis of our model is that a positive interaction would led to alignment between disciplinary profile, but not *vice versa*, that is the observation of alignment does not necessarily imply a positive interaction as well as the observation of misalignment does not exclude it. Our choice of the *generalized multicomponent spin model* is led by simplicity and because it guarantees the possibility to borrow the rigorous methodology developed by Boltzmann machine learning.

The aim of the present analysis is to derive the level of and the structure of these interactions. It is an inverse problem because the inference of the interactions is drawn from a set of data on the disciplinary profiles of countries. Judge and Mittelhammer (2011) clearly describe that inverse problems arise when one want to recover information on model parameters, i.e., coupling constants, by means of measurements of observable data. The solution of an inverse problem offers a connection between the data directly observed and the unknown information on model parameters. In an inverse problem, the model which generates the observed data is an input of the theory. The model can be gained by an a priori knowledge or hypothesized on general insights. In the latter case its strength can be a posteriori verified by testing its prediction.

We propose a new approach to make inference on the network topology and the related interdependencies between country-disciplinary profiles. The approach is developed in a Bayesian framework and relies on some recent pseudo-likelihood techniques introduced in the physics of complex systems (Ravikumar et al. 2010, Aurell & Ekeberg 2012, Tyagi et al. 2016; Marruzzo et al. 2016). In the following we briefly outline the proposed approach. For more details the reader is referred to the Appendix A. According to the Bayes theorem (see e.g. Barber, 2012):

$$p(\{J\}|\{s\}) = \frac{p(\{s\}|\{J\})p(\{J\})}{p(\{s\})} = \frac{p(\{s\}|\{J\})p(\{J\})}{\int_{\{J\}} p(\{s\}|\{J\})p(\{J\})}.$$  

where \(\{s\}\) are the data and \(\{J\}\) are unknown parameters of a given model, \(p(\ )\) states for a probability distribution and \(p( | \ )\) for a conditional probability distribution. We observe that \(\int_{\{J\}} p(\{s\}|\{J\})p(\{J\})\) is constant with respect to \(J\). The maximum of the conditional probability \(p(\{J\}|\{s\})\), is equal to the maximum of \(p(\{s\}|\{J\})\) the so called likelihood function, if one
assumes uniform the prior belief about the model parameters, \( p(J) \). We consider our system as a disordered system at equilibrium, described by a generalized multicomponent spin model. To this aim we define our variables as normalized shares of publications, which are the equivalent of the spin configurations, defined as:

\[
    s_i^{(\gamma)}(t) = \frac{\Delta_i^{(\gamma)}(t)}{\sqrt{\sum_{i=1}^{N} \Delta_i^{(\gamma)}(t)}}; \quad \Delta_i^{(\gamma)}(t) = n_i^{(\gamma)}(t) - \bar{n}^{(\gamma)}(t) = \frac{1}{N} \sum_{i=1}^{N} n_i^{(\gamma)}(t),
\]

where \( \gamma = 1, ..., D, t = 1, ..., T \), \( n_i^{\gamma} \) are the shares of articles published in a subject category \( \gamma \) for a given country \( i \), for \( i=1,...,N \), over the period \( t=1,...,T \) (here 1996-2012). They have the property that \( \bar{s}_i^{(\gamma)} = 0 \) and \( (\bar{s}_i^{(\gamma)})^2 = 1 \). In this way we account for the recent trend of increasing scientific production all over the world. By the normalization reported above in fact we define as variables only instantaneous fluctuations around the world average production in each given discipline at one data sample recording. Though the average scientific production is not constant in time the distribution of the deviations around the means can be considered as such. The assumption of equilibrium underlies a Boltzmann-Gibbs distribution,

\[
p(J, s) = \frac{1}{Z(J)} e^{-H(s|J)},
\]

where \( H \) is the Hamiltonian of the generalized Ising model (defined in Tab. 1) and \( Z \) is the partition function (normalization factor). It is also possible to draw a link between equilibrium and symmetry of the pairwise interactions. Symmetric couplings lead to a steady state described by the Boltzmann distribution while asymmetric ones to a non-equilibrium state (Krapivsky, 2010). It is also possible to assign to the system a particular dynamics, which leads it to a given steady state distribution. Recent developments achieved for dynamical inverse Ising model (Decelle, 2016, Nguyen, 2017) could represent an interesting extension of the present work, which is left for future research.

The Hamiltonian is obtained by a generalization of the Ising model, originally introduced to describe the behavior of ferromagnetic systems. In its more general formalism the Ising model can also account for a (parameter independent) weight, \( \beta \), and external biases, \( h_i \). When referred to magnetic systems, \( \beta \) is the inverse of temperature and \( h_i \) the magnetic external field. For sake of simplicity we fix here \( \beta = 1 \) and \( h_i = 0 \) for \( i \in (1, N) \). The Ising model has been largely applied in different fields, such as modelling the behaviour of magnets in statistical physics (Brush 1967), image processing and spatial statistics (Besag 1986, Geman 1984, Greig 1989), modelling of social networks (Banerjee 2008). Our choice is thus mainly justified from the possibility to recover and generalize tools developed and already tested in such different contexts. The Ising model, furthermore, is a classical example of a graphical model in exponential form, to which the Boltzmann machine learning (or approximation method related to it) can be applied, as discussed in Appendix A.

To solve the inverse problem we have to maximize the log-likelihood with respect to the set of parameters \( J \):

\[
l(J) = \log(L(J)) = \sum_{t=1}^{T} -H(s_t|J) - T \log(Z(J)).
\]

This is computationally hard to solve and for this reason a pseudolikelihood approach, which involves Boltzmann machine learning, is applied. The solution of the inverse problem consists in finding the optimal values of the set of parameters \( J \), which are supposed to generate the observable set of data. We can obtain the values of the set parameters \( J \) representing the interrelations between a pair of countries i) discipline by discipline by maximizing the discipline-dependent Log-Likelihood function, ii) for the full disciplinary profile by maximizing the Log-Likelihood function related to a cost function, which in turn depends on
the scalar product between the vectorial variables whose generic element refers to a given discipline (see Tab. 1 and Appendix A for details).

Given a set of parameters \{J\}, a zero value of the parameter \(J_{ij}\) between the pair \(ij\) means that the two countries are not interacting, a positive value indicate a tendency to align towards the same disciplinary profile, and a negative value, instead, shows a tendency towards ‘opposite’ disciplinary profile.

The following sections describe the data available and the main results of the analysis. The final section concludes the paper and outlines directions for further research.

Data

Data was extracted from the Scopus database and relate to the scientific production of world countries for 27 Scopus subject categories from 1996 to 2012.

Data problems in bibliometric studies are well known. A common way to reduce them is to analyse macro-level bibliometric data. According to Nederhof (1988) comparative analysis are more reliable when the unit of analysis is more aggregated because in a larger sample size, micro random errors mutually compensate.

Another issue of concern is given by the changes in coverage from inclusion or exclusion of journals which affect more small countries with less publications. This may lead to unreliable values when a country only has a small number of scholarly outputs (see e.g. Schubert et al. 1989). To avoid this problem, we investigate the disciplinary profiles of the 53 most productive countries, which account for more than 95% of the world scientific production in the considered period. To increase the number of available data we transformed yearly data into weekly data by means of a linear interpolation. The final number of observations considered is 833 and refers to weekly production of the number of articles (\(P\)) over the period 1996-2012. See Figure 1 for an illustration.

![Figure 1](image)

**Figure 1** Trends of the interpolated scientific production (\(P\)) in three disciplines: Physics and Astronomy, Computer Science and Medicine. For each discipline, the eight most productive countries are reported.

Results

Figure 2 shows the estimated interactions obtained by applying the method described in the previous section. We show only interactions strong enough, which significantly contribute to the cost function \(H\) (see Fig. 2). We infer a trend to clustering among countries belonging to a given geo-political or cultural area. By observing the interactions obtained for the network model with the overall Hamiltonian (i.e. the one describing the interrelations among disciplinary profiles) shown in Fig. 2 Panel IV we report a strong positive interaction between USA, Great Britain and Korea, whereas the USA interactions with all the other countries are
negative. Great Britain, in turn, weakly interacts with the other European countries, showing a positive interaction only with France and (quite weakly) with Spain. The Central Europe countries positively interact among them. When related to the recent historical context, it could result significant also that both Ukraine and Poland get a positive interaction with Russia. Taiwan, Korea and Singapore share positive interactions among each others.
Brazil, against trend, gets positive interactions with several countries world-spread but with none of the others Latin America countries. These results are in qualitative agreement with a quantitative measure of the overlap between disciplinary profiles of research systems discussed in Bongioanni et al. (2014). There, for example, a globalization of science in Europe was observed with a departure from the ‘European model’ by the leading countries such as Great Britain and Netherlands. By moving to the discipline-dependent interactions, i.e. the ones obtained by considering a discipline-dependent Hamiltonian, shown in Fig. 2 Panels I-III for representative scientific disciplines, it appears a larger number of positive interactions, in particular of USA with all the other world-spread countries. This could confirm a trend of globalization of science affecting not only Europe but all the world. We observe, e.g., that the interaction of USA with Russia, Japan and several European countries is in this case positive. The interaction of China with several countries is also positive, whereas for the interactions related to the overall Hamiltonian most of them are negative. In the case of Medicine, China disappears from the network, apart for a positive interaction with USA, probably due to a reduction of the number of articles published in this field. Figure 3 shows some examples of the outcome of our approach, which is the inferred network topology of selected disciplines.

![Graphical representation of the network topology](image)

**Figure 3.** Graphical representation of the network topology, for selected disciplines (Physics and Astronomy, Computer Science and Medicine), inferred from the values of the $J_{ij}$ parameters obtained by the maximization of the pseudo-likelihood function. The graphs report the most relevant interactions, i.e. those with $|J_{ij}| > 0.1 \max(|J_{ij}|)$. The diameter of the node representing the i-th country is proportional to the number of interactions $J_{ii}$. The thickness of the edge depends on the intensity of the related interaction (thicker edge means larger intensity).

Discussion and conclusion

The results presented in the previous section show the potential of the approach we propose. The policy of scientific research is an important subject. The requirements and the disciplinary orientation of research funding programs are incentive to creativity as well as to the scientific production of scientists (Azoulay et al. 2011). Recent studies on the economics and organization of science have highlighted the lack of tools and analysis to determine how to allocate the funds among different disciplines (Antonelli et al. 2011). Of course, it is the policy of research that has to choose how to distribute resources across different scientific areas. The approach we propose in this paper may provide a useful tool to support policy decisions. Once the reliability of the proposed approach is established, it is possible to exploit the additional features of the generalized multicomponent spin model, e.g. to include in the analysis some measures of country contextual variables through the external field $h_i$. For instance, an interesting extension of the study (left for future work) may be the inclusion of an external field given by a vector of research funding with elements country- and discipline-
dependent, which together with the mutual interactions between countries can direct the
disciplinary profile in a direction or in another.
Once the inverse problem is solved, the obtained results could be used to simulate the impact
of different levels of the funding (through the external field) on the disciplinary profiles
emerging as outputs of the generalized multicomponent spin model which considers the
interactions fixed to the one inferred, and change the external funding vector. This could
guarantee a larger and more solid predictive capability than the simple extrapolation of observed trends. Other interesting developments of this paper, which are left to future research, include:
-maximization of the Pseudo-Likelihood function with different samplings, e.g. accounting for country’s size;
-application of the approach to other indicators of citations, highly cited publications and so on to compare the estimated interdependencies and the network topologies obtained;
-refinements of the decimation (Marruzzo et al., 2016) to infer the network structure;
-overcome the limitations of the interpolation of data (to increase the number of observations) analyzing alternative data, such as downloads, which were not available for the present study;
and finally considering the intensity of the auto-interdependence of countries (through the J_ii), the so called “chemical potentials” of countries.

I. APPENDIX A

In this appendix we discuss the methodology used to obtain the parameters of the maximum Log-Likelihood function introduced in the paper. Firstly, we discuss the general grounds of the validity of the method used. Secondly, we deal with the application to our specific case.

Given the set of data, $\{X_n, n = 1, 2, ..., N\}$, assuming that the data are independent, and once defined the generative model, the Log-Likelihood function, $l(\{J\})$ becomes

$$l(\{J\}) = \log(L(\{J\})) = \sum_{\mu=1}^{M} -H(\{s^\mu\}|\{J\}) - M \log(Z(\{J\})), \quad (A1)$$

where $\mu = 1, ..., M$ is the label for a set of $M$ data. The inference problem consists in determining the set parameters $\{J\}$ which maximizes the function in Eq. A1.

We consider here the expression of the cost function (Hamiltonian) for a multicomponent variable $s = (s_1, s_2, ..., s_J)$, $H(\{s\}|\{J\})$, given by

$$H(\{s\}|\{J\}) = -\frac{1}{2} \sum_{i,j} J_{ij} s_i \cdot s_j, \quad (A2)$$

with $J_{ij} = J_{ji}$. The symbol “$\cdot$” in Eq. A2 states for a scalar product. The presence of a scalar product ensures that orthogonal or quasi-orthogonal vectors (i.e. countries which have a number of publications whatever large but in different fields) will have a small weight in the cost function. The sum is extended to all couples of nodes $(i, j)$ with $i \neq j$. The partition function $Z(\{J\})$ is

$$Z(\{J\}) = \sum_{\{s\}} e^{-H(\{s\}|\{J\})}, \quad (A3)$$

the sum is extended to all possible configurations in the phase space of the set of variables $\{s\}$.

The calculation of the above partition function is too demanding from a computational point of view already for a small number of variables. For this reason, we resort to the pseudo-likehood approximation (Aurell 2012, Tyagi 2016, Marruzzo 2016). It consists in maximizing a Pseudo-Log-Likelihood function based on the local conditional Log-Likelihood function at each node (see Eq.A6) in place of the Log-Likelihood function. It is possible to show that the estimation of the parameters obtained by a Pseudo-Log-Likelihood maximization is consistent with the maximization of the Log-Likelihood function, that the two functions are maximized by the same set of parameters. The hypothesis under which this statement holds, i.e. the strict concavity of the Pseudo-Log-Likelihood function with respect to the k elements of the set of parameters, is not too strict (see Hyvarinen 2006). Furthermore it is possible to show that under such a hypothesis the Pseudo-Log-Likelihood maximization is exact (i.e. equivalent to the Log-Likelihood maximization) in the case of infinite sampling (Aurell 2012). An important advantage of the Pseudo-Log-Likelihood function is that it is possible to maximize it in polynomial time.

We consider then the likelihood built on the local conditional probability on each variable $i$, one by one, rather than Eq. (A1). The cost function (Eq. A2), is rewritten as

$$H(\{s\}|\{J\}) = -s_i \cdot \left[ \sum_{i,j} J_{ij} s_j \right] - \frac{1}{2} \sum_{k, j \neq i} s_k \cdot J_{kj} s_j$$

$$= -s_i \cdot A_i(\{J\}) - \sum_{k \neq i} s_k \cdot B_{ik}(\{J\}) \equiv H_i(\{s_i\}|\{s_\backslash i\}, \{J\}) + H_{\backslash i}(\{s_{\backslash i}\}|\{J\}), \quad (A4)$$

where $s_\backslash i$ indicates the set of all input-variables except the $i$-th. The functions $A_i(\{J\}) = \frac{1}{2} \sum_{j} J_{ij} s_j$ and $B_{ik}(\{J\}) = \frac{1}{2} \sum_{j \neq k} J_{ij} s_j$ have been introduced in Eq. A4. The cost functions $H_i(\{s_i\}|\{s_\backslash i\}, \{J\})$ and $H_{\backslash i}(\{s_{\backslash i}\}|\{J\})$ are implicitly defined. Analogously we can rewrite the partition function as

$$Z(\{J\}) = \sum_{\{s\}} e^{-H(\{s\}|\{J\})} = \sum_{\{s_i\}} e^{-H_i(\{s_i\}|\{J\})} \sum_{\{s_{\backslash i}\}} e^{-H_{\backslash i}(\{s_{\backslash i}\}|\{J\})} \sum_{\{s_{\backslash i}\}} e^{-H_{\backslash i}(\{s_{\backslash i}\}|\{J\})}$$

$$= \sum_{\{s_i\}} e^{-H_i(\{s_i\}|\{J\})} \sum_{\{s_{\backslash i}\}} e^{-s_{\backslash i} \cdot A_{\backslash i}(\{J\})} \sum_{\{s_{\backslash i}\}} e^{-H_{\backslash i}(\{s_{\backslash i}\}|\{J\})} \prod_{\gamma=1}^{D} \frac{\sinh(A_{\gamma}(\{J\}))}{A_{\gamma}(\{J\})}$$

$$= \sum_{\{s_i\}} e^{-H_i(\{s_i\}|\{J\})} Z_i(\{s_{\backslash i}\}, \{J\}) \quad (A5)$$
where the local conditional probability at the \( i \)-th node is
\[
p(s_i|\{s_{\setminus i}\}, \{J\}) = \frac{1}{Z_i(\{J\})} e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})},
\] (A6)

and the local partition function is \( Z_i(\{J\}) = \sum_{\{s_i\}} e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})} \).

