**Inlinks to TTs in sub-Saharan Africa**

Inlink counts refer to the number of links to each site crawled from the other sites crawled in the same project. The inlinks are often used to depict “sitations”, which is used as equivalent of citations in scholarly publishing. As Xing & Chu (2006: 3) explain, “content-based hyperlinks are commonly regarded as bibliographic citations or citations in short”. The term *sitation* was coined by Rousseau in 1997 (Rousseau 1997). Various authors (e.g. Bar-Ilan 2010; Prime, Bassecoulard & Zitt 2002), too, have likened hypertext links to citations. As a result, the TTs’ inlinks in this study reflected the web impact of the TTs. Table 2 provides the inlinks to the TTs’ web pages, directories, domains or sites from each other. The most inlinked TT in terms of page inlink counts was FMF, which received a total of 2890 page inlinks. The Foundation also received 1207 directory inlinks, 2 domain inlinks and 2 site inlinks.
inlinks. The rest of the TTs received less than 500 page inlinks and/or directory inlinks from the other TTs.

Outlinks of the sub-Saharan African TTs

Outlink counts refer to the number of links from each site crawled to other sites crawled within a given project; outlinks are the opposite of inlinks. Outlinks are like references or in-text citations in scholarly publications whereby the website offering outlinks is likened to a citing publication (Bjorneborn & Ingwersen 2001: 65). Table 3, which provides the number of outlinks for each TT that produced at least one (1) site outlink, shows that the IRR yielded the highest number of outlinks to the rest of the TTs covered in this study. The number of IRR’s page outlinks was the only one that surpassed two thousand outlinks while the rest of the TTs posted less than one thousand page outlinks each. The number of domain and site outlinks was highest in Food, Agriculture and Natural Resources Policy Analysis Network (FARNPNAN) of South Africa.

</table>

**. Correlation is significant at the 0.01 level (2-tailed).
In order to assess the relationship between the TTs’ in- and out-linking patterns, a correlational analysis of the number of inlinks and outlinks was performed using Pearson correlation analysis (embedded in the SPSS software) and yielded the results in table 4. Whereas there were high scores of correlation between the page and directory inlinks, there were mixed patterns of linking domains and sites. Strong and significantly correlated relationships occurred between page inlinks and directory inlinks ($r=0.970$), domain inlinks and site inlinks ($r=0.847$), page outlinks and directory outlinks ($r=0.969$) and domain outlinks and site outlinks ($r=0.911$), all at a significance level of $p \leq 0.01$. The majority of the relationships were either negatively or positively correlated but not significant at $p \leq 0.01$. The strongly correlated relationships were between two-like variables, that is, an inlink against another or an outlink against another. Relationships between inlinks and outlinks were either weak or very weak (i.e. $r$ was between $\pm 0.001$ and $\pm 0.299$ at $p \geq 0.01$).

Table 5 shows the number of file links originating from one site to another. The file interlinking patterns reveal that the IRR had 2889 outlinks to FMF while the outlinks from IPSS to IPSS were 461. The other top ranking file interlinking patterns were as follows: ACCORD to ISSAFRICA (260), FANRPAN to FANRPAN (185) and ATPSNET to ATPSNET (114). Three of the aforementioned file interlinkages were self-links, while only two were external links. The rest of the file interlinks were external links, that is, from one crawled site to another crawled site within the project. In considering the outlinking and inlinking countries (i.e. countries from which the links originated to the countries to which the links are directed), we observed that there were some cross-border interlinkages as shown in table 5.

In terms of country-to-country interlinkages, South Africa (ZAF) provided links to seven countries as follows, in the order of number of outlinking TTs; number of links: Angola [AGO] (1; 185), Ethiopia [ETH] (2; 21), Botswana [BWA] (1; 2), Kenya [KEN] (3; 4), Nigeria [NGA] (1; 2), Tanzania [TZA] (1; 2), and Ghana [GHA] (1; 1). Tanzania’s outlinks were directed to ZAF (3; 100), ETH (1; 2), and GHA (1; 1). Somalia (SOM) had two file links to KEN while Kenya’s fourteen file links targeted ETH (1; 5), SOM (1; 1), South Sudan [SSD] (1; 3) and ZAF (1; 5). Ghana provided twenty two file links from one TT to ZAF. On the part of Ethiopia, three TTs received a total of five links while BWA provided one file link to ZAF. It was also observed that some branches of some of the TTs provided links to the parent or other branches across the boarders (e.g. FANRPAN in Angola which provided 185 links to South Africa’s FARNPAN).