Then, the weighted average over the ensemble of \( \{s_{\setminus i}\} \) configurations is substituted by the uniform average over the observed data sets \( \mu = 1, \ldots, M \). By defining \( \ell_i(\{s_i|\{s_{\setminus i}\}\}, \{J\}) = \log[p(s_i|\{s_{\setminus i}\}, \{J\})] \), the Pseudo-Log-Likelihood function is
\[
\lambda(\{J\}) = \sum_{\mu=1}^{M} \sum_{i=1}^{N} \ell_i^\mu(\{s_i^\mu|\{s_{\setminus i}^\mu\}\}, \{J\}) = \sum_{i=1}^{N} \ell_i.
\] (A7)

The gradient of the Pseudo-Log-Likelihood function with respect to the parameter \( J_{ij} \) is given by
\[
\frac{\partial}{\partial J_{ij}} \lambda(\{J\}) = \sum_{\mu=1}^{M} \left[ \frac{1}{2} \sum_{\mu=1}^{M} \frac{s_i^\mu \cdot s_j^\mu}{Z_i^\mu(\{J\})} - \frac{1}{Z_i^\mu(\{J\})} \frac{\partial}{\partial J_{ij}} Z_i^\mu(\{J\}) \right] = \frac{1}{2} \sum_{\mu=1}^{M} \left[ \frac{s_i^\mu \cdot s_j^\mu}{Z_i^\mu(\{J\})} \frac{\sum_{s_{\setminus i}} s_i \cdot s_j e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})}}{\sum_{s_{\setminus i}} e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})}} \right]
\] (A8)

\[
= \frac{1}{2} \left[ \frac{1}{M} \sum_{\mu=1}^{M} s_i^\mu \cdot s_j^\mu - s_i \cdot s_j >_{i,J} \right] = \frac{1}{2} [C_{ij} - \frac{1}{M} \sum_{\mu=1}^{M} s_i^\mu \cdot s_j^\mu >_{i,J}],
\]

where “ \( >_{i,J} \)” states for ensemble average calculated for the probability distribution \( p(s_i|\{s_{\setminus i}\}, \{J\}) \). It is possible to rephrase the term \( \frac{\partial}{\partial J_{ij}} \lambda(\{J\}) \) in the gradient of the Log-Likelihood function, obtaining
\[
\frac{1}{Z(\{J\})} \frac{\partial}{\partial J_{ij}} Z(\{J\}) = \frac{1}{Z(\{J\})} \sum_{\{s_i\}} e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})} \sum_{\{s_{\setminus i}\}} s_i \cdot s_j e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})} = \frac{1}{Z(\{J\})} \sum_{\{s_i\}} e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})} \sum_{\{s_{\setminus i}\}} s_i \cdot s_j e^{-H_i(s_i|\{s_{\setminus i}\}, \{J\})} >_{i,J} >_{i,J} >_{i,J}
\] (A9)

and
\[
\frac{\partial}{\partial J_{ij}} \ell(\{J\}) = \frac{1}{2} [C_{ij} - s_i \cdot s_j >_{i,J} >_{i,J}].
\] (A10)

By comparing Eq. A8 and A10 it is possible to infer that in the limit \( M \to \infty \) i) both the gradients go to zero for the set of parameters \( \{J\} \) generating the observed data, ii) \( \frac{\partial}{\partial J_{ij}} \lambda(\{J\}) \to \frac{\partial}{\partial J_{ij}} \ell(\{J\}) \). This finally establishes the consistency of the maximum Pseudo-Log-Likelihood estimator and, furthermore, its coincidence with the maximum Log-Likelihood estimator in the limit \( M \to \infty \).

The gradient of the Log-Likelihood function can be calculated exactly, thus facilitating the computational solution of the inference problem. The explicit expression of \( \frac{\partial}{\partial J_{ij}} \lambda(\{J\}) \) is reported in the following.

To deal with a lower number of parameters in place of maximizing the Pseudo-Log-Likelihood function, given by the sum of the single-node Pseudo-Log-Likelihood functions (Eq. A7) we maximize each single-node Pseudo-Log-Likelihood function. Since the couplings in the Ising model should be symmetric the final estimate of the \( J_{ij} \) parameter is obtained by taking the average \( (J_{ij} + J_{ji})/2 \). When a standard Pseudo-Log-Likelihood maximization is used, some couplings can be largely overestimated. To avoid such drawbacks we used a \( b_2 \) regularizer (Ravikumar 2010), i.e. in place of maximizing the \( \lambda(\{J\}) \) function we maximize the function \( \lambda(\{J\}) - b_2 (\sum_{i,j} J_{ij}^2)^{1/2} \), where \( b_2 \) is a suitable chosen constant.

The maximization of the single-node Pseudo-Log-Likelihood functions has been performed by means of the MATLAB fminunc package by selecting a trust-region optimization algorithm.

In the following we first rephrase the expression of the Log-Likelihood function by isolating the contribution of the \( i \)-th node. We finally calculate the gradient of the Pseudo-Log-Likelihood function with respect to \( J_{ij} \).

The sum \( \sum_{\{s_i\}} e^{-s_i A_i(\{J\})} \) in Eq. A5 has been calculated by assuming that the values of the \( i \)-th input variable can continuously vary in the interval \([-1, 1] \), obtaining
\[
Z_i(\{J\}) = \sum_{\{s_i\}} e^{-s_i A_i(\{J\})} = \int_{-1}^{1} ds_i e^{-s_i A_i(\{J\})} = \prod_{\gamma=1}^{D} \int_{-1}^{1} ds_{\gamma} e^{-s_{\gamma} A_{\gamma}(\{J\})} = \prod_{\gamma=1}^{D} \frac{2 \sinh(A_{\gamma}(\{J\}))}{A_{\gamma}(\{J\})}.
\] (A11)
Similarly, it is possible to write the function \( Z_{\gamma}(\{J\}) = \sum_{\{s_{\gamma}\}} e^{-H_{\gamma}(\{s_{\gamma}\},\{J\})} \), by exploiting the function \( B_{i,k}(\{J\}) \) defined above, obtaining
\[
Z_{\gamma}(\{J\}) = \sum_{\{s_{\gamma}\}} \prod_{i} e^{-H_{\gamma,i}(\{s_{\gamma}\},\{J\})} = \sum_{\{s_{\gamma}\}} \prod_{i} e^{-H_{\gamma,i}(\{s_{\gamma}\},\{J\})} \sum_{\{s_i,k\}} B_{i,k}(\{J\}) = \sum_{\{s_{\gamma}\}} \prod_{i} e^{-H_{\gamma,i}(\{s_{\gamma}\},\{J\})} \prod_{\gamma=1}^{D} \frac{\sinh(B_{i,k}^{(\gamma)}(\{J\}))}{B_{i,k}^{(\gamma)}(\{J\})}.
\]
(A12)

By iterating this procedure to the remaining variables it is finally possible to write the partition function as the product
\[
Z(\{J\}) = \prod_{\gamma=1}^{D} \frac{\sinh(A_{i}^{\gamma}(\{J\}))}{A_{i}^{\gamma}(\{J\})} \prod_{\gamma=1}^{D} \frac{\sinh(B_{i,k}^{(\gamma)}(\{J\}))}{B_{i,k}^{(\gamma)}(\{J\})} \frac{\sinh(F_{i,k}^{\gamma}(\{J\}))}{F_{i,k}^{\gamma}(\{J\})}.
\]
(A13)

The Log-Likelihood function becomes
\[
I(\{J\}) = \sum_{\mu=1}^{M} \sum_{i=1}^{N} [s_{i}^{\mu} \cdot A_{i}(\{J\}) + \sum_{k \neq i} s_{k} \cdot B_{i,k}^{(\mu)}(\{J\})] - M \sum_{\gamma=1}^{D} \left[ \log\left( \frac{\sinh(A_{i}^{\gamma}(\{J\}))}{A_{i}^{\gamma}(\{J\})} \right) + \log\left( \frac{\sinh(B_{i,k}^{(\gamma)}(\{J\}))}{B_{i,k}^{(\gamma)}(\{J\})} \right) \right] + \log\left( \frac{\sinh(F_{i,k}^{\gamma}(\{J\}))}{F_{i,k}^{\gamma}(\{J\})} \right),
\]
(A14)

The Pseudo-Log-Likelihood function, defined in Eqs. A6 and A7, takes now the expression
\[
\lambda(\{J\}) = \sum_{\mu=1}^{M} \sum_{i=1}^{N} [s_{i}^{\mu} \cdot A_{i}(\{J\})] - \sum_{\gamma=1}^{D} \log\left( \frac{\sinh(A_{i}^{\gamma}(\{J\}))}{A_{i}^{\gamma}(\{J\})} \right)
\]
(A15)

The difference between the Log-Likelihood function and the Pseudo-Log-Likelihood function clearly appears by comparing Eqs. A14 and A15.

We can now explicitly calculate the gradient of the Pseudo-Log-Likelihood with respect to the set of parameters \( J_{ij} \). From Eq. A8, we need to calculate the quantity \( \langle s_{i}^{\mu} \cdot s_{j}^{\nu} \rangle_{i,j}(\{J\}) \). It is (for sake of clarity the index \( \mu \) is omitted)
\[
\langle s_{i}^{\mu} \cdot s_{j}^{\nu} \rangle_{i,j}(\{J\}) = \frac{\sum_{\{s_{\gamma}\}} s_{i}^{\mu} \cdot s_{j}^{\nu} e^{-\sum_{\gamma} H_{\gamma}(\{s_{\gamma}\},\{J\})}}{\sum_{\{s_{\gamma}\}} e^{-\sum_{\gamma} H_{\gamma}(\{s_{\gamma}\},\{J\})}} = \frac{1}{Z(\{J\})} \sum_{\{s_{\gamma}\}} s_{i}^{\mu} \cdot s_{j}^{\nu} \int_{-1}^{1} ds_{i} \cdot s_{i} e^{-\sum_{\gamma} \sum_{\alpha=1}^{D} s_{i}^{\gamma} A_{i}^{\gamma}} = \frac{1}{Z(\{J\})} \sum_{\gamma=1}^{D} s_{i}^{\gamma} \int_{-1}^{1} ds_{i} \cdot s_{i}^{\gamma} e^{-\sum_{\gamma} \sum_{\alpha=1}^{D} s_{i}^{\gamma} A_{i}^{\gamma}} = \frac{1}{Z(\{J\})} \sum_{\gamma=1}^{D} s_{i}^{\gamma} \left[ \prod_{\gamma=1}^{D} \frac{2}{A_{i}^{\gamma}} \sinh(A_{i}^{\gamma}) \right] = \frac{2}{A_{i}^{\gamma}} (A_{i}^{\gamma} \cosh(A_{i}^{\gamma}) - \sinh(A_{i}^{\gamma})).
\]
(A16)

The expression of \( Z(\{J\}) \) is reported in Eq. A11. It is possible to rewrite it, for a given index \( \gamma \), as \( Z_{i} = 2 \sinh(A_{i}^{\gamma}) \prod_{\alpha \neq \gamma}^{1} A_{i}^{\alpha} \). By inserting this latter expression in Eq. A16, we obtain
\[
\langle s_{i}^{\mu} \cdot s_{j}^{\nu} \rangle_{i,j}(\{J\}) = \sum_{\gamma=1}^{D} \frac{s_{j}^{\gamma} (2 \sinh(A_{i}^{\gamma}) \prod_{\alpha \neq \gamma}^{1} A_{i}^{\alpha})}{2 (A_{i}^{\gamma})} (A_{i}^{\gamma} \cosh(A_{i}^{\gamma}) - \sinh(A_{i}^{\gamma})) = \left[ \frac{1}{\tanh(A_{i}^{\gamma})} - \frac{1}{A_{i}^{\gamma}} \right],
\]
(A17)

and finally
\[
\frac{\partial}{\partial J_{ij}} \lambda(\{J\}) = \frac{1}{2} M \left[ C_{ij} - \frac{1}{M} \sum_{\mu=1}^{M} \sum_{\gamma=1}^{D} s_{j}^{\gamma(\mu)} \left[ \frac{1}{\tanh(A_{i}^{\gamma(\mu)})} - \frac{1}{A_{i}^{\gamma(\mu)}} \right] \right]
\]

National Research University Higher School of Economics (Russia)

Abstract

Research evaluation recently became a widely disseminated exercise aimed in the end of the day at improving the cost efficiency of public funding of national R&D sectors. In November 2013, the Government of the Russian Federation initiated a national evaluation exercise of public research institutions (PRIs) to provide information basis for development of S&T policies aimed at increasing effectiveness and strengthening the role of R&D performing institutions in economic and social development. The aim of this paper is that of providing an approach for multidimensional assessment of R&D performance based on quantitative data derived from the national evaluation exercise, specifically looking at its applicability and limitations for further analysis and preliminary differentiation of PRIs as well as for use in policymaking.

Conference Topic
Science policy and research assessment

Introduction

Research evaluation of public institutes is considered important for measuring the performance of R&D sector, first of all, in terms of improving the cost efficiency of public funding. Various studies (e.g. see Luwel et al., 1999; Senker 2001; Coccia, 2004; Abramo & Angelo, 2015; Ancaiani et al., 2015) show a growing interest in evaluating national scientific performance with the use of different metrics and models.

In Russia the first round of the national evaluation exercise that covered around 400 PRIs subordinated to the national science academies and federal agencies was implemented in 2009-2011. This initiative involved a wide range of indicators (R&D expenditure, personnel, research equipment, publications, citations, journal impact-factors, patents and other IPRs, cooperation, innovation infrastructure, income and profitability, etc.), but its results did not lead to any substantial change neither in policy instruments nor in the institutional structure of the national R&D sector. As for the use of performance-based indicators for evaluating individual researchers, there was no common framework established at the national level, but a number of research institutions and universities adopted certain practices within their human resource development strategies.

In 2013, a new round of research evaluations was launched taking into account the lessons learnt from the previous round. The distinctive features of this latest initiative included (1) an open and interagency approach in selecting criteria for evaluation; (2) combination of quantitative and qualitative (peer-review based) assessment procedures applicable, if necessary, also at the level of research teams; (3) grouping of R&D institutions into “reference groups” on the basis of respective research fields and basic functions; (4) a 5-year
evaluation period. A list of indicators was revisited and comprised both conventional inputs (R&D expenditure and personnel) as well as research equipment and novel output categories. In particular, there were added different types of publications (journal articles, conference proceedings, books and book chapters), citations and impact-factors; results of inventive work like designs, blueprints, patents and other IPRs; and financial results such as income from technology transfer or S&T services.

While this exercise has not yet been finished and its results have not been implemented for decision-making, it allowed constructing an advanced model of knowledge production function taking into account different types of R&D outputs. Furthermore, the exercise stimulated ‘Agora processes’ (Barré, 2001, 2005) in the scientific community around the use of S&T indicators for research evaluation and motivated academics to accept expert roles in forthcoming peer-review procedures.

The aim of this paper is that of providing an approach for multidimensional assessment of R&D performance based on quantitative data, specifically looking at its applicability and limitations for further analysis and preliminary differentiation of organizations as well as for use in policymaking.

**Data sources and methods**

Data for this study is derived from the Federal System for Monitoring of R&D Performance maintained and updated by the Ministry of Education and Science of the Russian Federation (http://www.sciencemon.ru/) in September 2016. Reference year is 2015. Primary information was collected from institutions performing R&D in line with the guidelines explaining definitions of key terms and methodology for reporting key variables. The dataset available included information on different characteristics of R&D performance for the 1625 institutions including PRIs, universities and research divisions of state companies. For further analysis to provide higher homogeneity of objects under assessment only PRIs were selected. Additionally arithmetic and logical controls were conducted for key variables to construct a final sample covering 815 observations. Research outputs considered for further analysis were journal articles, conference proceedings and book chapters indexed in Web of Science; blueprints and designs, registered intellectual property rights (IPRs) and others. Additionally a number of financial results such as income from technology transfer, S&T services and contractual works provided were taken into account.

Preliminary correlation analysis demonstrated strong significant cohesion between basic research and publication output. At the same time, as seen from the table 1, organizations implementing applied research and experimental development are likely to be the main providers of S&T services and have weak linkages to IPR protection. In other words organizations with identical balance between different types of research activities may have different results and vice versa. Therefore, they cannot be included into a single and homogenous reference group and compared. Similarly, it could be shown that other characteristics such as type of institution, legal status of an organization or its size are weak to differentiate R&D outputs.

In order to construct the reference groups for PRIs a two-step algorithm was implemented. At the first step, research organizations were divided into groups by field of science (the first level of the OECD FOS classification (OECD, 2002) in line with the specific research areas mentioned by the organizations. As a result, an organization may refer to more than one field of science. At the second step, within each field of science, a research profile of an organization describing its orientation towards one or several social functions, i.e. knowledge generation, technology development or provision of S&T services, and consequently corresponding with certain types of research outputs was identified. Herewith a research profile was determined with the use of the following key indicators:

A. The number of papers indexed in Web of Science per 100 researchers.

B. Number of IPRs registered in the Russian Federation or abroad as well as the number of issued design documentation per 100 researchers.

C. Income from contractual R&D, S&T services provided and technology transfer per total R&D personnel of an organization.

As seen from the above, to reduce scale effects each indicator (A – C) reflecting certain type of outputs is divided by the number of employees, mainly involved in its acquisition. While researchers tend to be mostly engaged in publications and IPR production, financial results require involvement of different categories of R&D personnel.

Consequently, an organization refers to a particular research profile reflecting its bent for certain research function and corresponding output, if one or more of the indicators mentioned above (A – C) is not zero and equal or exceeds the median value for the field of science. It allows identification up to eight research profiles (see figure 1). An intersection of field of science and a research profile constitutes a reference group.

![Figure 1. Research profiles of organisations](image-url)
demonstrating lower level of research productivity by all indicators. At the same time, it may have some other characteristics, not included to the initial selection criteria.

According to the requirements mentioned in the related legal documents regulating overall evaluation procedure (see: http://www.sciencemon.ru/legal/acts/postanovlenie-pravitelstva-rf-ot-1-noyabrya-2013-979/), the leadership within the reference group is distributed as follows:

- 1st category (leading institutions) = median + 25%
- 3rd category (loosing research functions) = median – 25%
- 2nd category (stable research organisations) = others

General distribution of organisation by reference groups and performance categories is provided below as a possible solution obtained from the available sample and implementation of the above-mentioned criterion. To distinguish between 2nd and 3rd performance categories within the VIII research profile it was suggested to use additional criterion measured as a share of private funding in the intramural R&D expenditure. The role of private financing was discussed in (Coccia, 2004). In other words if an organization demonstrates poor performance level, but not "at public expense" (the share of private funding in total R&D expenditure is equal or above the median level within the relevant field of science) it falls into the 2nd category. Otherwise, it is associated with institutions loosing their research functions and requires further peer-review based expertise.

**Preliminary results**

Achieved sample allowed identification of eight research profiles in six fields of science, which provides adequate representation of reference groups and thereby – the statistical significance of the derived threshold values. In the present structure natural sciences, medical and agricultural sciences as well as technology studies are well represented. Somewhat lower concentration of organizations is seen in in the social sciences and humanities (table 2).

Each research profile is characterized by a unique configuration of resources and results that can not apply the same evaluation criteria and thresholds to the whole population of organizations. In particular, the resulting distribution naturally include confluent profiles of technology developers and service providers (VI) in the field of humanities. Similar misbalances can be seen in other fields.

**Table 1. Model distribution of PRIs by reference groups and performance categories**
Different fields of science demonstrate different functional roles. In particular, in the field of medical sciences most of the organizations appear in the group of technology developers (II and IV profiles, mostly first and second performance categories), agricultural sciences also dominated by the developers as well (specifically in the first category). Social sciences are represented mostly in the VIII profile that is characterized by a high number of ulterior (unexpressed) results mostly due to the high number of libraries and infrastructure elements historically holding status of research organizations. The latter is also true for the technical and technological and natural science areas having a number of pilot plants, experimental stations, etc. The second reason for over-representation of the VIII profile is multiple research orientation by fields of science and inability within the existing framework to divide measurable types of outputs by corresponding fields of science, which is one of the limitations of the proposed approach.

**Discussion and further research**

The proposed approach for reference group identification and assessment could be easily replicated in different samples. However, it has several significant limitations.

The results of the described distribution are largely determined by the boundary values set for the each reference group. Changing these values may lead to significant changes in the whole picture. In the proposed model the thresholds are set automatically, depending on the behavior of all scientific organizations in a sample. Accordingly, any change in the sample can make a difference in the assessment for an individual organization. Such changes may be both productive (e.g. increased performance indicators of some organizations over time can worsen the situation for others) or counterproductive (for instance, through the introduction of unusual objects in the sample for which the proposed indicators would not be relevant).

Secondly, the method does not exclude the possibility for an organization to change its category due to minimal change in one of the performance indicators. In other words, when two organizations in the same field of science demonstrate about the same level of performance and one of them lies on the threshold separating research profiles, then they may be included in different categories that is logically incorrect, taking into account their almost complete identity. Thus, the organizations holding leadership positions in the same pure profiles (I to III) may lose their advantage in relation to one of the mixed profiles (IV to VII), i.e. improving value of an additional indicator, it may lose its leading position by another one.
Third, the current approach does not allow further differentiation of R&D outputs by field of science. Therefore, performance is measured by the overall output of an organisation that may significantly distort the assessment results in case of its multidisciplinary specialization. Further approach might include development of approaches for bibliometric data verification and application of fractional counting for more accurate assessments.

In the end, it should be mentioned that, such an exercise is rather declarative and should be considered only as a preliminary and rough assessment the results of which though may be used for further detailed analysis and peer-review bases evaluation. Further research is aimed at overcoming the described constraints and searching for an optimized solution.

Measuring knowledge exchange of internationally mobile scientists -
A bibliometric approach based on similarity

Abstract
This study introduces a new bibliometric approach to study the effects of international scientific mobility on knowledge exchange. It is based on an analysis of internationally mobile and non-mobile German scientists publishing in journals that are indexed in Scopus. Using bibliometric data such co-authored articles, keywords and references from the Scopus database, I present a technique based on cosine similarity to measure structures of scientific communication. This quantifiable method is capable of revealing patterns of knowledge exchange between internationally mobile scientists and the absorptive capacity of the receiving research groups. Analyses are presented for an overall 9-year publication period (2007 to 2015), split into a pre-mobility phase, a mobility phase and a post-mobility phase, each of which lasts for three years. I compare internationally mobile scientists with non-mobile scientists and discuss the potentials and limitations of the method presented. It is concluded that the bibliometric approach proposed is useful when applied on a large scale to test for significance. International mobility proves to benefit the exchange of ideas between scientists from different countries.

Conference Topic
Methods and Techniques
Studies on the level of individual scientists

Introduction
The internationalization of science systems makes international mobility (IM) relevant to dynamics of knowledge production and knowledge exchange. IM is supposed to facilitate the acquisition and recombination of knowledge that is located at distant places (Laudel, 2003; Gläser, 2006) and is indispensable when the knowledge to be transferred is tacit and thus requires personal contact, observation of colleagues, or informal meetings (Collins, 1974, 2001). It is therefore crucial to understand how IM influences the exchange of scientific knowledge across national borders.

In this study, international mobility of scientists is understood as the physical transition between research organizations that are located in different countries of the world. Cross-border mobility is a means to gain access to international research groups (Ackers, 2008). Previous literature related to geographic mobility and exchange of knowledge focused mainly on the size and direction of migratory flows, neglecting the mechanisms underlying knowledge exchange. In contrast, Ackers suggests that the “focus should shift towards the quality of flows and the nature of knowledge transfer processes” (2005, p.116). Moreover, there is no systematic body of empirical knowledge that allows examining the implications of mobility for the dynamics of the production and diffusion of knowledge (Cañibano et al., 2008). Most previous studies mainly consider patents, investments, and spin-offs as mechanisms of knowledge transfer (Fernández-Zubieta et al., 2015). These formal communication channels are especially common in studies of technology and knowledge transfer. Patent citations were, for instance, used as a proxy for knowledge transfer and frontier innovation by Gibson and McKenzie (2014). Although the circulation of knowledge
at the transnational level is often desired and facilitated by organizational support or job change, the relationship between international mobility and knowledge circulation is relatively under-researched and the field of study suffers from a lack of empirical results. Studying star scientists (authors of highly-cited journal articles) Trippl (2013) also argued that little is known about the nature of knowledge flows of mobile scientists. Most of the existing studies are speculations about the impact of international mobility on knowledge production and transfer, whereas published studies of true knowledge transfer are rare. However, Collins (1974) described a case where an innovative laser could be constructed by scientists who had seen the original set-up and interacted with the constructors, but could not be replicated by scientists who had only read about it and studied diagrams.

This study aims to update our knowledge on the role of international mobility in knowledge exchange processes, by trying to contribute to empirical results that are based on bibliometrics. Bibliometrics can not only be used for institutional evaluations and individual research assessments, but also for measuring intellectual influences of scholarly activities. One of the first studies exploring bibliometric methods related to international mobility was published by Laudel (2003). Additional bibliometric analyses of scientific mobility focused on a defined group of scientists, e.g. doctorate holders (Gaulé & Piacentini, 2013) or the overall population of scientists of a set of countries (Conchi & Michels, 2014; Moed & Halevi, 2014). International scientific mobility can be traced by looking at scientists’ affiliations through the years and their scientific output throughout their career. There are no bibliometric methods yet to indicate the exchange of knowledge. The approach presented in this study aims to provide a first understanding of how internationally mobile scientists engage in knowledge exchange mechanisms. The study examines German scientists and their co-authors publishing between 2007 and 2015 in journals that are covered by Scopus. The scientists under study are not German by nationality but by publishing mainly from German institutions. Internationally mobile German scientists are compared with non-mobile scientists in different scientific fields to account for epistemic characteristics. The cosine similarity of German scientists and their co-authors in publication practice is compared. Salton and McGill (1983) were the first to introduce the cosine between two vectors A and B into information science. The large data set used in this study allows for statistical tests and robust findings. In the rest of the paper, I present a theoretical background that is linked to bibliometrics and explain the database and method.

**Theoretical background and bibliometrics**

Knowledge exchange cuts across a variety of academic fields and application contexts and therefore lacks a common definition; it especially depends on how knowledge itself is defined (Edler et al., 2011). Whereas the term *knowledge transfer* implies that knowledge has been transferred from A to B (and possibly got lost at place A), the term *knowledge exchange* is considered a more appropriate term to describe the exchange of knowledge between (at least) two individuals. In contrast to information that is codified and stored in publications, software or manuals, knowledge is less tangible, has a tacit component and is stored in people’s heads. Assuming that knowledge is embedded in people (Bozeman et al., 2001) the physical interaction and involvement of the knowledge carrier is crucial for any knowledge exchange. Although science invests considerably in codification of knowledge in form of scientific publications, a large part of the knowledge produced remains tacit. Seminal empirical studies on the role of tacit knowledge were published by Collins (1974, 2001) arguing that the transfer of tacit knowledge can only be solved by physical mobility in form of exchange of visits.

Knowledge exchange is tied to knowledge production which is a collective endeavor (Polanyi, 1962) taking place at the level of the individual, the research group and the scientific community. Scientific communities extend over the globe and their members produce new
knowledge claims by interpreting existing knowledge and identifying research gaps that they address in their work (Laudel & Gläser, 2008). Most research efforts result in publications that are available to the scientific community. Peer-reviewed publications assure a minimum level of quality and provide detailed information on the content (title, abstract, and keywords), influential work (references), scientists and organizations, grants, and the geographical location (affiliation). Thus, scientific publications are not only the elementary unit of formal scientific communication, but they also constitute a crucial element in knowledge exchange mechanisms.

The main assumption of this study is that the bibliometric database Scopus covers the core communication channel of some scientific communities. Thus, every active participant contributes to the common body of knowledge by publishing and referencing knowledge claims (Gläser & Laudel, 2001). Journals constitute a major part in the scientific publishing process. Authors choose deliberately appropriate journals to submit their work to and have a specific journal profile that may change over their career.

International mobility is often considered as an integral part of an academic career. Mobility episodes are sequential throughout a career trajectory and can be tracked on the basis of the publication history of a scientist. Finally, research cooperation can describe two different types of co-authorships. Co-authorship can result from the work of a local group of scientists or from a cooperation network that is translocal and relatively stable over time. Both types of co-authorships enable knowledge exchange. The integration of internationally mobile scientists into research groups abroad can manifest itself in co-authorships. Therefore, knowledge exchange is operationalized as co-authored publications which result from formal as well as informal communication and interaction.

Data and methods

Data base
The data were retrieved from Scopus (Elsevier) that is licensed as custom data at the Competence Centre for Bibliometrics and is integrated in an in-house database. A scientist is specified as an author ID in Scopus. The author ID is supposed to combine all publications of an author under a single ID to handle common first and last names (Moed et al., 2013). In order to associate an author with his publication oeuvre, the algorithm uses a multifaceted approach where name spelling variants, affiliations, co-authors, subject areas and the prior publication history are taken into account. The algorithm aims at higher levels of precision than recall. Thus, as soon as a publication cannot be assigned to an existing author ID, a new profile will be created under which the publication appears. The algorithm is supplemented by an author feedback system where an author can indicate whether publications are wrongly attributed to his profile. Only the author ID enables large-scale analysis of international mobility, because it is imprecise to disentangle scientists simply on the basis of their first and last name.

Moed et al. (2013) and Conchi and Michels (2014) published on the reliability of Scopus’ author ID to trace scientists’ mobility and found it acceptable if applied on a large data set so that certain flaws are counterbalanced. Kawashima and Tomizawa (2015) evaluated the accuracy of Scopus’ author ID on the basis of the largest funding database in Japan that provides a unique researcher number. Recall and precision of Scopus author ID for Japanese researchers were reported as 98% and 99%, respectively, showing that the author ID is sufficiently reliable.

To test the precision of the Scopus author ID for German scientists, CVs of all 193 Leibniz-laureates (1999-2016) were coded. The Leibniz Prize is the most important research prize in

---

Germany and approx. ten scientists are awarded each year for their outstanding work. Having compared the laureates’ publication country with the country of residence as derived from CV data it can be concluded that author ID has a high degree of precision for these authors. However, this set is not representative as it includes authors who have a large set of publications. The attribution of a new publication is more precise if it is compared with a large set of previous publications to define it as a similar publication that must belong to the laureate. The ideal case was found for the majority of laureates: a scientist publishing in sources that are covered by Scopus has a single author ID and each author ID relates to a single scientist. Thus, the validation process proved that the author ID algorithm produces good results for German authors.

Internationally mobile scientists are specified as those whose affiliation changes from one country to another. A country relates to the geographic location of the institute at which a scientist conducted and published his work. It is not the country of their nationality or official country of residence.

Erroneous attributions affect not only the accuracy of mobility data but also those on co-authors. Co-authors may be affected by profiles containing papers that in reality belong to other authors. The more common a name, the more papers will be assigned to the profile, which is especially true for Asian scientists (Moed et al., 2013). A co-author’s oeuvre might be split between different profiles due to diverse metadata of publications. As a result, one profile will contain the majority of publications and several smaller profiles only 1-3 papers (Moed & Halevi, 2014). The study takes the potential errors into account by setting restrictions on the data.

Data selection

In a first step, all authors were selected that have at least one paper published with a German affiliation between 2007 and 2015 (n=47,814). Publications are limited to articles and reviews in journals only. German authors are defined as those who have at least half of their publications published with a German affiliation.

The publication period is limited to 2007 to 2015. I distinguish three phases: a pre-mobility phase that ranges from 2007 to 2009, a mobility phase of an undefined duration between 2010 to 2012 and a post-mobility phase that lasts from 2013 to 2015. The mobility episode is characterized as a phase where at least one publication is affiliated to a non-German institution. The duration of the international mobility phase is not defined. Due to Scopus limitations, mobility is measured on a yearly basis (Moed & Halevi, 2014). By international mobility I consequently refer to stays abroad that last from one to three years according to publication data. All of the German scientists under study publish in the phase prior to international mobility as well as after the mobility episode exclusively from German institutions.

Only those German scientists are under study who have published between 6 and 200 papers. By this limitation I try to avoid merged or split identities and also exclude those authors with few publications, because they hardly provide information on how authors move from one country to another. All these restrictions result in 8,371 German scientists.

Co-authors under study are specified as those who have at least two joint publications in at least one of the three phases with German scientists. This guarantees that a co-author and a German author were interacting and not affiliated on the basis of a large collaboration. To exclude errors of homonyms (one author name relating to different persons – common name) and synonyms of co-authors (scientists having more than one author name – split identity), these are limited to those who publish between 3 and 200 publications (2007 to 2015) and are

---

2 A single author may be affected by both types of error.
affiliated at most to 4 countries. Thus, the number of German scientists who co-published with co-authors as described diminishes to 2,134.

As a comparison group, I selected a random sample of 10,000 German scientists who have exclusively published with a German affiliation in the period 2007 to 2015. To measure effects of co-authorship I also distinguish the three phases described above (2007-2009, 2010-2012 and 2013-2015). The same restrictions to co-authors were set as to the group of German scientists who have been abroad. Thus, the number of German scientists in the comparison group diminishes to 2,487.

Methods

The main methodological question is to what extent bibliometrics is capable of indicating knowledge exchange. As stated above, knowledge exchange is operationalized as co-authored publications. Since knowledge exchange manifests itself in the content of the publications of the recipients of knowledge, it is possible to see whether the same sources, keywords and references are used for publications.

To take epistemic practices into account, the authors are grouped by the research field they belong to. This classification scheme is necessary to compare scientists among their scientific peers. Overall, there are 26 research fields distinguished in Scopus’ All Science Journal Classification (AJSC).

Five different publication profiles are considered for each German scientist under study:

(I) The first publication profile contains all publications of the scientist in the post-mobility phase.

(II) The second publication profile contains all publications of the scientist in the pre-mobility phase.

(III) - (V) The other three publication profiles contain all pre-mobility phase publications of the scientists’ co-authors in the pre-mobility phase (III), the mobility phase (IV) and the post-mobility phase (V).

The similarity of German scientists and their co-authors was computed on the basis of the journals. Therefore, the vectors of the numbers of articles per journal in the respective publication profiles are considered. For two vectors A and B, the angle $\alpha$ between them is computed using the following formula:

$$\cos(\alpha) = \frac{A \cdot B}{\|A\| \cdot \|B\|}.$$ 

Cosine similarity is defined as the cosine of the angle of two vectors. The smaller the angle the bigger is the similarity. Figure 1 illustrates this notion of similarity for the publication practice of two authors. The closer the vectors the more similar authors are in their choice of journals. A paired t-test was used to the test the significance of the differences in similarities between publication profile (I) and (II), (I) and (III), (I) and (IV) and (I) and (V).
Results

The following Table 1 provides an overview of the angles between the vectors of number of publications by journal for German authors being internationally mobile (mobile group) and those who were not mobile (comparison group). Only 20 of the 26 AJSC fields are displayed where the number of scientists is at least 80. Note that scientists publish in journals that are assigned to more than one scientific field.