In-country (i.e. file links within the same country) file interlinkages occurred in the following countries in the order of number of TTs and number of links: ZAF (9; 3157), TZA (1; 114), and ETH (4; 467). Similar patterns were witnessed in the directory and domain interlinkages, although there were differences in the volume of links whereby directory and domain links were fewer than the file links. If the inlinks within the same country is a reflection of the recognition of each TT by another, then the patterns of interlinking among the TTs imply that some TTs within some countries have no recognition of one another as there were no links between them. South African TTs were the most interlinked.

Networking of TTs in sub-Saharan Africa

Figure 1 shows a single network map, combining files on the websites of the TTs investigated in this study. The network map was developed using the Pajek software. The key players in the huge clusters marked A to H are the FMF (clusters A, B, and C). The files or pages that recorded the most number of outlinks belonged to the FMF. The files provided the most number of outlinks as follows: freemarketfoundation.com/view-event?1=107 (352); freemarketfoundation.com/view-event?1=103 (350); freemarketfoundation.com/view-event?1=104 (350); freemarketfoundation.com/view-event?1=105 (349); freemarketfoundation.com/view-event?1=111 (322); freemarketfoundation.com/view-event?1=100 (350); freemarketfoundation.com/view-event?1=95 (335). The rest of the pages provided less than 100 file links each.

Figure 1. Network map for TTs in sub-Saharan Africa

Most targeted sites by sub-Saharan African TTs

The external links, as explained in the methodology section, consists of a list of URLs targeting pages outside of each site. The links are rich in information which can point out the type of information that exist outside their own websites and which TTs deem to be important and valuable for their users. The URLs can partially provide the link analysers with information on the factors motivating web developers to provide links to external websites. Table 6 provides the list of the sites with the most number of links from the TTs’ websites. These links are targeting website developers (e.g. juizi.com), social networking sites (Facebook, LinkedIn, Twitter and YouTube), information access tools (e.g. online public access catalogue – OPAC), information databases (e.g. SABINET – South Africa Bibliographic and Information Network), and electronic e-mailing systems (e.g. mail.google.com), and more. All in all, a total of 5 047 772 external links were targeted by the sub-Saharan African TTs.

The network map, which was generated using the list of unselected external links, provides a partial revelation of the words that occurred twice or more in the hypertext links. There were 303 items that met the threshold. The words generated 121 clusters with 454 links and a “total link strength” of 551. A closer look at the top-level domains that were the most targeted shows that the .org (organization) was the most visible target with 418 occurrences, followed by .com (76) and .net (57). The presence of html, pdf and doc reveals the type of documents.
that have received links from the TTs while the regional names such as South Africa, Libya, Tanzania and Africa provide a glimpse of the type of geographic context of the type of information that is targeted by the TTs. The words publications, report, book, paper and articles as well as news and stories are some of the channels of information that are deemed important and therefore constitute the sources of information as well as channels of information dissemination for TTs and their targeted audiences. Examples of words that were indicative of the topics that were most regarded by the TTs, in the order of their frequencies of occurrence, include: business, women, agriculture, politics, law, youth, climate, economy, climate change, development, growth, jobs, peace, budget, democracy, partnership, security, and statistics, just to name those terms that occurred five or more times.

Conclusions and recommendations

The paper sought to assess the performance of TTs in sub-Saharan Africa on the Web. It was encouraging to note that the number of TTs that own websites in sub-Saharan Africa has
increased from 50% in 2010 (Mouton 2010) to 72.5% in 2016. Sadly, however, a sizable number of TTs, accounting for approximately 30%, still do not own websites. The institutions are likely to lose out on the benefits associated with the Web. Given the immense benefits associated with institutional presence and participation on the Web and other Internet-based applications such as social media technologies, and whereas the ranking of institutions has witnessed a paradigm shift whereby web presence, reach and impact are key indicators in the ranking systems, it is strongly recommended that the TTs which have not developed their own websites do so. The institutions’ Web presence may enhance their accountability status, both to the sponsors (e.g. government) and to the public.