For most disciplines, the similarity of the authors’ post-mobility phase publication profile (I) to the post-mobility co-authors pre-mobility phase publication profile (V) is significantly higher than the similarity of the authors’ post-mobility phase publication profile (I) to their own pre-mobility phase publication profile. This is true both for the internationally mobile German scientists as well as the non-mobile German scientists. Results are inconclusive for the following disciplines: Chemical Engineering (both groups), Energy (both groups), Engineering (both groups) and Materials Science (both groups). Interestingly, the exceptions are Mathematics and Computer Science. In these disciplines German scientists are more similar in the post-mobility phase to themselves in the pre-mobility phase than to any of the co-authors in the pre-mobility phase.

For the disciplines Agricultural and Biological Sciences (both groups), Biochemistry and Molecular Biology (both groups), Immunology and Microbiology (both groups), Medicine (both groups), Neuroscience (both groups), Physics and Astronomy (comparison group), Psychology, Veterinary (comparison group), the similarity of the authors’ post-mobility phase publication profile (I) to the mobility co-authors pre-mobility phase publication profile (IV) is significantly higher than the similarity of the authors’ post-mobility phase publication profile (I) to their own pre-mobility phase publication profile. This is true both for the internationally mobile German scientists as well as the non-mobile German scientists. Results are inconclusive for the following disciplines: Chemical Engineering (both groups), Chemistry (both groups), Dentistry (both groups), Earth and Planetary Sciences (both groups), Environmental Science (both groups), Materials Science (both groups) and Pharmacology (both groups). Again, in Computer Science (both groups), Engineering (both groups) and Mathematics (both groups) German scientists are more similar to their pre-mobility publication profile than to the pre-mobility phase of the co-authors of the mobility phase.
Table 1. Overview of the angles between the vectors of number of publications by journal for German authors being internationally mobile and those who were not mobile. N is the number of scientists in each of the two groups. Column A: Similarity of post-mobility phase (I) to pre-mobility phase (II). B: Similarity of post-mobility phase (I) to co-authors from pre-mobility phase (III). C: Similarity of post-mobility phase (I) to co-authors from mobility phase (IV). D: Similarity of post-mobility phase (I) to co-authors in post-mobility phase (V).

</tbody>
</table>
For the disciplines Agricultural and Biological Sciences (both groups), Biochemistry and Molecular Biology (both groups), Immunology and Microbiology (mobile groups), Medicine (both groups) and Neuroscience (both groups) the similarity of the authors’ post-mobility phase publication profile (I) to the pre-mobility co-authors pre-mobility phase publication profile (III) is significantly higher than the similarity of the authors’ post-mobility phase publication profile (I) to their own pre-mobility phase publication profile. 

In Chemical Engineering (mobile group), Computer Science (both groups), Engineering (both groups), Materials Science (both groups), Mathematics (both groups) and Physics and Astronomy (both groups), German scientists are significantly more similar to their pre-mobility phase publication profile than to the pre-mobility publication profile of the co-authors in the pre-mobility phase. Results are inconclusive for the following disciplines: Chemistry (both group), Dentistry (both groups), Earth and Planetary Sciences (both groups), Energy (both groups), Environmental Science (both groups), Nursing (both groups), Pharmacology (both groups), Psychology (both groups) and Veterinary (both groups).

Figure 2 illustrates the cumulative distribution of angles between pre- and post mobility publication profiles of internationally mobile scientists and non-mobile scientists. 

The distribution of angles is computed over all scientists and is not distinguished by disciplines. It is evident that internationally mobile scientists are more similar to themselves than non-mobile scientists. Non-mobile scientists show a high share (ca. 30%) of post-mobility publication profiles that are (journal-)orthogonal to their 2007-2009 publication profiles, i.e. in the 2013-2015 phase they publish in other journals than in the 2007-2009 phase. In comparison, 20% of internationally mobile scientists publish in the post-mobility phase in completely different journals than in the pre-mobility phase. The degree of the angle between the pre- and post-mobility publication profiles of the internationally mobile scientists is 70.05, whereas the angle of the non-mobile scientists is 73.29.

Assuming that publications sharing the same keywords result from interaction or a common language, knowledge exchange was also operationalized as the shared keywords and references of German scientists and their co-authors Thus, the vectors of the number of
articles by keyword and the number of articles by reference in the respective publication profiles were considered. The closer the vectors the more similar authors are in their choice of keywords and references. The tables are not listed due to space limitations but the results are overall similar to the results presented on the basis of journals. However, the angles are higher because the number of keywords and references to be used is higher than the limited number of journals covered in Scopus.

**Discussion**

The study aimed at measuring the impact of international mobility on publication practices, where knowledge exchange was operationalized as co-authorships. The study revealed that in some disciplines the similarity of German authors to their co-authors increases with international mobility during the period of investigation, whereas in other disciplines authors remain similar to themselves.

In general, the degree of similarity is higher for the mobile scientists in comparison to those without a mobility phase between 2010 and 2012. Evidently, scientific mobility is more than meetings between individuals. When scientists meet in person, they can screen each other’s skills and adjust to each other making the knowledge exchange more efficient. Especially, disciplines in which the research work is often conducted outside the national borders of a country and scientific findings result from interaction triggered by international mobility and collaboration, an increased similarity of the publication practices were measured. In contrast, in Mathematics and Computer Science where the knowledge is mostly codified, no positive impact of co-authors during the mobility phase is measurable.

The methodology presented does not aim at assessing the performance of individual scientists but rather the effects of international mobility at higher aggregation levels. The analysis of large datasets and the choice of a comparison group tend to cancel out randomly distributed errors. However, systematic errors are not accounted for, because certain limitations are inherent to bibliometric studies of international mobility. Bibliometric research allows tracking mobility only to the extent that scientists publish and that the affiliation is stated on the publication and is linked to them. Another factor influencing results is that a stay abroad does not necessarily result in a publication, and thus cannot be measured as a stay abroad. Moreover, the publication delay has to be kept in mind, thus a mobility episode that becomes evident between 2010-2012 on the basis of publication from this phase, may result from earlier stays abroad.

Another challenge to the bibliometric approach is that it is based on the use of unique author profiles that rely on the Scopus algorithm (Moed et al. 2013). Additional distortions may derive from scientists who move to another country but continue to publish with colleagues from their old institution and from double affiliations, thus when scientists are simultaneously appointed at institutions that are located in different countries. A limited coverage of the database can also cause inaccuracies in detecting mobility episodes.

I tried to minimize the limitations by restricting the period to recent years (2007-2015) because the Scopus author ID works best for recent publications. Moreover, on the basis of German authors whose residence countries (as provided in their CVs) were compared against the country codes in the affiliations of their publications, I made sure that the precision of the author ID is sufficiently high. Additional restrictions were set in regard to the publication counts and the co-authors.

**Conclusion**

The mere inflow and outflow rates of mobile scientists are insufficient to studies of the impact of international mobility on knowledge aspects. The need to study the effects of international mobility on knowledge exchange constitutes new challenges for empirical research. The aim
was to provide insight into the uses and limits of the new approach. The author ID and the affiliation information in Scopus made it possible to distinguish German scientists that were internationally mobile from those who were not. Using a bibliometric approach that is based on affiliation data in scientific publications it is possible to draw some conclusions regarding the similarity of authors and their co-authors abroad as well as in their country of residence. Thus, it can be concluded that bibliometrics can provide insight into research processes and indicate knowledge exchange and that the pilot study provides significant outcomes in terms of similarity of mobile authors and their co-authors abroad.

However, the methodology presented is only able to show patterns of similarity on the publication practice and covers the specific content of the knowledge, thus the semantic relationship of research terms (i.e. keywords), only to some degree. The topical orientation accompanying knowledge exchange can be analyzed on the basis of abstracts and language processing techniques such as co-word analyses. Thus, it remains important to develop tools for better understanding the nature of knowledge flows of mobile scientists and the value added that international mobility brings to the individual scientist as well as to research. In the current study, every journal is treated as completely distinct from every other journal. Future work should consider the similarity of journals and incorporate this similarity into the calculation of the similarity of publication profiles.

Finally, it is important to be keep in mind that co-authorships can stand for different relationships and therefore need to be distinguished in future work. Co-authorships can either occur because scientists are diametric in their research focus and complement each other’s work or because they are similar in their topical orientation and work on the same issue.

Acknowledgments
The study was funded by the Bundesministerium für Bildung und Forschung (BMBF) under the grant number 01PQ16002. The data builds on the bibliometric database provided by the Competence Centre for Bibliometrics (grant number: 01PQ17001).

Abstract

Most uses and investigations of scholarly journals rest on implicit understandings of journals as communication channels which are rarely made explicit, let alone discussed. In this paper, we argue that by theoretically embedding and operationalizing ‘internationality’, bibliometrics can contribute to the study of social structures of scientific communities. We consider journals as communication channels in the production process of scientific communities and define their internationality as the links they create between community members from different countries. This definition can be operationalised with four sets of variables describing the international composition of the set of authors, the selection processes and their impact on the international composition of the set of authors, the international composition of the journal’s audience, and knowledge flows between authors and audiences. We analyse six journals from different regions of the world in the field of International Relations and find that the supposedly ‘leading international journals’ are in fact closer to being domestic US-journals, while European and Asian journals show a much higher diversity of authors, audiences and editorial boards. We confirm that a differentiated analysis of international diversity contributes to theory-driven investigations of scientific communities. Our approach appears to be transferable to questions about the thematic diversity of journals.

Introduction

Scholarly journals are one of the core empirical objects of bibliometrics. Journal-to-journal citations are used for the mapping of scientific fields (Leydesdorff 1987) and the construction of science overlay maps (Leydesdorff and Rafols 2009). Journal-level citation indicators such as journal impact factors are critically assessed, and suggestions for further developments are made (Moed et al. 1996; Glänzel and Moed 2002). In addition, a variety of properties of journals including gatekeeping functions (Braun and Bujdosó 1983; Ni et al. 2013) and internationality (Zitt and Bassecoulard 1999; Aman 2016; Andrei et al. 2016) are studied. These uses and investigations of scholarly journals rest on implicit understandings of journals as communication channels which are rarely made explicit, let alone discussed. In this paper, we argue that by paying attention to theories of scientific production and the role of journals in this production process, bibliometric studies of journals can make major contributions to science studies. By theoretically embedding and operationalising the idea that ‘internationality’ is a theoretically important property of journals, we illustrate possible contributions by bibliometrics to the study of social structures of scientific communities. We thereby take on the task formulated by Leydesdorff (1989: 339) nearly thirty years ago:

*Only by further specification of what empirical studies contribute to specific theoretical questions can we systematically further the relations between qualitative theory and scientometric methods in S&T-studies.*
Theory

Journals as communication channels

A common weakness of both the Mertonian and the constructivist sociology of science is their implicit separation of a local construction and subsequent certification and circulation of contributions to scientific knowledge. This separation is explicit in Zuckerman’s and Merton’s (1971) consideration of the peer review as a process of certifying knowledge. Despite their explicit rejection of Merton’s structural-functionalist approach, constructivist science studies implicitly kept this distinction by strongly focusing on micro-social processes of knowledge construction, a focus which included a relative neglect of wider knowledge structures and the role of published scientific knowledge in the laboratory (Lynch 1985: 153).

If we start from the idea that scientific knowledge is produced collectively by scientific communities, scientific communication must be reconceptualised as a part of the production process rather than a process of circulating products. In this production process, individual publications are offers of intermediate contributions to a common product, which might or might not be accepted by further use in subsequent knowledge production processes. Changes in communication practices re-structure a community’s knowledge production process.

From this perspective, a scholarly journal can be defined as a formally organised communication channel that contributes to maintaining the collective production of scientific knowledge by periodically making publicly accessible selected scientific contributions for use by others. The selection process is under control of members of scientific communities who form an editorial board and provide peer reviews. In most cases, the communication channel is not internal to one scientific community but makes accessible contributions from several communities for the use by several (not necessarily the same) communities, as is reflected by Bradford’s law (Brookes 1969).

The communicative function of journals consist in linking specific contributions to specific audiences. This function varies in several dimensions. The most important dimension for science studies is content, i.e. the knowledge flows through journals. These knowledge flows are produced by gatekeeper decisions on scope, quality standards, publication language, and other properties of the journal. The perception of these decisions and their implementation in the day-to-day selection of contributions shape self-selection processes among potential authors and decisions to become part of the journal’s audience. By providing selected content from a self-selected (and subsequently externally selected) set of authors to a self-selected set of readers, journals contribute to the emergence of content-based sub-communities, i.e. community members who address the same topic.

Another dimension that is relevant to the study of scientific communities, which we will operationalise and investigate in more detail in this paper, is the internationality of a journal. The ‘internationality of journals’ has enjoyed considerable attention, partly because it is considered an aspect of a journal’s quality (Buela-Casal et al. 2006) and partly because it reflects the communicative function of linking national sub-communities to their international communities (Aydinli and Mathews 2000; Andrei et al. 2016). Unfortunately, the concept is usually taken for granted and not theoretically defined. The attempt by Buela-Casal et al. (2006) to derive an understanding from encyclopaedia entries illustrates the problem, namely the absence of a theory in which the concept is embedded.

1 Actor-network-theory and its account of fact-making as a collective process (Latour 1987: 29) may look like an exception but still leaves out the process that turns isolated facts into scientific knowledge.

2 From other scientific perspectives, scholarly journals could be defined differently, i.e. as products of a commercial publisher (Volkmann et al. 2014).
If we consider journals as communication channels in the production process of scientific communities, the internationality of a journal can be defined as \textit{the link it creates between community members from different countries}. This link is rather complex and can be described by four sets of variables, namely
- variables describing the international composition of the set of authors;
- variables describing the selection processes and their impact on the international composition of the set of authors;
- variables describing the international composition of the journal’s audience; and
- variables describing knowledge flows between authors and audiences. Similar to content-based communities, journals can create national or regional sub-communities if self-selections and selections are based on nationality or region.

The internationality of journals in the field of International Relations

The field of International Relations has discussed its own international relations for a long time. Beginning with Hoffman’s (1995 [1977]) “An American Social Science: International Relations”, members of the IR community have examined the degree to which their field includes contributions from countries beyond the US or the North American and Western European core. Contributions to this discussion are often based on the analysis of journal publications, which play an important role in IR. For example, Aydinli and Mathews (2000) studied the dynamics of core-periphery relationships in IR by analysing the authorship of 20 leading IR journals in the 1990s. They constructed four categories of countries (core of the core, periphery of the core, core of the periphery, and periphery of the periphery) and found proportions of publications from these groups to be constant during the 1990s. Turton (2016) analyses contributions to 12 IR journals in an attempt to answer the question whether scholars from the US dominate the field of IR. Her investigation goes beyond bibliometrics by categorising article content. She did not find much evidence supporting the thesis of US dominance. However, her conceptualisation of dominance as intentional or at least conscious process (ibid, 11-12) seems unduly narrow because it does not pay enough attention to predominance as an emergent effect of individual actions.

This discussion and its empirical referents can be framed as the sociological question of the internal structuration of scientific communities. The sociology of science has analysed the differentiation of scientific communities in center and periphery (e.g. Crane 1972; Chu 1992a; b; Hwang 2008) as well as the role of language (Brittain 1984) and of nationally specific research objects (Reguant and Casadella 1994; Rey-Rocha and Martin-Sempere 1999) for the emergence of national sub-communities. However, empirical studies have been separated from theory, and measures have rarely been operationalisations of theoretical concepts. The IR field appears to be ideally suited for a study of sub-structures because it utilizes journal-based communications but at the same time features nationally or regionally specific research objects, a variety of publication languages, and theoretical pluralism. In the context of a larger project on the internal structuration of and knowledge flows in the IR field, the question arose how the internationality of journals and possible internal boundaries created by communicative functions of journals could be explored. In order to contribute to this investigation, we operationalised the concept of internationality and tested our indicators on six journals in the field.

\footnote{A short description of the project can be found at https://www.researchgate.net/project/Overlapping-Scientific-Communities-Internal-Structuration-and-Knowledge-Diffusion-in-International-Relations.}
Data and Methods

Data

We test our approach by applying it to six journals (Table 1). From the discussion of core-periphery relationships in IR follows that the internationality can be expected to vary between US-based journals and journals in other regions. The population from which journals can be selected is limited due to biases of the Web of Science. We therefore included one journal indexed in the SciELO database, whose records can also be downloaded from WoS in the same format. Five of the journals publish in English. We used all document types. Most of the documents in Revista Contexto Internacional (176) were published in Portuguese, 20 documents were published in English.

The data originate from the bibliometric database of the German Centre for Bibliometrics, which builds upon licensed custom data files of Thomson Reuters’ Web of Science (WoS). The journal Revista Contexto Internacional is not part of WoS’ Core Collection and is thus not included in our licensed version of WoS data. We therefore downloaded the full records manually from the SciELO Citation Index that is implemented in WoS. The data were edited (e.g. coding the country codes of authors and citers) and integrated in the local database. The publication period ranges from 2006 to 2015.

Since IR scholars, and thus potential authors and readers, are unevenly distributed across countries, distributions observed for the six journals must be assessed against reference values. We construct the baseline from all journals in WoS that are assigned to the Subject Category ‘International Relations’ and are covered in WoS for at least five years within the period 2006-2015 (91 journals). The reference set contains authors from a total of 151 countries and citers from 170 countries.

Data about editorial board membership of the six journals were downloaded from the internet (online versions of journals and journal websites).

Methods

We operationalise the international composition of a journal’s author set as the number of addresses from each country. If authors provide addresses from more than one country, all countries are counted equally. Countries are counted fractionally, i.e. a value of 0.25 is added to each country if an article is linked to addresses from four countries.

The international composition of a journal’s audience is operationalised as the number of addresses from each country for citing articles. This operationalisation is problematic for two...
reasons. First, citers constitute only as small proportion of a journal’s audience. Second, the nationality of citers can be determined only for the source items, i.e. for those citing articles that are indexed in the WoS. Since IR as a social science relies on several communication channels beside WoS-indexed journals and is ill represented due to the English language bias of the WoS, the citing source items on which the analysis of audience internationality is based constitute only a fraction of citing publications. Taking into account the citation dynamics of the social sciences, citation counts were calculated for a five-year period of the actual year of publication plus the four subsequent years. Thus, for papers published in 2006, citations from the publication period 2006–2011 were considered. This 5-year-citation window allows calculating citation rates of papers published up to 2011. Self-citations were included because they contain important information, namely authors’ belonging to the audience of the journal in which they publish.

Selection processes cannot be analysed bibliometrically. However, some information on selection processes is indirectly provided by looking at ‘regulatory body’ internationality, which we operationalize as international diversity of editorial boards.

The analyses of author sets, audiences and ‘regulatory bodies’ measures several aspects of the international diversity of the three groups of actors. A system’s diversity is commonly understood as the heterogeneity produced by the disparity of its elements (Stirling 2007; Gläser et al. 2015). It can be analysed by categorising the elements of a system and measuring three properties, namely
- variety (the number of categories, here: countries),
- disparity (the dissimilarity of categories, here: countries), and
- evenness (the distribution of elements across categories, here: the number of authors/editorial board members/readers from each country).

Since there is no meaningful measure for disparity of countries, we only use variety and evenness, which are combined in the Shannon Index

\[ I = -\sum_{i=1}^{n} p_i \ln(p_i) \]

where \( I \) is the Shannon Index of the distribution of elements across categories, \( n \) is the number of categories and \( p_i \) is the share of elements in category \( i \). For any number of categories the Shannon Index \( I \) achieves its maximum when all \( p_i \) are all equal (all categories have the same share of elements). The Shannon Index \( I \) drops to 0 when all elements belong to one category.

A disadvantage of synthetic diversity measures such as the Shannon Index is that differences in diversity cannot be easily ascribed to one of the properties. This is why it is useful to look at variety and evenness separately.

In order to measure the internationality of authorship, the Shannon Index was computed for the period 2006 to 2015 on a yearly basis as well as for the whole publication period.

The internationality of knowledge flows is assessed by two variables. First, we measure journal self-citation rates in order to assess the degree to which a communication channel is closed (i.e. author set and audience coincide) at the journal level. Second, we measure country-self-citation rates, i.e. the share of references by authors of a country that refer to publication of their same country. This measure goes beyond the international diversity of author sets and audiences by asking to what extent knowledge flows run across countries (are indeed international) or are just national knowledge flows that co-exist in journals.

Results

Authorship internationality

Table 2 provides an overview of the variety of authorship internationality for the six journals, i.e. the number of countries that had authors in the six journals between 2006 and 2015.
Table 2. Variety of authors’ countries and comparison to baselines, 2006-2015.

The evenness of authorship internationality is described by Table 3, which lists the distribution of authorships across countries for the ten most frequently occurring countries. The dominant authoring countries are the publishing countries shown in Table 1.

The proportions of countries with the highest shares of authors in a journal’s total output range between 29% and 82%, and considerably deviate from the proportions of the 91 journal baseline. These striking differences already suggest influences of publication language, topics and national sub-communities.

Table 4 lists the Shannon Index for the six journals for the whole period, which must be compared to the baseline of I= 1.88 for the 91 journals.

Figure 1 shows that authorship diversity is slightly increasing over time for all journals and the baselines with the exception of the *Chinese Journal of International Politics*, whose diversity markedly increases and moves it from the group of lower-diversity journals to the group of higher-diversity journals.

![Internality of authorship graph](image)

**Figure 1. Shannon diversity of authorship for the six journals and the 91 journals baseline, 2006-2015.**

**Citer internationality**

The variety of citer internationality is provided in Table 5. Table 5 also lists the share of journal self-citations, which indicates the degree to which a journal provides a ‘closed’ communication circuit. Given the low share of self-citations for all journals, none of them can be considered ‘closed’. Finally, the table lists the proportion of source items in the journals’ references on which these and the following data are based. These must be compared to an overall share of 25.05% source items in all 91 IR journals.

<sup>5</sup> Due to the different data set, proportions of journal self-citations and of source items in *Contexto Internacional* could not be analysed.
The evenness of citer distribution across countries is provided in Table 6. Again, a baseline needs to be considered because the citations received depend on the country distribution of readers, which is best estimated by author distributions because authors are potential citers. Table 6 shows a higher evenness of citer distributions than author distributions for all journals except Revista Contexto Internacional. The extreme values for Revista Contexto Internacional are easily explained by the predominant publication language. Between 2006 and 2011, all articles were published in Portuguese.

The predominance of citing countries coincides with the predominance of authoring countries for four journals, while Chinese Journal of International Politics and International Relations of the Asia-Pacific were mostly cited by US scholars, who are not the most frequent authors of these journals. Although the audiences appear to be dominated by citers from the US, the attention of US authors is clearly focused on the US journals, which have more than 50% citers from the US compared to the baseline of 32%.

Figure 2 illustrates how the internationality of citing authors developed over the years. Overall, the internationality increased over the years. Again, the Chinese Journal of International Politics shows a marked increase of diversity and moves from the group of lower-diversity journals to the group of higher-diversity journals. The low values for Revista
Contexto Internacional are likely due to the publication language - almost all citers are from Brazil.

Figure 2. Overview of the Internationality of citing countries for the six journals of interest and the average journal internationality of 91 IR-journals in the publication period 2006-2011 and a citation window of 5 years.

'Regulatory body' internationality
Differences and changes in author internationality would be explained by self-selections and selection processes, which is why it is important to look at the composition of the group of scholars who make decisions on the acceptance of submissions. We focus on the international composition of editorial boards (editorial committees in the cases of The European Journal of International Relations and Revista Contexto Internacional). Table 8 provides data on the diversity of these boards/committees.

Knowledge flow internationality
We analyse two variables describing knowledge flows. Table 9 provides journal self-citation rates for the five journals for which they could be calculated. Journal self-citation rates indicate the extent to which journals constitute closed communication circuits. None of the
journals is closed in this sense, a large majority of citations links the journals to other communication channels. This is not surprising given the large proportion of non-source items in IR journals. WoS journals are only one of several important channels of communication in IR.

<table>

</tr>
</tbody>
</table>

Table 10 summarizes the country self-citation rates of the five WoS journals calculated for papers published between 2006 and 2015. In order to avoid distortions by low numbers of references, we selected the ten countries with the most references from each journal. The country self-citation rate expresses the share of references to publications from the author’s country. For example, papers published by authors from the US in CJIP contain 73.6% references to publications from other US authors. Country self-citation rates must be compared to the country-self citation rate among all 91 journals, which is 37.77%.

Discussion

Despite the severe limitation by the low proportions of source items in IR journals, our analysis exemplifies the advantage of a multidimensional analysis of internationality. First, it suggests that some allegedly international or regional journals are better considered domestic journals because scholars from the same country are predominant among authors and audiences (low variety, evenness, and Shannon diversity). This applies to International Organization and International Studies Quarterly, which are both considered “leading international journals” in the field but effectively channel communications between US scholars. The higher audience diversities indicate that the international community observes these communications, but country self-citation rates show that scholars from outside the US
are not really part of them. Revista Contexto Internacional also appears to be a domestic journal. Its diversity appears to be constrained due to the publication language. These three journals are also those whose editorial boards are dominated by one country and show the lowest Shannon diversities in our sample, which points to the impact of editorial policies. These editorial policies must not necessarily target the selection of authors from particular countries but can include preferences concerning empirical objects, theories or methods. Thus, author internationality might be an unintended side-effect of editorial policies on other matters.

The Chinese Journal of International Politics shows an interesting dynamics. Both its authorship diversity and its audience diversity have markedly increased between 2006 and 2015, and it moved from the group of ‘domestic’ to the group of ‘international’ journals in this period. The diversity of the international board in 2015 suggests that this might be due to a policy to increase diversity.

High country self-citation rates point to internal communication of national sub-communities through the analysed journals. This internal communication behaviour is particularly strong in the case of the US national sub-community. In some cases national sub-communities either don’t exist or communicate through other channels.

Conclusions
Due to space limitations, we could only provide a ‘proof of concept’ of our approach. Nevertheless, our analysis enables three conclusions.

First, bibliometric analyses can provide a nuanced picture of journal internationality that supports the study of internal structuration of international scientific communities. As is usually the case, the identification of interesting patterns by bibliometrics raises questions that cannot be answered by bibliometrics alone. However, raising these questions and contributing to the triangulation of qualitative methods and data that must be used to answer them is an irreplaceable contribution of bibliometrics to science studies.

Second, our analysis of IR suggests that IR might still be an ‘American discipline’ in the sense of the US national sub-community being predominant (being the largest sub-community) and introverted (one is tempted to say ‘parochial’). It might well be that the field of IR looks completely different to US and non-US scholars, a question that can be further explored by both bibliometric and other methods.

Finally, the approach applied here can be extended to properties of scholarly communication beyond internationality. For example, keywords or content analyses of articles can be used to study the communicative function of journals with regard to topics. In this case, questions of topic diversity, thematic diversity of audiences, and knowledge flows within and between topics could be studied in a similar fashion as internationality.

Authors’ Publication Strategies and Citation Distributions in Journals

Abstract
Psychology is a discipline standing at the crossroads of hard and social sciences. Some of psychology journals are attributed to SCIE in Web of Science database while others to SSCI (and some to both). So it is especially interesting to study bibliometric characteristics of psychology journals. We study not the citedness itself (IF etc.) but the citation distribution across papers within psychology publications. This is, so to say, “indicators of the second order” which measure the digression of the citations received by individual papers from the journal’s average. This also influences the publication strategies of the authors. Some journals guarantee to the author receiving of the mean number of citations while others have much more “All or Nothing” grade when any individual paper may have many cites or not have them at all. We also define four different types of psychology journals and explore their characteristics separately.

Conference Topic
Journals; Databases and electronic publications; Citation and co-citation analysis

Introduction
Citation distributions are generally characterized as “highly skewed”, this means a non-Gaussian pattern and high concentration of citations on some items while others are low-cited or non-cited at all, see papers by Whitehand (1985), Seglen (1992) and many others. Still, the uneven distribution of citations has its own levels of inequality and may be measured by common indicators such as Gini index, which will be used in the present paper.

The Gini index is a measure of inequality of a distribution. In terms of citation distribution it is a comparison of the journal where all citations are received by one paper with the case when each journal’s paper gets the same number of citations. The Gini index ranges from 0 to 1 where zero corresponds to perfect equality (each paper receives the same number of citations) and 1 corresponds to perfect inequality (only one paper has citations while others are not cited at all).

We are interested in how different journals gain their average citedness per paper. Some may get citedness from close to even distribution of citations, when each article has a high probability to receive an average number of cites. Other publications get their averages from a limited number of highly cited papers, while all others are not cited. The same research question was raised by Nuti et al. (2015) for cardiovascular journals. We choose psychology journals to investigate the issue. Psychology is chosen as a discipline standing at the crossroads of hard and social sciences, which makes it especially interesting for the analysis.

Gini index is used to measure the inequalities of citation distributions by Chi (2016) where the unevenness of book citations is compared with journals and the strong influence of uncited items on Gini coefficient is observed. Wren (2016) plainly states that “The higher Gini coefficients for bioinformatics journals suggest that development of novel bioinformatics resources may be somewhat ‘hit or miss’. That is, some approaches become widely adopted and produce a disproportionate number of extremely highly cited papers, while most are not widely adopted <...>.”
Gini coefficients for citations to a particular journal were also studied by, for example, Chatterjee, Ghosh & Chakrabarti (2016) and by Stegmann & Grohmann (2001). The latter paper analyzes journals on dermatology and explores the dependence of Gini index from journal impact factor. We address this question in the present paper too. Gini indices for leading multidisciplinary journals (Science, Nature, PNAS etc.) and for PhysRev series may be found in (Ghosh, Chattopadhyay & Chakrabarti, 2014).

Gini measure of inequality is also used in the other applied informetrics studies. For example Pislyakov (2008) applies this indicator to usage statistics of electronic journals. Leydesdorff & Rafols (2011) use it, along with other inequality indicators, to measure interdisciplinarity of a journal. They also agree that "The Gini coefficient <...> has the advantage of having been widely used in bibliometrics".

The new thing we want to introduce is the connection between the citation patterns in the journals and the choice the author makes when he/she chooses the appropriate journal to submit his/her manuscript. The choice is whether an author prefers to securely receive the average level of citations which is common to the journal (the case of publications with uniformly distributed citations across papers) or he/she wishes to risk and submit the paper to a journal where just several papers get extremely high level of citedness while others are being under-cited.

This choice marks different publication strategies of a scientist (whether chosen consciously or not). “All is safe” vs. “All or Nothing”.

Data and Methods

Data on 40 psychological journals from Social Sciences Citation Index (SSCI, Web of Science, Clarivate Analytics, ex-Thomson Reuters) were used (Table 1). We limit our analysis only to psychological journals, so there is no problem of cross-disciplinary comparison. However, we distinguish four types of journals in psychology, which, as we will further observe, demonstrate different patterns of citation inequality.

We have identified four types of psychological journals: multidisciplinary, sub-disciplinary, journals dedicated to a single particular topic, and methodological publications. In Web of Science there is another classification schema, with ‘Psychology: Experimental’, ‘Psychology: Developmental’ and others (8 different categories), but for the present research we need the classification ranging across all the sub-disciplines of psychology but marking the specific type of a journal.

Multidisciplinary group of journals publishes research on all spectrum of the science of psychology. For example, Psychological Science publishes papers on topics ranging from cognitive, social, developmental, and health psychology to behavioral neuroscience and biopsychology. Sub-disciplinary group includes journals which cover only one area of psychology. For example, Journal of Personality and Social Psychology publishes papers in areas of personality and social psychology while Cognitive Psychology publishes papers about attention, memory, language processing, perception, problem solving, and thinking. The group of journals dedicated to a single particular topic is focused on some special research area. For example, Depression & Anxiety focuses on studies related to different aspects of mood and anxiety disorders and related phenomena, and Personal Relationships publishes studies focused on attributes of individual partners in personal relationships, interactive relationship processes, and relationships in social contexts. Finally, methodological group includes journals which are...
devoted to research design, methodology, measurement, quantitative and qualitative data analysis. For example, *Behavior Research Methods* publishes papers on methods, techniques, and instrumentation of research in experimental psychology, and *Psychological Methods* on methods for collecting, analyzing, understanding, and interpreting psychological data. The sample includes different journals in terms of impact factor and publisher.

Five-year journal impact-factors (2015) for each journal were extracted from Journal Citation Reports (JCR, Web of Science, Clarivate Analytics, ex-Thomson Reuters). Five Gini indexes were calculated for each journal. Every Gini index was based on citations of papers published in each single year, from 2010 to 2014 (only “articles” and “reviews” document types were taken into calculation). These five indexes were then aggregated using the arithmetic mean. The five-year 2015 impact is used as the same papers are assessed by it: citations of articles/reviews from 2010 to 2014 are included in the formulae of impact-factor.

For the data preparation, analysis and visualization we used R, a programming environment for statistical computing (R Core Team, 2016). The Gini indexes were calculated by the *reldist* package (Handcock, 2016). Additional packages were used: *dplyr* (Wickham & Francois, 2016), *ggplot2* (Wickham, 2009), *readxl* (Wickham, 2016).

### Results and Discussion

Table 1 shows Gini index for 40 psychological journals chosen for our analysis. The Gini varies from 0.41 to 0.64 proving that there are different citation patterns, from close to “All or Nothing” as in *Psichothema* or *Behavior Research Methods* to “All is safe” as in *Psychology of Men and Masculinity*.

If we plot the dependence of Gini index from IF for all 40 analyzed journals, no clear regularity is observed (Figure 1). It seems that journal’s citedness has no evident connection with the distribution of citations across its papers.

But when psychological publications are subdivided into classes by types of journals, the relationship of inequality of citation distribution to impact factor becomes more obvious. We may see it in Figure 2, where linear regression lines with 95% confidence intervals for predictions from a linear model are shown.

What is interesting, and what is the main point of our paper, this has a clear connection to a publication strategy of an author. For example, if you publish in sub-disciplinary journals, the more cited journal you choose, the more “safety” in receiving average citations you get (Pearson’s $r = -0.87, p < 0.001$). But when an author submits his/her paper to a multidisciplinary journal, he/she may choose several ones with the same IF but with significantly different risk of receiving/non-receiving the average number of citations (so to say “All or Nothing” grade).