Although the Think Tanks and Civil Societies Program (TTCSP) at the University of Pennsylvania highly ranks some of the TTs in sub-Saharan Africa, for example CODESRIA, the current study found that some of these TTs are not performing well on the Web in terms of the number of pages and even links. This pattern can be attributed to the language in which some of the websites are constructed and/or poor design of the affected TTs’ websites. Thirteen of the 91 TTs’ websites are constructed in a language other than English, a situation that might be limiting their Web visibility, reach and impact. For instance, it was noted that the most highly ranked TT whose website was constructed in non-English language was in position 28; all the top 27 positions were occupied by TTs whose websites are constructed in English language. Furthermore, the Webcrawler used to extract data from the websites did not recognize some pages and URLs, hence the poor performance of some of the TTs. Poorly designed and constructed websites may cause disasters to many organizations (Ahmad, Li & Azam 2005). The disasters may be in terms of loss in potential sales (Lu, Deng and Wang 2007). The TTs may be disadvantaged when it comes to the global ranking of institutions. It is therefore imperative that only professional web designers should be engaged to design and develop websites for TTs.

The analysis of the inlinks and outlinks demonstrates a limited activity among most TTs in sub-Saharan Africa. Only 24 and 21, out of the 66 TTs whose sides were crawled, received or provided links from and to one another, respectively. The number accounted for less than 40% in each case (i.e. inlinks and outlinks). This pattern may be taken to imply that there is limited knowledge sharing among the TTs. However, given that the web links alone cannot be an absolute indicator of the extent of knowledge sharing among institutions on the Web, there is a need for a study to investigate collaboration (including research collaboration) among the TTs in sub-Saharan Africa. Such a study will unearth the patterns, type and nature of collaborations among the TTs, a situation that may inform decisions on the management of TTs in the region. A content analysis of the internal links (links between pages in a site) nevertheless revealed that the most common usage of the sites lies in the organization of events (e.g. freemarketfoundation.com/view-event), publication and dissemination of documents (including reports), and showcasing the services offered by the TTs.

The file links in table 5 demonstrates a preference for in-country linkages (links among TTs in the same country) while links to external sites (links to sites outside Africa) was equally prominent (see table 6). There are minimal inter-country linkages in sub-Saharan Africa. This pattern follows the patterns of research collaboration whereby “internal” (within same institution or country) and foreign collaborations (between African and foreign countries) have been reported (see Onyancha & Ocholla 2007; Onyancha & Maluleka 2011; Narvaez-Berthelemot, Russell, Arvanitis, Waast, & Gaillard 2002; Sooryamoorthy 2009). Similar findings, whereby African-based institutions provide or receive links from or to institutions within the same country as well as provide links to institutions outside Africa,
have been reported in Onyancha (2007), Onyancha and Ocholla (2008) and Sooryamoorthy (2009).

The external links largely belong to institutions (mainly companies, organizations or networks) that offer essential services (e.g. web design, e-mail services, or social networking) or information (e.g. news). The TTs in Africa have paid little attention to their counterparts in the world as exhibited to the absence of even one TT based in a foreign country in table 6. This scenario may be attributed to lack or minimal contact or collaboration between the African-based TTs and their counterparts in the rest of the world. Finally, the content analysis of the hypertext links reveals the main areas of focus by the TTs (see Figure 2). It will be interesting to find out if these areas correlate with the research areas focused on by the same institutions in the region. A study of the subject content of the research publications is therefore recommended to unearth the relationship between the content of the hypertext links and research.

Bibliometrics to Knowledgometrics: Theory Method and Principle of Metrics Science

S.L. Sangam
Visiting Professor DRTC Indian Statistical Institute, Bangalore
Formerly UGC Emeritus Fellow
Dean Faculty of Social Science
Professor and Chairman
Department of Library and Information Science
Karnatak University, Dharwad – 580 003
E-mail: slsangam@gmail.com

Abstract
The terms librametry, bibliometrics, scientometrics, informetrics, webometrics and knowledgometrics refer to fields related to the study of the dynamics of disciplines as reflected in the production of their literature. These terms are used to describe similar and overlapping methodologies. The origins, historical survey, scope, application and development of each of these terms are presented in this paper.