There is different level of inequality of citation distribution between groups of journals. Gini indexes of all journals from the methodological group are higher than 0.5, whereas Gini indexes of only a couple of journals from sub-disciplinary and special topic groups exceeds 0.5. It means that in general the inequality of citation distribution is higher in journals, which publish papers on methodology, methods, and tools of psychological research. These results are in accord with Wren (2016) that bioinformatics journals, which publish top papers, have higher Gini indexes. Publishing on methodology and research methods in psychology seems also to be 'hit or miss' in terms of citedness. The probable explanation may be that some methodological papers attract attention of many researchers who will use and cite them because these methods are well-
received by psychologists and are becoming widespread. While other papers are not so interesting and popular being rather complex or addressing too specific problems. It is in the methodological part of the science the inequality is therefore becomes more pronounced.

Figure 1. Relationship between average Gini index and 5-year impact factor (the whole sample of journals).

Figure 2. Relationship between average Gini index and 5-year impact factor by types of journals (linear regressions are shown, grey color displays 95% confidence interval for predictions from a linear model).
For instance, the most cited paper from methodological journals in our sample (860 total citations at the moment of data extraction) is an introduction to propensity score methods for observational studies (Austin, 2011) which are relevant not only for psychological research but also for all fields with observational (or nonrandomized) studies. And the third most cited paper (540 citations in total) demonstrates how to use Amazon’s Mechanical Turk web site for conducting behavioral research (Mason & Suri, 2012) which is extremely useful tool for many researchers in psychology.

We may also remind the well-known ‘Acta Crystallographica A case’ when only one methodological paper (Sheldrick, 2008) has changed the impact factor of the whole journal which has reached the top-3 overall (i.e. within all Web of Science) IF ranking. It was more than 20 times IF-rise for this journal. So, the methodological inequalities are common to the science and we may observe this in case of psychological publications too.

**Conclusion**

It is well known in bibliometrics that journal citedness (for example impact factors) should be compared only within the same scientific discipline. Moreover, there are differences between journal types (those which publish more review papers are generally cited more, for example). The present paper shows that the same approach should be used when we study not only average citedness but also patterns of digression of received by individual papers’ citations from this average journal citedness. Psychology journals of different types have different Gini indices and different relationship between Gini and 5-year impact factor.

This clearly marks differences in publication strategies. Of course, when the author chooses the publication venue, at the first place stands the subject matter of the journal and its aptness to his/her research interests. Next, generally goes the international visibility/popularity of the journal which is often proxied by the citedness of the periodical.

But as we may see from our research, another characteristic of the journal also matters. It is so to say the grade of “All or Nothing”. How strong the scientist may be confident in receiving average number of journal’s citations to his/her individual paper. Some journals have more equal citation distribution across their papers than the others with the same IF.

Though often this choice is made not consciously by the authors, they may feel it from empiric impressions from different journals (if they have a scholarly career long enough). Anyhow, the authors should know and keep in mind these “differences of the second order” which may influence their publication strategies.

At last, we should underline that though the average of Gini for five years was taken for the present paper, the further research is needed to examine whether the regularities found are robust over time. Moreover, the effect most probably will vary across scientific disciplines which is also a fascinating topic of future analysis.

Abstract
Social media stand as perfect examples of Web 2.0 applications. Baidu Baike, a wiki-like online encyclopedia, is analyzed as a typical collaborative project contributed by experts and users. How do the contributors communicate during the edition of entries? In order to seek answers to the question, scientific entries are chosen for citation analysis to reveal relationships among entries, which could indicate communication of entries’ contributors. The relationship between online entries and traditional literatures is discussed on the basis of reference analysis, which indicates communication between entries’ contributors and literatures’ authors. Cooperation analysis among experts or users is also conducted. Analysis on coupling entries helps to indicate the common interests of contributors. The crossing and integration of disciplines was confirmed in this paper. It is found that people’s online communication was affected by traditional knowledge carriers. The majority of experts cooperated with someone in the common affiliation while cross-unit cooperation also existed. There are clusters of common interests of experts, which indicate that the specialist only masters his own field. Moreover, users, who are typical general public, have wide range of interests and full of enthusiasm for entry contribution. Their participation is of great importance to development of science and technology.

Citation and co-citation analysis; Co-occurrence analysis; Science communication

Introduction
Knowledge management has received growing attention from both researchers and practitioners. With the rapid development of Web 2.0 applications, knowledge communication and sharing has moved beyond face-to-face exchanges to social media contexts such as blogs, Bulletin Board System (BBS), Wikipedia, Facebook, Twitter, and so forth. (Kling & McKim, 2000; Kling, McKim & King, 2003; Hoisl, Aigner & Miksch, 2007; Hsu, et al. 2006; Klamma, Cao & Spaniol, 2007) The feasibility of using social media in scholarly communication has been researched. Both of Koh(2007) and Wagner(2014) pointed out that social media could be used for knowledge sharing and communication. Eijkman(2010) thought that Wikipedia could be used in scholarly communication. Other researchers (Park, 2009; Liu, 2010; Dantonio, 2012) gave affirmative opinions on social media in study, research and cooperation. Moreover, influence of social media on scholarly communication was studied. Collins(2010), Kirkup(2010), and Gruzd(2012) agreed that social media can be used to build connections in order to stimulate new research ideas. Letierce(2010), Tiryakioglu(2011), and Gruzd(2012) found that scholars benefited from social media for academic exchange or scholar communication. See Yin
Lim(2014) indicate that the performance of undergraduate informatics students was more excellent after using social media for academic purpose. Those online encyclopedias, such as Wiki, were considered as valuable tools for knowledge communication and group collaboration (Wagner, 2004; Sauer, 2005). Moskaliuk (2009), Cho (2010), and Begoña (2011) investigated the use and influence of Wiki during knowledge sharing and communication. It is reasonable to consider online encyclopedias as an effective way for scholarly communication though qualitative research methods were used in the past research work mentioned above. However, Wiki is so free that every user can change the content arbitrarily. In order to investigate scholarly knowledge communication on social media, an online wiki-like encyclopedia, Baidu Baike, is chosen. The reason is as follows. Baidu Baike is a free, open, and typical online encyclopedia platform on the Web operated by Baidu Online Network Technology Co., Ltd., whose official version was released on April 21, 2008. More than 13 million entries had been included by April, 2016. And more than 5.8 million people who are on Baidu Baike involved in the edition of entries. Baidu Baike is considered as the world's largest Chinese Encyclopedia. The scholarly entries on Baidu Baike are user-generated and locked after review or modification by experts to keep them scientific and authoritative, which is so different from normal Wikipedia in which only users contribute to the entries. The scholarly entries are reliable and scientific. The scholarly communication on Baidu Baike is so potential that the hyperlinks, historic versions, and references behind will be analyzed. In this paper, the answer to these questions will be discussed. (1) What is the composition of related entries on Baidu Baike? (2) Are online entries related to traditional literature? (3) How did the contributors of entries cooperate together? (4) Is it possible for us to reveal the interest of contributors?

Methods and data collection

Methods

Scientometrics is becoming increasingly important, common, and sophisticated (Bornmann and Daniel, 2008). Scientometrics provides new metrics of scholarly impact on the social Web and useful tools to analyze developments of scientific fields (Rip & Courtial, 1984; Courtial, 1994; Hassan & Loebbecke, 2010; Priem & Hemminger, 2010). Citation analysis and co-words analysis is used to identify research group (Reyes-Gonzalez et al., 2016; Shiau & Dwivedi, 2013). Knowledge flow is investigated with citation analysis and co-word analysis (Tsay, 2015; Lee, 2017; Ravikumar et al., 2015).

Scientometric methods are used to analyze the relationship among the entries, contribution and cooperation from users and experts. Citation analysis is used to reveal communication among citing and cited authors or entry contributors taking hyperlinks and references as pointcuts. Co-word analysis is used to investigate cooperation among entry contributors including users and experts. Besides, it is also used to find out relationship among entries in the field of Biomedical Science. Bibliographic coupling is used to reveal the relationship among entries based on their references and contributors including users and experts. Knowledge aggregation is the act of perspective extraction of information, from a group of information sources based on divergent human perception, reasoning, and learning (Abiodun Robert, 2009).

The methods of knowledge aggregation are used to analyze linked data for knowledge discovery (Jun et al., 2015), survey of websites of academic libraries regarding the adoption of Web 2.0 technologies (Mahmood & Richardson, 2011), and online privacy and reputation management (Portmann & Pedrycz, 2014).
Data Collection

The study focuses on online scholarly entries in the field of Biomedical Science. The related data of entries is collected from official website of "Science" section of BaiduBaike (http://baike.baidu.com/science). And the data is processed through several technologies such as data mining and data cleansing.

There are 251 academic entries in the field of Biomedical Science on BaiduBaike. However, there are some repeated entries including “biomacromolecule mechanics”, “tissue engineering”, and “dental Biomechanics”. In addition, the entry “corneal contact lens” and “contact lenses” are same because they are synonymous exactly. We keep “contact lenses” instead of “corneal contact lens” for the sake of simplicity. Therefore, dereplication is used on the repeated and synonymous entries. There are 247 entries finally. The references, hyperlinks, and historic versions of each entry were collected manually. And information on experts who contributed to the entries was also recorded.

Composition of Related Entries on Baidu Baike

Is every entry isolated? Is there any relationship among entries? Although some entries “stay alone” without any hyperlink, it does not mean they are isolated exactly. The number of hyperlinks in the entry depends on edition of contributors.

It is hyperlinks in entries that indicate that editors of one entry have found, referred and cited other entries during the edition process, which is a typical communication activity. The hyperlinks of each entry on Baidu Baike are other entries. We tried to collect the hyperlinks data of 247 entries mentioned above in order to reveal the relationship among citing and cited entries, which indicates communication among entries contributors.

There are only 40 out of 247 entries which cited other entries. There are 6 entries self-cited including “contact lenses”, “regenerative medicine”, “biological solid mechanics”, “Bioregenerative Life Support System (BLSS)”, “implant denture”, and “Prostate cancer stem cells (PCSCs)”. The entry “Bioregenerative Life Support System (BLSS)” cited itself for 3 times. And there is no citation among these 40 entries. However, they cited other 618 entries. The citation network of entries is shown as Figure 1.

The entry “magnetic resonance” cited 116 entries. It cited entry “magnetic moment” for 18 times, “nuclear magnetic resonance” and “ferromagnet” for 11 times respectively, and “ferromagnetic resonance” for 10 times. The entry “cell cycle” cited 81 entries while “contact lenses” cited 62 ones, “nanomaterials” cited 59, and “color Doppler flow imaging” cited 54.
Each of “Carbon nanotubes”, “tissue engineering”, “Oral CT”, and “catheter” cited more than 20 entries. There are 8 entries which cited only one entry respectively, including “bite force”, “boneresorption”, “Biophotonics”, “respiratory quotient”, “biological solid mechanics”, “nano-biomaterials”, “stasiology”, and “respiratory mechanics”.

It is found that entry contributors put in some hyperlinks citing other related entries in order to explain the entry they were working on. Thus they searched, read, chose and cited some related information from other entry contributors. The process indicates communication among entry contributors beyond limit on time and space.

Analysis of citation among entries indicates the composition of entries online. The hyperlinks cited by the entries in the field of Biomedical Science come from other disciplines such as Chemistry, Physics, Oncology, and so forth. To some extent, it indicates cross and integration of disciplines. There are no borders within Science.

The Relationship between Online Entries and Traditional Literatures

In addition, there are references in some entries to provide readers with more related further reading materials and clues to the literature to help them access the original literature. Analysis on the references of entries is of great help to reveal relationship between online entries and traditional literatures, such as journal articles, books, conferences and so forth.

The 247 entries cited 1252 references in total, including 1026 journal articles, 133 books (monographs and teaching materials), 45 conference literatures, 18 web pages, 15 dissertations, 2 patents, and so on. There are 5 references which are internal handouts or news without clear sources.

There are 11 books that were cited by the entries more than 3 times. For example, Sport Biomechanics written by Hu(2013) was cited for 10 times. Theory and technology of Bioregenerative Life Support System by Liu(2009) was cited for 8 times. Besides, the number of books which were cited for more than 3 times is 9. There are 50 literatures which were cited twice, including 28 journal articles, 17 books, 4 dissertations, and one conference literature. It is seemed that academic journals and monographs were preferred by entry contributors because of their mature theoretical system and novel knowledge which will make the entries more scientific and reliable.

There are some entries which have the mutual references. Entry bibliographic coupling based on references is used to reveal potential relationship among entries and communication among their contributors (shown as Figure 2).
It is found that some entries are linked so closely that some small network or clusters appear. For example, some entries are about life support, including the space life support system, technology, ecosystem, and so forth. Some entries related to biomechanics are clustered, such as ankle biomechanics, hip biomechanics, shoulder joint kinematics, and so on.

The online entries are new form of knowledge but some of their roots come from literatures. It seemed that content-rich entries’ contributors had absorbed academic and scientific knowledge from journals, conferences, books, and even patents. Another way to think about it is the cited literatures’ authors transferred knowledge to these contributors. Their communication was across the time and space.

**Cooperation of Contributors**

It is found that there is no less than one contributor for each entry. Some entries only have one contributor who creates the entries. Some are results of some normal users. The others are contributed by users and experts. The co-occurrence of experts or users is considered the cooperation of them. It is obvious that cooperation is common during the contribution of entries. The cooperation may be among users or experts. It is also possible that users and experts mutually contributed to the entries. According to the historic versions of entries on Baidu Baike, it is quite easy to find out the time and the users who contributed to them. However, some entries were modified by experts without the record of details including the time, the way, and the content. It is difficult to investigate how the users and experts cooperated during the contribution though the cooperation really happened. What we can do is to analyze the cooperation among experts and cooperation among users.

**Cooperation among experts**

There are 206 entries whose contribution with the involvement of 89 experts in all. Each of them involves 1 to 3 experts. There are 96 entries which are results of cooperation of experts. Both of GuHanqing and Wan Rongxin from Tianjin Medical University contributed to 35 entries, followed by NiuWenxin from Tongji University and Fan Yubo from Beijing University of Aeronautics and Astronautics. Besides, there are 6 experts who participate in more than 10 entries respectively. There are 39 experts who only involve in one entry. The cooperation network can be drawn based on occurrence analysis of experts (see Fig.3). The affiliation of experts was analyzed. And it is found that overwhelming majority of experts preferred to cooperating with their workmate or someone who work in the same affiliation. But there are exceptions. For example, cooperation of Tongji University and the 307th Hospital of Chinese People’s Liberation Army, Peking University and Tianjin Medical University, Suzhou University and Hong Kong Polytechnic University can also be found, which break through the limitation of time and space. It is Internet and communication technology that made it true.
Cooperation among users

The historic versions of each entry, which showed the created time, modified time and participated users, were analyzed in order to find out who had contributed to the entries. The number of historic versions of the entry “contact lenses” is up to 296. There are 236 users who contributed to the entry, in which there is one user who participate the edition of this entry for 18 times.

There are 115 entries which are results of cooperation of users while 132 entries were contributed by the user named “csbme” alone. There are 1379 users who had participated in contribution of these 115 entries. The cooperation network of users (see Figure 4) is the result of analysis on historic versions of each entry. There are some active users who contributed to entries for many times and cooperated with others a lot. For example, the user named “fodaoshuangxiu(佛道双休)” participated in the edition for 441 times and cooperated with the user named “matalvshenglingshe(马他吕圣灵社)” for 315 times, with the user named “yashangyougedan(牙上有个蛋)” for 294 times. The user “baike ROBOT(百科 ROBOT)” cooperated with the user “w_ou” for 97 times, and with the user “csbme” for 68 times. It is found that the potential connection of these users is built based on the occurrence of the users of each entry. The users would participate in some edition because of their common interest in some entries. Although the users did never met one another, they mutually contributed to the entries through the online platform.
The cooperation among experts or users reveals the potential communication online, in which experts or users may not know each other, especially users’ true identity is hidden in the virtual environment. However, communication and cooperation did happen indirectly, which is different from traditional face-to-face communication. It is common interests that make people who do not know each other work together to create, modify, and perfect entries.

**Analysis on Interest of Contributors**

It is found that entries are connected with experts or users as some entries have the common contributors. Coupling analysis is used to reveal the relationship of entries which are results of common experts or users, which could also indicates the common interest of contributors.

**Common Interest of Experts**

Entries coupling analysis based on experts is shown as Fig.5. There are many clusters of entries. It is hard to master all of branches of Biomedical Science for every expert. It is said that specialist only masters his own field. Entries coupling analysis based on experts will show the relevance of these entries to some extent though the entries seemed isolated. For example, some experts (e.g. Gu Hanqing) who focused on Tissue Engineering and artificial organs contributed to the entries including “artificial skull”, “artificial skin”, “artificial kidney”, and so forth. From the related entries clustered together, branch of discipline and research hotspot could be indicated.
Common Interest of Users

Entries coupling analysis based on users is shown as Fig.6. It is a huge and complex network which is different from the network based on experts. The entry “contact lenses” is the contribution of 236 users, whose number of users is the most. There are 1379 users who contributed to the entries. It is found that the users were of multiple interests. The user “csbme” contributed the most entries whose number was up to 237. There are at least 83 users who contributed to no less than two entries. For example, the user “yangke19941112” contributed to 11 entries while “w_ou” contributed to 47 ones. It is found that the entries were collected together because of the active contribution of the users. It seemed that the users were interested in many entries in the field of Biomedical Science.