Keywords: Bibliometrics, Scientometrics, Knowledgometrics

Conference topic: The theory method and principle of five metrics science concepts.

Introduction
In recent days, statistics has been applied to a number of areas such as perspective planning, industrial and agricultural development, etc. Library and Information managers have adopted a number of quantitative methods in order to evaluate library resources and services more objectively and effectively. Scientometrics/ Informetrics refer to quantitative techniques applicable to measure the records of human communicated literature. Over the years, several new terms have appeared on the horizon representing quantitative studies in library and Information Science.

The History of comparative Anatomy Part-I: A Statistical Analysis by Cole and Eale (1917) is considered to be the first bibliometric study in 1917. Hulme (1923) was the first to use the expression ‘statistical bibliography’ in 1923; later several studies have been conducted. Gross and Gross (1927) study is considered to be the third study in the field based on citations. After Hulme, the term statistical bibliography was used by Henkle in 1938 in his article “The periodical literature of Biochemistry” and Gosnell (1944, 1943) in his dissertation in 1943, and later in his article 1944. The historical development of the term statistical bibliography has been traced by Witting (1978) in a foot note. As the term was considered very clumsy, not very descriptive, and can be confused with statistics itself or bibliographies on statistics.

Librametrics
In 1948 at the Aslib’s (1949) conference in Lamington Spa, Ranganathan introduced the term Librametry for the first time. He suggested to develop librametry on the lines of biometry, econometry, and psychometry. His suggestions were avidly welcomed at the conference by Bernal and others. The term Librametrics has two roots: Libra and
**Metry.** The word ‘Libra’ connotes ‘library’ and ‘metrics’ means measurement. Further, as the librarian of the Madras University Library, he practiced various librametric techniques way back in 1925, in order to solve day today library problems and to streamline the day-to-day library activities, services for their clientele and also for the betterment of library professional as a whole.

The scope of the library is limited to the quantitative study of books, readers and staff. Here the books, readers and staff are the three constituent elements or factors of the library. The absence of any one of the three will make the library cease to exist. Each has its own potentiality and it is only a sum of the three that makes a library. Thus we can measure all the Characteristics of books, readers and staff.

Ranganathan (1969) in his paper presented in the DRTC 7th Annual Seminar (1969) suggested a few examples of statistics to library science. Based on his experience and the experiments carried out at the Documentation Research and Training Centre outlined the applications for Librametrics:

1. Determination of the strength of library staff;
2. Disposition of library staff for circulation work during different library hours;
3. Disposition of library staff for reference service during different library hours
4. Organization of Library System; Establishing the distinction between “service library” and “dormitory library”;
5. Design of library building, fittings, and furniture;
6. Book selection;
7. Absolute syntax and facet syntax in relation to classification;
8. Length of class number; and
9. Variation in style in writing catalogue entries; and

The librametrics studies if developed properly as suggested by Ranganathan could become a good indicator for measuring various activities of librarianship both quantitatively and qualitatively. It is therefore imperative on the professional schools of library and information science to incorporate Librametrics as a foundation course. Such a step would help us to have an objective as systematic approach to the field of library and information science.

**Bibliometrics**

The term bibliometrics was first coined by Prichard (1989) in 1969 in preference to existing terminology ‘statistical bibliography’. The word “Bibliometrics” has two roots: ‘biblio’ and ‘metrics. The term ‘biblio’ is derived from the combination of Latin and Greek word ‘biblion’ equivalent to Bylos, meaning book, paper which in turn was derived from the word Bylos, a city of Phenonicia, a noted city for export trade in paper. The word ‘metrics’, on the other hand, indicates the science of meter, i.e., measurement and is derived either from Latin or Greek word ‘metricus’ or ‘metricos’ respectively, each managing measurement. This term was coined for the first time by Alan Pritchard. He used the term to describe all ‘studies which seek to quantify the process of written communication’. Fairthorne (1969) also defined it as 'the quantitative treatment of the properties of recorded discourse and behaviour pertaining to it.'
Bibliometric studies include studies of the growth of the literature in some subject, how much literature is contributed by various individuals, groups, or organisations or countries; how much exists in various languages; how the literature on some subject is scattered (e.g., over documentary types, language journals); and how quickly the literature on some subject becomes out-of-date (Studies of obsolescence). Another important group of bibliometric studies relates to what sources author cite. Day-by-day this study is attaining sophistication and complexity, having national, international and inter disciplinary character. The backbone of Bibliometrics lies in its sound theoretical foundation most effectively laid by some pioneers like Lotka (1926), Bradford (1934), Zipf (1949), Duck J de Sola Price (1963), Bookstein (1976), Mandelbrot (1952), Brookes (1968,1969a,1969b,19905), Garifield (1976a, 1976b), Egghe (1990) and many others, and their techniques are capable of throwing light on various complicated problems faced by information scientists to quantify the process of written communication. The bibliometric tools can be applied to