The co-contributed entries can be considered as medium which is of great importance during the communication among contributors. Each contributor expressed one’s ideas in the form
of modifying content of entries. Then others could see, think and express their own opinions by further modification. The common interested entries became the platform on which contributors expressed their views. The modification would not end until the contributors and readers were satisfied with the content. The whole process contains a number of communication activities.

**Conclusion and Discussion**

In general, there are four questions answered in the paper. The composition of related entries on Baidu Baike is analyzed with citations among entries. It is found that citations among entries involved in other disciplines beyond Biomedical Science. It is not a simple citation activity but a kind of signal of disciplinary crossing and integration, which is the main trend of modern science and technology development. The crossing and integration of disciplines is not only growth point of new disciplines, but also leads to the emergence of scientific discoveries of great importance.

The relationships between online entries and traditional literatures have been discussed based on analysis of cited references of each entry. It shows that traditional knowledge carriers such as books, journals, conference have still profoundly affect people’s communication habits. These traditional knowledge carriers are considered reliable, scientific, and reasonable.

Cooperation network is drawn to show how experts or users work together. It seems that majority of experts prefer to cooperate with someone who works in the common affiliation while cross-unit cooperation also exists. For example, experts from Peking University and Tianjin Medical University cooperated on the entry “cochlear implant technology” and “Artificial dura mater”. The experts from the Hong Kong Polytechnic University and Suzhou University collaborated on entries related to ankle movement and its mechanical function.

And coupling analysis of entries is used to reveal the common interest of contributors. The clusters of coupling entries based on experts indicate that the specialist only masters his own field while users have wide range of interests and are fired with an enthusiasm for entry contribution. The development of science does not only depend on scientists or government, but also need participation of the general public. Encouragement to users to devote to entry contribution should be attached great importance to.

However, there are still some questions which need to be answered in the future research.

*How did experts collaborate or cooperate with users during the contribution of the entries?*

According to the historic versions of each entry, the modified time and reason of users could be found out. But we could hardly find out when and how the experts interfere with the content of entries. As a result, it is very difficult to know exactly the way experts cooperate or communicate with users. Maybe the questionnaires can be conducted on the users and experts in order to investigate the process.

*What factors did affect the entry contribution? What are essential factors on communication among the contributors?*

To answer these questions, personal interviews and questionnaires should be conducted on the base of quantitative analysis which is of great help to find out the target objects. It is necessary and vital to adopt combined quantitative analysis and qualitative analysis.

*How about the entries of other fields or other disciplines beside of Biomedical Science? How about other online encyclopedia?*

The number of studied entries should be increased as 247 entries are only a drop of the ocean compared with all the entries on online encyclopedia. And the Biomedical Science entries
were analyzed. The preliminary work of data collection was conducted manually. It is necessary to develop a web crawler to pull the data from each entry. It is known that a new trend of interdisciplinary research is increasingly common. The citation among entries from different disciplines can be expected. It is necessary to collect enough data from different disciplines to reveal interdisciplinary integration behind potential relationship of the entries.

Abstract
Bibliometrics, scientometrics, and informetrics (also called the three metrics) differ in subject background but are the same in theories, methods, technologies, and applications. Analyzing their current situation and relationships can help comprehensively understand the three fields. In this study, we collect the data of the three metrics through keyword search in 2007–2016. We also compare and visualize the three metrics in terms of the distribution of publications and cooperation (recognition level), the main research topics (intellectual structure), and the reference situation (knowledge communication). Results show that the three metrics differ in the degrees of utilization and recognition but are similar in the general direction. We recommend the addition of bibliometrics in the title of the International Society for Scientometrics and Informetrics.

Keywords
Bibliometrics; Scientometrics; Informetrics; Knowledge Domain Visualization; CiteSpace

Conference Topic
The relationship and development of five metric science concepts: Bibliometrics, Informetrics, Scientometrics, Webometrics, and Knowledgometrics.

Introduction
Bibliometrics, scientometrics, and informetrics (also called the three metrics) are three related terms in metrology. These terms are used to describe similar and overlapping methodologies; however, their well-documented historical origins differ, and they are not necessarily synonymous (Hood & Wilson, 2001). The rapid progress and development of science and technology have improved the research objects, goals, and methods of the three metrics. New branches such as webmetrics and altmetrics (Egghe, 2005), and new indexes and evaluation measures including Citescore and the H index, have also appeared (Hirsch, 2005). Although these terms differ in disciplinary background and emergence time (Qiu et al., 2017), they are used in accordance with their own cognition and position, thereby causing significant confusion. There are many journals with “scientometrics” or “informetrics” in their titles exist, but few journals with “bibliometrics” in their titles exist. The International Society for Scientometrics and Informetrics (ISSI) is the most significant conference in the three metrics. ISSI contains scientometrics and informetrics in its title but has no bibliometrics. Given that confusion can harm the development and application of the three metrics (Hood & Wilson, 2001), the development of the three terms and their relationships should be examined. This study explores the current situation and relationships of the three metrics from the following three aspects: the number of published papers and cooperation (recognition level), the main research topics (intellectual structure), and the reference situation (knowledge communication).
Background

Definitions of bibliometrics
Bibliometrics methods have been applied in various forms for more than a century (Hood & Wilson, 2001). The term “bibliometrics” was first introduced by Pritchard (1969), who defined it as “the application of mathematical and statistical methods to books and other media of communication.” Fairthorne (1969) expanded the definition scope of bibliometrics by defining it as the quantitative treatment of the properties of recorded discourse and behavior appertaining to it. Then, Broadus (1987) defined bibliometrics as the quantitative study of physically published units, or of bibliographic units, or of alternatives of either.

Definitions of scientometrics
Nalimov and Mulchenko (1971) coined the Russian equivalent of the term “scientometrics” in 1969, and defined it as the quantitative study of various kinds of intelligence process in the development of science. The term has obtained broad acceptance from the journal Scientometrics, which was built in 1978. Scientometrics is a discipline that uses mathematical methods to quantify the scientific research personnel and achievements to reveal the process of scientific development, and can provide scientific basis for scientific decision making and management (Qiu et al., 2017). Scientometrics uses citation analysis and other quantitative methods to evaluate scientific research activities and thus guide the policy of science (Egghe, 2005).

Definitions of informetrics
Nacke first proposed the German term “informetrie.” By the early 1990s, the term “informetrics” obtained wide recognition. Nacke believed that informetrics is a study applied in mathematical methods for information science objects (Qiu et al., 2017). This definition is slightly one sided because it limits the scope of informetrics in information science. Tague-Sutcliffe extended informetrics to the quantitative study of any form of information; thus, informetrics is not simply a bibliographic record or any social group, or not limited to scientists (Fairthorne, 1969). This definition enlarges the research scope and content of informetrics. Qiu et al. (2017) divided informetrics into two aspects of broad and narrow senses. The broad sense of informetrics research is very broad, whereas the narrow sense of informetrics mainly uses mathematical, statistical, and other quantitative methods to study the characteristics and laws of information quantitatively.

Relationships among the three metrics
The three terms have evolved to share many of the objectives and have many methods and tools in common (Qiu et al., 2017). The three metrics refer to “component fields related to the study of the dynamics of disciplines as reflected in the production of their literature” (Hood & Wilson, 2001). The three terms often appear simultaneously, or used interchangeably by authors, such as the Second International Conference on Bibliometrics, Scientometrics, and Informetrics (now called “ISSI”). However, the terms differ in their discipline attribute; specifically, bibliometrics belongs to library and document science, scientometrics belongs to the science of science, and informetrics belongs to information science (Brookes, 1990; Qiu et al., 2017; Wang, 1998). Scientometrics and informetrics have been proposed for nearly 50 and 40 years, respectively; however, they lack their own uniform concepts that can be widely accepted by the public. Different definitions of bibliometrics also exist (Hood & Wilson, 2001). The relationship among the three metrics has long been investigated. Brooks (1990) explored the origin and interrelationship of the three metrics. Glänzel and Schoepflin (1994)
emphasized that the authors’ use of “bibliometrics” synonymously for the three metrics has resulted in chaos. Hood and Wilson (2001) analyzed the differences among the three metrics by investigating the history of the three terms through analyzing the number of papers and journals between 1968 and 2000. Wen and Qiu (2006) suggested that the three metrics belong to different superordinate disciplines; however, they have the same research objects, indicators, and methods. Some believed that the three metrics present a crossing and partial overlapping relationship, but others argued that the three metrics exhibit an inclusive relationship; for example, informetrics has many meanings and includes bibliometrics and scientometrics (Qiu et al., 2017).

Data and method
A subject or discipline is often analyzed using the literature statistics, which accesses data samples in two ways: (1) choosing the top journals or core journals in the field as the data source (Milojevic & Leydesdorff, 2013), and (2) obtaining data source through the retrieval of representative keywords (Hood & Wilson, 2001). The journals in the three metrics present great repeatability and are widely distributed. Thus, this study uses keyword research to obtain data for the comprehensive comparison of the differences among the three metrics.

Method
The current situation and relationships of the three metrics include various aspects. In this study, we analyze only three major areas: 1) the usage and distribution of the three terms on the basis of the number of publications and cooperation; 2) the research contents and intellectual structure on the basis of field topics; and 3) the knowledge communication and flow on the basis of the citation and reference. We use EXCEL and CiteSpace for data statistics and network development.

Data
We downloaded data sets comprising articles, reviews, and papers from SCI-Expanded, SSCI, and A&HCI between 2007 and 2016. Following Hood and Wilson (2001), we retrieve the literature of the three metrics using “TS = (bibliometric* or bibliometry or bibliometrical* or bibliometrician* or “statistical bibliography” or bibliometrie),” “TS = (scientometric* or scientometry or scientometrical* or scientometrician*),” and “TS = (informetric* or informetry or informetrician* or informetrie).” Finally, we combine the three search strategies to investigate the overlapping situation of the three metrics.

Result

Overall situation
The retrieval results show that bibliometrics has the largest number of publications, which is approximately four times of that of scientometrics and 20 times of that of informetrics. A large difference is found in the number of literature among the three fields in 2007–2016, possibly because of the difference in their history and degree of social recognition. In the past 10 years, the annual volume of publications on bibliometrics is higher than that on scientometrics and informetrics, the number of publications on bibliometrics has the largest increase among the three fields, the increase for scientometrics is at an intermediate level and informetrics presents the smallest increase.
**Figure 1** Search results of combining the three metrics

**Distribution of publications and cooperation**

**Number of publications in different levels**
The European countries dominate more than half of the top 10 national rankings of the three metrics, indicating that Europe is the core area of international research on the three metrics. Europe is the origin of the three fields and has a long history of research; thus, it is home to popular research institutions and experts. With regard to American countries, the United States and Brazil as the main country, the number of publications in the field of bibliometrics and scientometrics are higher than informetrics. Scientometrics has been widely explored and is highly recognized and utilized in Asia. In Oceania areas, the degrees of utilization and recognition of bibliometrics are much higher than those of scientometrics and informetrics. Regarding African countries, the number of articles on the three areas is few and the level of scientific research and production is low.

At the institutional level, universities account for the majority of the top 10 institutional rankings of the three metrics. A total of 6, 7, and 4 European institutions enter the top 10 institutional rankings of bibliometrics, scientometrics, and informetrics. This finding shows that European institutions play an important role in the three metrics. The main institutions of Asia are mostly from China. With regard to American countries, only Indiana Univ enters the top 10 institutional rankings of bibliometrics and scientometrics, and also ranks at the top in informetrics. In African countries, South Africa’s Univ S Africa ranks fourth in informetrics. This finding combined with the number of articles of South Africa shows that South Africa presents strong research strength in informetrics.

At the author level, the top 10 high-yield authors in bibliometrics mainly include Bornmann, Abramo, and Ho; those in scientometrics mainly include Groneberg, Ho, and Leydesdorff; those in informetrics mainly include Egghe, Rousseau, and Burrell. Egghe and Rousseau enter only the top 10 author rankings in informetrics.

**Cooperation network**

Author cooperation network

Figure 2 shows that seven large groups are present in the author cooperation network of bibliometrics in 2007–2016. Notably, the size of the nodes represents the number of publications of authors. D’Angelo, Abramo, Bornmann, and Ho, and other high-yield authors, have their own fixed partners and present close cooperation within the group. Some authors publish few articles but present many partnerships. For example, Waltman is in Ho’s collaboration group and has a small number of articles but has six cooperative partners in the threshold range. Moreover, Kostoff publishes few articles but collaborates with every member.
of the group. The said authors are inclined to conduct scientific research through cooperation. In general, many cooperative groups exist in bibliometrics. The internal cooperative relationship is close, collaborations between only two authors are few, and the degree of cooperation is high.

Figure 2 Author cooperation network of bibliometrics
Figure 3 shows that scientometrics presents a large cooperation group and that Groneberg is the center of the group. Leydesdorff and Bornmann are included in this group; however, the two authors locate in the extension of the group. This group exhibits an intricate connection and a close relationship. A prominent cooperative group exists, in which Ho of four fixed partners is the center. Therefore, this group has a stable partnership. Many two- and three-author groups exist. In general, the scale of the author collaboration network of scientometrics is sparse.

Figure 3 Author cooperation network of scientometrics
Figure 4 shows that informetrics has a main cooperative group, in which Egghe and Rousseau are the core, and includes Ye and Liu, among others. Egghe and Rousseau publish the largest number of articles on informetrics. The rest of the groups is dispersed. Apart from the largest group, more than 10 three- and two-author groups exist. The scale of the author cooperation network is small.
The size of author cooperation depends on two main factors: the total number of articles and the habit of research. With regard to the first factor, authors with large numbers of articles have high numbers of cooperative relationships, thereby leading to large-scale cooperation. For the second factor, some authors prefer to cooperate with other authors, thereby forming large-scale and stable cooperation. Under the same thresholds, the number of large-scale cooperative groups (more than five authors) in bibliometrics is more than that in scientometrics and informetrics; however, the group relationships of the three metrics are tight. Bibliometrics obtains the maximum number of literature and degrees of utilization and recognition. The cooperative group with Groneberg as its core in scientometrics is the largest among the three fields. The cooperative relationships among members are also frequent in the three metrics. The decentralization degree of the author collaboration network of informetrics is the sparsest among the three fields. Although its size of cooperative groups is the smallest, informetrics possesses a major group with Egghe and Rousseau as its core.

Institutional cooperation network

In bibliometrics, the connection among institutions is tight and cooperation between institutions is close. Europe is home to many research institutions, which attach great importance to cooperation in bibliometrics. Only the Chinese Acad Sci has a purple aperture in the cooperative network. Therefore, this institution presents high centrality and is an important mediator in the entire cooperative group to date. Leiden Univ, Univ Granada, Asia Univ, and CSIC exhibit many cooperative relations and publish several articles on bibliometrics. Some institutions are very successful in cooperation even if they do not publish many articles, such as Univ Amsterdam and Univ Carlos III Madrid.

The institutional collaboration network of scientometrics shows three large cooperative groups (more than five institutions). In the first group, Asia Univ and Univ Amsterdam and other high-yield organizations are the core. This group presents the largest number of cooperative institutions among other groups, but its internal cooperation is sparse. In the second group, Goethe Univ Frankfurt is the core. In the third and final group, Univ Granada and CSIC are the core. In general, scientometrics presents a large number of cooperative groups but in a small scale.

During the study period, informetrics possesses a significantly large cooperative group with Katholieke Univ Leuven and Univ Antwerp as the core. This group also includes Univ Hasselt and KHBO Assoc KU Leuven and other institutions. Notably, European institutions account for the majority of the group. Some Chinese institutions are also present in this group, such as Zhejiang Univ, Chinese Acad Sci, and Nanjing Univ. Therefore, Chinese and European institutions exhibit frequent cooperation in informetrics. Indiana Univ (American) and Dalian Univ Technol (Chinese) assume the role of intermediaries in their respective groups. Although they are excluded in the main cooperative group, their degree of cooperation is high.
In general, under the same parameter setting, the degree of cooperation among the institutions of bibliometrics is the highest, and the cooperative relationship of bibliometrics is close and of the largest scale among the three metrics. Meanwhile, the cooperative relationship of scientometrics and informetrics is dispersed. Only one to three large groups exist in scientometrics and informetrics; thus, the scale of other groups is very small. However, the scale of institutional cooperation is also affected by the total amount of literature and the habit of specific authors.

**Subject structure**

We choose the co-words analysis to explore the subject structure of the three fields. Considering the color confusion after clustering, we provide a screenshot of categories depending on the color of each node prior to labeling the category name. The latter analysis is based on the cluster name provided by Citespace. The clustering results are shown in Figs. 5, 6, and 7.

Figure 5 shows five main subjects in bibliometrics: 1) research on the general development trend and influence of bibliometric analysis; 2) research based on bibliometric indicators of the scientific research output, the ranking of universities, and the evaluation on individual academic; 3) application of bibliometrics in scientific research management; 4) research on cooperation network and model, application of text mining, and other new technologies in other disciplines; 5) the use of the H index and other indicators to analyze the citation of papers or other publications from various databases and thus evaluate the academic capability and scientific research achievements.