1. Studies related to scattering of articles
2. Geographical distribution, language-wise distribution, institution-wise distribution of articles
3. Age distribution of documents
4. Use of information storage and retrieval
5. Application, in the library use studies.
6. To study the trends in research and identifying the growth of literature.
7. To identify authorship trends in documents on various subjects.
8. To measure the utility of library services
9. To evaluate the library collection, etc.

These definitions of librametrics and bibliometrics show that librametrics primarily aims at the quantitative analysis of the management of libraries and bibliometrics is limited to recorded knowledge. The publication in both the fields suggests that in librametrics and bibliometrics, one examines the statistical distributions of the processes relating to the utilization of documents, Library staff, and Library users, to establish a theory for the structural aspects of library. Bibliometrics and librametrics may therefore be commonly defined as areas in which one studies ‘information processes and information handling in libraries and information centres by quantitatively analyzing the characteristics and behaviour of documents, library staff, and library users.’

Scientometrics

In the 1960s, particularly in Eastern Europe, the term “scientometrics” was used to denote “measurement of informatics process.” The term informatics was then widely used to mean “documentation / information handling activities;” obviously, there is not much difference between bibliometrics of the West and the scientometrics of the East Europe. The term Scientometrics originated as a Russian term for the application of quantitative methods to the history of science, which studies the quantitative aspects of science. It was suggested by Dolrov and Kormoni (1969), often used with same meaning as the bibliometrics to mean ‘the application of quantitative methods to history of science’. This term came into prominence with the founding of the journal
named ‘Scientometrics’ by T. Braun in 1977, originally published in Hungary and currently from Amsterdam, The Netherlands. Scientometrics used to mean communication process in science including socio-cultural aspects, and appears to be almost synonymous with science of science with more stress on its quantitative aspects. It is also used as a generic term for a system of knowledge, which endeavours to study the scientific (and technological) system by using a variety of approaches within the area of science and technology studies. Scientometrics is concerned with the quantitative features and characteristics of science and scientific research. Emphasis is placed on investigations in which the development and mechanism of science are studied by statistical mathematical methods. Scientometrics is now considered as a part of the sociology of science and is applied to science policy making. Thus Scientometrics involves studies in:

1. Sociology of Science,
2. History of science,
3. Growth of literature
4. Behaviour of of scientists,
5. Science indicators.

Derek John de Solla Price (1963) was treated as the father of scientometrics. He was a physicist, a historian of science, an information scientist and worked as a teacher of applied mathematics at Raffles College (which was to become part of the University of Singapore in 1948). It was there that he formulated his theory on the exponential growth of science, an idea that occurred to him when he noticed the growth in the Philosophical Transactions of the Royal Society between 1665 and 1850. He had the complete set in his home while Raffles College had its library built. Further, Garfield's contribution (1976a, 1976b) to scientometrics is quite significant; his contributions are evolved through his Science Citation Index. Merton (1952) also had his view on scientometrics.

**Informetrics**

Information, in its most restricted technical sense, is a sequence of symbols that can be interpreted as a message. Information can be recorded as signs, or transmitted as signals. Information is any kind of event that affects the state of a dynamic system. Conceptually, information is the message being conveyed. The English word was apparently derived from the Latin stem (*information*-) of the nominative (*information*): this noun is in its turn derived from the verb "informare" (to inform) in the sense of "to give form to the mind", "to discipline", "instruct", "teach":. Metrics means measuring. Informetrics is the study of quantitative aspects of information. This includes the production, dissemination and use of all forms of information, regardless of its form or origin.

According to Brookes (1990) the word ‘Informetrics’ was first proposed by Otto Nacke of West Germany in 1979. FID constituted a committee with this name and Nacke was its first Chairman. Rajan (Rajan &Sen 1985), the next Chairman of the Committee, reformulated the objectives of informetrics as to (Almi&Ing 1997) provide reliable data for research and development, policy-making, planning; to evaluate institutions, projects, articles, products, and other academic activities, and (to
identify or to develop the techniques to trace the origins and development of concepts. Ravichandra Rao (1985, 1993, 1996) in a short communication on “Informetrics vis-à-vis Bibliometrics: Scope and its Development”, mentioned that it is a field wherein the flow of information and behavior of information are analyzed, measured and quantitative relationships are established. It is a scientific field wherein the developments of measurement of impact of information are assessed continuously. Bibliometrics may therefore be treated as synonymous to informetrics having a scope to analyze quantitative characteristics of information. An FID Committee constituted with broadly defined objectives in the provision of research and technical data subsequently gave this name.

Third International conference on Informetrics was held in Bangalore in 1991. 'Informetrics’ was used as a generic term to mean “The use and development of a variety of measures to study and analyse several properties of information in general and documents in particular the study of the quantitative aspects of information in any form, not just records or bibliographies. Informetrics is the study of quantitative aspects of information. This includes the production, dissemination and use of all forms of information, regardless of its form or origin. As such, informetrics encompasses the fields of which studies quantitative aspects of science. It is mostly concerned with development of models to explain and identify the various characteristics of the literature. It also discusses scientific productivity, collaborative research, etc.

**Webometrics**

The science of webometrics (also cybermetrics) tries to measure the World Wide Web to get knowledge about the number and types of hyperlinks, structure of the World Wide Web and usage patterns. According to Björneborn and Ingwersen (2004), the definition of webometrics is "the study of the quantitative aspects of the construction and use of information resources, structures and technologies on the Web drawing on bibliometric and informetric approaches." The term *webometrics* was first coined by Almind and Ingwersen (1997). A second definition of webometrics has also been introduced, "the study of web-based content with primarily quantitative methods for social science research goals using techniques that are not specific to one field of study" (Thelwall, 2009), which emphasizes the development of applied methods for use in the wider social sciences. The purpose of this alternative definition was to help publicize appropriate methods outside of the information science discipline rather than to replace the original definition within information science.

Cybermetrics is one of the recently emerged fields in the line of metric studies. It has gained much popularity since the mid-1990 with the advent of Information Technology. As it is mainly concerned with the computer-science-based approaches, it has superseded all other metric studies in this Internet Era. Cybermetrics is proposed as a generic term for “The study of the quantitative aspects of the construction and use of information resources, structures and technologies on the whole Internet drawing on bibliometric and informetric approaches.” Cybermetrics thus encompasses statistical studies of discussion groups, mailing lists, and other computer – mediated communication on the internet, including the www. Besides
covering all computer-mediated communication by using internet applications, this
definition of cybermetrics also covers quantitative measures of the internet backbone
technology, topology and traffic. The breadth of coverage of cybermetrics implies
large overlaps with proliferating computer-science-based approaches in analyses of
web contents, link structures, and web usage and web technologies. The Webometrics
which studies are the quantitative aspects of the World Wide Web. The Cybermetrics
which is similar to webometrics, but broadens its scope which include namely the
electronic resources. Research of all network-based communications by using
informetrics or other quantitative measures is called webometrics.

There has been a revolutionising symbiosis between computer and communication
technologies in the west over the past ten years. The invention of World Wide Web
(www) a part of the ‘INTERNET’, which is the mother of networks, has practically
webbed the information globally under less than one roof. There has been a shift in
navigational approaches from syntactical to semantic (i.e., from sentences to words),
as an ever increasing number of research institutes, universities and business
organisations are currently providing information about themselves in the form their
articles, publications, reports, catalogues and other information resources on the
INTERNET in general and the www in particular. This is now becoming the
accepted method of disseminating and sharing information resources in hypermedia.
Information science research has also changed, with much research to find out, how
the new technologies are being used, particularly e-mail and the web. In addition to
user studies there have been attempts to extract new kinds of information from the
web. Being a global document network initially developed for scholarly use, it is now
inhabited by a diversity of users, and the web constitutes an obvious research area for
bibliometrics, scientometrics and informetrics.