Figure 6 shows five main subjects in scientometrics; 1) application of scientometrics methods in biology, indicating the extensive application of scientometrics methods in other fields; 2) research on the quality of scientific research output and the research trend of scientometrics as a branch of science; 3) research on scientometrics methods (such as citation analysis and impact factors) based on journals and other research outputs, indicators (such as the H index), and their application; 4) development trend of scientific cooperation, cooperation model, and academic cooperation network based on scientific research output; 5) ranking or visualization of discipline contents, personnel, and journals through scientometrics methods, as well as research on the development trend of disciplines.
Figure 6 Subject structure of scientometrics

Figure 7 shows five main subjects in informetrics; 1) research and application of the H index and other new metrics in network environment, as well as research on information systems; 2) research on the influence of articles and authors on the basis of informetrics methods and citation analysis; 3) research on the distribution and ranking of high-impact articles, authors, and journals based on the H index, as well as research on the model of informetrics; 4) research on the development of informetrics and its relationship with bibliometrics and scientometrics; 5) effect of network environment on the patterns of scientific research activities.

Figure 7 Subject structure of informetrics

According to the keyword frequency, “science,” “citation,” “impact,” “Journal,” “citation analysis,” “H index,” and “impact factor” rank among the top 10 keywords in the three areas. Therefore, the three fields are concerned on the research and evaluation of the influence of scientific research output. Most studies use the citation analysis method and pay attention to the innovation and application of indexes.

In summary, the three metrics focus on evaluating scientific research output and investigating the innovation and application of indexes (such as the H index) and the cooperation mode and network. Bibliometrics focuses on exploring the development trend and research on the application of bibliometrics in scientific research management. Scientometrics focuses on exploring the application of its methods and techniques in other areas, the development of citation analysis and other methods, and the quality of scientific research output and development trends. Given that information is highly dependent on computer technology and
mathematics, informetrics focuses on examining information system and the combination of mathematical models and methods.

Citation situation—Mainly based on document co-citation network
According to the document co-citation network, the knowledge structure of bibliometrics includes five components. Scientometrics is composed of six knowledge bases. Given that three of these bases have the same theme (but different direction), we merge the three identical parts into one. Finally, four components are obtained. The knowledge base of informetrics consists of five parts. The connection between nodes in the graph represents the citation relationship between the documents; the node with the purple aperture represents its high important, and the size of the node represents the cited frequency. We compare the three metrics on the basis of the cited literature with high centrality and high cited frequency. According to the specific literature list, Hirsch’s *An index to quantify an individual’s scientific research output* and Egghe’s *Theory and practice of the G index* are important documents in the three fields. The two articles have been used as the bases for the study on the H index in bibliometrics and scientometrics. Meanwhile, Hirsch’s article has also been used as the basis for the study on evaluation and ranking in informetrics. Therefore, the same literature is used in different angles in dissimilar fields. Hirsch (2005) proposed the H index to evaluate the academic influence and the research level of researchers; this document is the first of the branch. Egghe (2006) proposed the G index in 2006 to overcome the shortage of the H index, and used the former index to measure the overall citation performance of a group of articles. The H index is the common knowledge base of the three areas, which indicate that the three metrics have attached importance to research on the innovation and application of evaluation indicators.

As shown in Figure 7 and Table 1, #0 research trend, #3 scopus, and #4 gender disparity are peculiar knowledge components of bibliometrics. #0 research trend involves the review on the history of each specific research direction and the future prediction under the premise of innovation of indicators and progress of research methods. Alonso et al. (2009) studied the H index and the subsequent derivative index, and measured the application of the H index in different fields. Bornmann and Daniel (2008) conducted a review of scientists’ citation behavior and analyzed the motivations, impact factors, and trends of the citation. #3 scopus presents diverse data sources in the context of the development of network; in this part, researchers focus on emerging data search tools and their data coverage, search capabilities, and the impact of scientific research (Meho & Yang, 2007; Falagas et al., 2008). #4 gender disparity is the part wherein researchers in medicine evaluate the academic productivity and influence of researchers using the H index to study whether the gender differences can lead to differences in academic productivity (Eloy et al., 2012).

![Figure 7 Literature citation figure of bibliometrics](image-url)
As shown in the document co-citation network and the specific literature list of scientometrics, #1–4 scientometric approach and #5 scientometric are peculiar knowledge components of scientometrics. #1–4 scientometric approach is the basis of two research directions. King measured (2004) the status and influence of national scientific research with scientometrics methods, and Moed (2005) explored the application of citation analysis in scientific evaluation. The two documents provided an empirical basis for the application of scientometrics methods in the scientific evaluation. Konur applied scientometrics methods to the quantitative research in biochemistry, and this document provided the knowledge base for the application of scientometrics methods to different fields. #5 scientometric mainly contains the scientific basis of visualization technology and social network analysis in scientometrics. Chen (2006, 2010) developed CiteSpace, which is an important visualization tool for studies on subject topics and trends, and its functions are constantly optimized and improved to date.

As shown in the document co-citation network and the specific literature list of informetrics, #0 ranking, #2 pagerank, and #4 Lotkas law are peculiar knowledge components of informetrics. #0 ranking is mainly based on the articles of Hirsch (2005) and Braun et al. (2006), who studied the assessment and ranking of academic impact on individuals and journals using the H index, thereby establishing the foundation for the innovation and application of indicators in ranking and evaluation of scientific research. #2 pagerank is the part wherein Ding (2009) studied factors that affect the ranking of the PageRank algorithm, and proposed the weighted PageRank algorithm. The study provided experience for the further application of the PageRank algorithm in informetrics. #4 Lotkas law is the part wherein the basic knowledge theory is comprehensively explored and the mathematical model is applied to the theoretical hypothesis.

## Discussion and Conclusion

We retrieve the literature (such as articles, reviews, and proceeding papers) on the three metrics from SCI-Expanded, SSCI, and A&HCI using the three terms between 2007 and 2016. The results show that the three metrics differ in the degrees of utilization and recognition but are similar in the general direction.

1) Recognition. Combining the number of articles in national and institution levels shows that Europe is the core area of the three fields. The degrees of recognition of bibliometrics and scientometrics are high in America. The degree of recognition of scientometrics is higher than that of the two other fields in Asia, and the degree of recognition of bibliometrics is much higher than that of the two other fields in Oceania. The degrees of recognition of the three fields are low in Africa, but the degree of recognition of informetrics is high in South Africa. Bibliometrics is the most frequently used and has the largest degree of increase among the
three terms, so we think that the term "bibliometrics" can be used as a general term for "scientometrics" and "informetrics" in order to avoid confusion in terms.

2) Cooperation. Universities are the main institutions in the three metrics. The scale of the cooperative group of bibliometrics is larger than that of scientometrics and informetrics, and the group relationships of bibliometrics are tight. Many two-author cooperative groups with scattered scale exist in scientometrics. The author cooperative network of informetrics is the sparsest and has the smallest scale among the three metrics. Bibliometrics has the highest degree of institutional cooperation and the largest scale of institutional cooperation network. On the contrary, the cooperative relationships of scientometrics and informetrics are dispersed, and the size of the group is small.

3) Subject structure. Bibliometrics attaches great importance to the development of itself and the application of bibliometric methods in scientific research management. Other disciplines use scientometrics when applying metrological methods, such as citation analysis. Scientometrics emphasizes the quality of scientific research output and focuses on research on scientometrics development trends. In the network environment, researchers prefer to use informetrics when researching information systems and the combination of mathematical models and informetrics methods.

4) Knowledge base. A significant difference is found in the knowledge base of the three metrics. The H index is the common knowledge base of the three fields in focusing on innovating and improving indicators. The peculiar knowledge bases of bibliometrics include review on the history of each specific research direction, data coverage and search capabilities of emerging data search tools, and application of bibliometrics in the medical field. The peculiar knowledge bases of scientometrics include the application of scientometrics methods in scientific evaluation and other disciplines, such as visualization techniques and social network analysis. The peculiar knowledge bases of informetrics include comprehensive exploration of the basic theory of and research on the PageRank algorithm.

This study presents a few limitations. The overall situation of the three metrics can be accurately compared using long data period. However, this study uses only the data from 2007 to 2016. Although we carefully refine some terms and construct a document retrieval formula, the data collection is still incomplete and thus cannot fully represent the data for the three metrics. The current situation and relationships of the three metrics include various aspects, but this study focuses on only three major areas. Therefore, the comparative analysis is insufficient. Future research can conduct interview with experts, extend the data period, perform in-depth content analysis, and use other methods in comparing the relationships among the three metrics.

Abstract
This paper reports preliminary findings of an ongoing project on the assessment of the performance of think tanks (TTs) in sub-Saharan Africa. The purpose of this paper was to investigate the performance of the TTs on the web through the webometrics analysis of their websites. In crawling the websites of the TTs, using the SocSciBot crawler, the study found that a sizable number of TTs in sub-Saharan Africa do not have their own websites; TTs in South Africa performed much better in terms of web pages and web links than the TTs in the rest of sub-Saharan Africa; South African TTs provide compact interlinkages as opposed to those in other sub-Saharan African countries; although there were positive correlations between in- and out-links, the relationship was not significant; the external links largely targeted organizations (.org) and commercial companies (.com); subjects or topics reflected in the external links included business, women, agriculture, politics, law, youth, climate, economy, climate change, development, growth, jobs, peace, budget, democracy, partnership, security. The study has major implications as far as the web presence, reach and impact of TTs as well as their performance and accountability are concerned.

Conference topic
Think tanks construction and evaluation

Introduction
The role and value of think tanks (TTs) in socio-economic development as well as shaping policies in political and governance arenas in developing economies such as those in sub-Saharan Africa cannot be overemphasised (Abelson 2000; Johnson 2009; Mbabazi, MacLean & Shaw 2002). Mbabazi, MacLean and Shaw (2002) have observed that TTs have emerged in Africa as major producers of the literature on the political economy of violence. The authors argue that, in by so doing, the TTs have helped to explain the link between African conflict to the “imperatives of production and consumption in relation that juxtaposes Africa’s political institutions and cultures with international and global economies”. The role of TTs is more pronounced in linking knowledge to government policy or policies effecting civil societies in which the TTs are located. McGann (2015: 6) puts it thus: “across both developed and developing countries, governments and individual policymakers face the common problem of bridging expert knowledge to bear on government decision-making. Policymakers need reliable, accessible, and useful information about the societies they govern.” Simply put, TTs exist solely to support self-sustaining economic, social and political progress of all regions of the world for public good (McGann 2015). There has been a rapid growth in the number of TTs in the world, while the scope and impact of TTs’ work has equally expanded, just as has their potential to support and sustain democratic and civil societies (Krastev 2008; McGann 2015: 9). In Africa, TTs are viewed as agents of shaping the African futures because “they can be used to influence and inform public policy in real time and space” (Mbadlanyana, Cilliers & Sibalukhulu 2011: 65). TTs draw their strength from their ability to act as a bridge between the academic and policymaking communities (Mbadlanyana, Cilliers & Sibalukhulu 2011: 65).
Yet, as recently as 2000, Stone (2000) noted that policy research institutions and TTs were a neglected phenomenon in the social science literature. TTs in Sub-Saharan African are said to be challenged on several fronts, some of which are weak financial base and dependence on donors (especially foreign ones) and human resource challenges, which include inadequate policy analytical expertise in the staff, too few people with management expertise, stiff competition for a small pool of competent and committed staff, lack of opportunities for training core staff in areas of operations, high staff turnover, and a lack of international exposure among staff (Johnson 2009: 486). Johnson (2009: 486) further explains that TTs in sub-Saharan Africa suffered from a dilapidated and an underdeveloped state of infrastructure, especially in the area of telecommunications. Johnson (2009) noted that, by 2009, African think tanks not only were difficult to reach by phone, they also had very limited access to or presence on the Internet … only two groups outside of South Africa had their own websites by then. Mouton (2010), too, has reiterated the absence of sub-Saharan Africa’s research institutes, centres and networks on the World Wide Web. By the time of publishing his findings in the UNESCO report in 2010, Mouton (2010) found that only 53% of the institutions had active websites, but hastens to clarify that “active” websites did not necessarily mean that the content on the websites was current. Mouton (2010) further has vividly captured the unfortunate state of research institutions (including TTs) in sub-Saharan Africa by observing that the institutions hardly receive any government support, with the exception being the Human Sciences Research Council (HSRC) in South Africa.

### Problem statement and purpose of study

The problem statement for the current study is threefold. Firstly, we have noted that the Webometrics Ranking of Research Centres (WRRCs) (Cybermetrics Lab 2015) does not cover all TTs in sub-Saharan Africa, most probably due to the nature of some of the TTs which may not be considered as research centres. Secondly, the Think Tanks and Civil Societies Program (TTCSP) at the University of Pennsylvania ranks TTs according to a number of variables such as influence, output and impact. The ranking system does not consider one of the variables that have increasingly become valuable in assessing the performance of institutions, namely the web-based indicators, for example, web presence, visibility and impact (Aguillo 2009; Aguillo, Ortega, Fernandez & Utrilla 2010; Kenekayoro, Buckley & Thelwall 2014). It is widely acknowledged that the Web has increasingly become one of the essential tools with which not only organizations market themselves but communicate their research and share their policy documents thereby influencing policy changes in their respective countries or geographical context (Thelwall, Klitkou, Verbeek, Stuart, & Vincent 2010). Finally, sub-Saharan Africa is home to a large number of TTs, yet it is one of the least investigated regions by scholars in terms of the TTs’ performance on the Web.

### Purpose of the study

The purpose of this study was therefore to assess the Web visibility and reach of think tanks in sub-Saharan Africa through webometrics means. The study investigated the number of pages, outlinks and inlinks as well as the content of the links and pages in order to gauge the performance of the TTs in sub-Saharan Africa on the Web.

### Methods and materials

The study adopted a webometrics approach to investigate the presence, visibility and impact of think tanks (TTs) in sub-Saharan Africa on the World Wide Web, simply and hereafter referred to as the Web. A list of the TTs, as provided in Appendix A, was obtained from the 2014 Global Go to Think Tank Index Report, prepared by James McGann (McGann 2015: 1520).
The list contained a total of 91 TTs for sub-Saharan Africa. All TTs were included in this study for investigation. Once the TTs were identified, a Google search for their official websites was conducted to obtain the URLs (Uniform Resource Locator), or simply put, the web addresses which were in turn used to crawl the web for data. A total of 66 TTs were eventually selected for the study as these are the only ones that owned websites. The SocSciBot web crawler was used to obtain data from the TTs’ websites. According to the developer of SocSciBot, Mike Thelwall, the “SocSciBot, like any web crawler, works by recursively requesting web pages. It extracts URLs from the HTML of web pages and repeats the process with each new URL found” but is limited in that it does not “check for pages duplicated across different sites” (Thelwall 2015a). As Thelwall (2015b) observes, the limitation only becomes an “issue if a site crawled contains a large mirror site” (Thelwall 2015b: 14). The search for each of the TT’s web data was conducted in the months of July to September 2016. The search limits were set as follows in order to extract relevant data: (a) the number of URLs to crawl was set to a maximum of one million; and (b) the URLs with question marks were omitted.

Data analysis was conducted using the analyse links with SocSciBot tools option that is embedded in the crawler. The analysis generated the following files that contained pertinent data for the current study: ADM count summary (which provided standard link counting data); all external links (a list of URLs targeting pages outside of each site, i.e. site outlinks); all links with counts (a list of all links that match the current project options and accompanied with link counts); directory interlinking (the number of links, counted directory by directory, i.e. the number of pairs of directories with a link from the first to the second directory [directory ADM]); domain interlinking (the number of links, counted domain by domain, i.e. the number of pairs of domains with a link from the first to the second domain [domain ADM]); file interlinking (the number of links, counted page by page, i.e. the number of pairs of pages with a link from the first to the second page); page and link counts (the number of pages in each crawl; and the number of links found in the web pages of each crawl).

In addition, the crawler provided some information that was used to discuss the findings obtained in the above outlined files. This additional information included:

- Selected external links with counts (a list of links, with counts, from each site to the other sites crawled, excluding self-links)
- Unselected external links with counts (a list of all links, with counts, from each site to other sites except the crawled sites).

The analysis tool also produced a map of the file and domain interlinkages among the TTs. The map was prepared and produced using the Pajek software. Finally, the most common words within the links were analyzed using the VosViewer software and visualized on a map to reveal the content of the web linkages amongst the TTs.

**Results and discussions**

**Number of pages and outlinks**

Collectively, the TTs that were under investigation in this study produced 3.3 million pages, which have had over 140 million outlinks by September 2016. The TTs that yielded over 500 thousand pages included the *African Centre for the Constructive Resolution of Disputes* (ACCORD), which yielded approximately one million pages that accounted for 30% of all the number of pages of TTs in sub-Saharan Africa; *South African Institute of Race Relations*
[IRR] (915 213 pages, 27.58%); Economic Policy Research Centre [EPRCU] (740 454 pages, 22.32%); and Afro-Middle East Centre [AMEC] (514 486 pages, 15.51%). In terms of the number of outlinks, the four institutions yielded the most. Collectively, they had 136 million outlinks, which constitutes approximately 97.16% of all outlinks. Among the top TTs in terms of the number of pages, the Free Market Foundation [FMF] yielded the highest number of outlinks per page (i.e. 72.47) followed by the Ethiopian Economics Association (62.19), AMEC (60.59), EPRCU (57.49) and the United Nations Economic Commission for Africa [UNECA] (56.31). The analysis of the correlation between the number of web pages and outlinks yielded a positive Pearson correlation coefficient (r) of 0.926 (where N = 66), which was significant at p \leq 0.01.

**Table 1: Number of pages and links per TT in sub-Saharan Africa**