**Altmetrics**

Altmetrics or alternative metrics for measuring research impact emerged as a subfield
of webometrics (Priem, 2011). It is largely depend on social web has expand the
scope of webometrics. Application designers should continue to build systems to
display altmetrics, develop methods to detect and repair gaming, and create metrics
for use and reuse of data ultimately. With the setting up of a metric to be used for
performance assessment; researchers will modify their behaviour to optimize their
performance. By promoting their work through publishing, giving talks at meetings,
doing interviews, things like that, it helps raise awareness of their work and
apparently increases its impact. The focus of Altmetrics is the attention received by
their work in social media namely Facebook, Twitter, blogs, forums, micro blogs,
social networks, products/services reviews, virtual world and others. No one can
claim that Altmetrics is perfect but it is one way forward in the quest for perfection
(Sangam, 2015).

**Knowledgometrics**

Knowledge metrology is an interdisciplinary integrated research topic. "Knowledge
Metrology is the scientific evaluation of Wuhan University, China Research centre in
bibliometrics, information metrology, scientific metrology, network metrology etc. It
is having its own theory, method and application (1-4-2017). It further studies the
whole human knowledge system as research object, and study the social ability of knowledge, and the social relationship of knowledge through the quantitative analysis and computing technology. In addition to the important research of Wuhan University. Early in 1998, the discipline planning of the “knowledge metrology” was put forward in the International Symposium on Research Evaluation and Scientometrics held in Beijing, the idea oriented from the concept of “element of knowledge” created by Hongzhou Zhao (1999). Another notable study was The “element of knowledge” theory put forward by Hongzhou Zhao was published in Chinese Journal in 1990, and which has been re-visited in detail in Chapter 2 of Turning Points-The Nature of Creativity written by Chaomei Chen (2011) The emerging of “Knowledge domain mapping”, “Knowledge discovery” “text mining” used in knowledge management are all the important development in knowledgometrics. Apart from this, China has big contribution from WISE Lab and other Research Institutes and Universities.

**Theoretical Principles and Science Concepts**

Bibliometrics is concerned with theoretical and philosophical foundations. Some of the important studies on theoretical and philosophical foundations are in the area of:

- Law of Scattering (Bradford’s law)
- Author productivity (Lotka’s law)
- Word productivity (law of Least Efforts)
- Impact Factor of Journal
- H-index
- Success-breeds success phenomenon
- Circulation theory
- Information Product and Processes (IPP) and Duality in IPPs

There are other theoretical studies, especially in the area of circulation theory, citation analysis, sources-items relation, etc. Some of these are discussed in:

- Proceedings of the ISSI Conferences in Scientometrics and Informetrics (held bi-annually since 1987)

Studies based on citation data have several limitations. They are:

- Citation studies are mostly dependent on data from databases such as Web of Science, SCOPUS, etc. which cover only a limited number of journals and its
coverage does not remain constant since new journals are added regularly and some are dropped,

- Solutions to problems of eliminating self-citation are cumbersome.

A primary objective of bibliometric research is the development of a general and systematic set of theories from which hypotheses can be generated and tested. Scientometric studies vary from each other from several points of view. They adopt different methods of data collection as well as different techniques. Even there are no universally accepted terminologies. In addition, use of algebraic symbols varies from one study to another. Under these circumstances, it would be difficult to think of “bibliometric or scientometric standards” let alone formulating them.

Most of the scientometric studies are empirical in nature. In such circumstances, to reproduce the research, one has to repeat the survey and analyse the data right from the beginning. Even then, we may not get the same result. In natural sciences, it is possible and quite common that research may be repeated in laboratories. But in social sciences this is not only difficult, but is not possible. Further, an important cause of the overall unreliability and therefore a cause of invalidity in any basic research in the social sciences are due to space and time factors. It is therefore difficult to reproduce the results of research.

The fact, whether we call our research area as librarmetry or bibliometrics or scientometrics or informetrics most of the topics we deal with are:

- Quantitative aspects of library and information studies, especially use and user studies, growth of collection, age distribution of documents, circulation statistics, etc.
- Journal productivity (by coverage, by use, by citation, cost-effectiveness measures, impact factor, h-index, sources of citations, immediacy of citations, age of sources cited, coverage in databases, etc.)
- Measures of productivity or author productivity, including studies related to multiple authorship (number of publications, cost-effectiveness measures, impact factor, h-index, reprints request, photo copies made, sources of citations, immediacy of citations, number of reviews, adoption rates (text books) etc.)
- Obsolescence and growth of literature
- Co-citation, bibliographic coupling, co-word analysis, rank distribution of words, etc.
- Quantitative analyses of science (science indicators -- country-wise, language-wise, subject-wise, etc.)
- Identifying relationships among various disciplines, structure of subjects, etc.
- Evaluation of scientific research (by institutions, by individuals, by countries, etc.)

Acceptance of a single term to define a subject and acceptance of its scope are necessary for any scientist. Otherwise, it is difficult to include it in a syllabus. It is also difficult to get research grant from different agencies. It helps us in identifying
the research groups especially at national and international levels. At present, the term 'scientometrics' is used as synonym to both 'bibliometrics' and 'informetrics'.

In order to encourage communication and exchange of professional information in the field of scientometrics and informetrics, a Society, called 'the International Society for Informetrics and Scientometrics' (ISSI) was founded in 1993. It is an association of professionals active in the emerging interdisciplinary fields of informetrics, bibliometrics / scientometrics, technometrics and webometrics. Among its membership are scientists from over 30 countries representing all five continents. The Articles of Association state that the aim of ISSI is the advancement of the theory, methods and explanations through the following two main streams:

1. Quantitative Studies related to
   - Scientific, technological and other scholarly substantive information.
   - Science of science and technology, social sciences, arts and humanities'.
   - Generation, diffusion and use of information.
   - Information systems, including libraries, archives and databases

Associations/ Institutions/Organizations

The Society was founded at the International Conference on Bibliometrics, Informetrics and Scientometrics held in Berlin, 11-15 September in 1993. This conference was the fourth of a series of prominent biennial conference that subsequently have been held under the auspices of the Society. The first three earlier conferences were held in Diepenbeek, Belgium (1987, Chairman: Dr. Leo Egghe), London, Ontario, Canada (1989, Chairman: Dr J M Tague) and in Bangalore, India (1991, Chairman: Dr I K Ravichandra Rao). The Society was incorporated with formal Articles of Association in 1994 in the Netherlands (Utrecht.) Dr. Hildrun Kretschmer was elected its first President.

With Berlin as its virtual center COLLNET was set up on January 1st, 2000, under the leadership of Hildrun Kretschmer, in her capacity as coordinator. The network is to comprise the prominent scientists, who work at present mostly in the field of quantitative science studies, coming from 15 countries of America, Asia, Australia and Europe. The intention is to work together in co-operation both on theoretical and applied aspects. COLLNET conducts every year International Conference in scientometrics.

There are four important journals in scientometrics - Journal of Scientometrics, Journal of Informetrics and COLLNET Journal of scientometrics and Information Management, Journal of Scientometrics Research (edited by S. Bhattacharya, CSIR NISTADS India). These journals are publishing original studies, short communications, and preliminary reports, and review papers, letters to the editor and book reviews on scientometrics. Due to its fully interdisciplinary character, the journal is indispensable to research workers and research administrators. It provides valuable assistance to librarians and documentalists in central scientific agencies, ministries, research institutes and laboratories.
On 27th March 2011 at Tumkur in India, “Institute of Scientometrics” was founded by Prof. S. L. Sangam along with his research students, with an objective to promote research in Scientometrics. It is a virtual and non-profit organization. Much of the research works in this area were carried out in National Institute of Science Communication and Information Resources (NISCAIR, a wing of CSIR) (formerly known as INSDOC), National Institute of Science Technology and Development Studies (NISTADS, a wing of CSIR) and Documentation Research and Training Centre of the Indian Statistical Institute. In recent times, a number of research works were published from Departments of Library and Information Science of many Universities in India. In 2009, UGC recognized Department of Library and Information Studied of the Karnataka University, Dharwad a Special Assistant Program (SAP) in scientometrics.

**Challenges of future research in the field of Scientometrics**

Scientometrics has strong connections with economics and sociology of science as well as science policy. It has many challenges for future research:

1) Delineation and mapping of scientific areas;
2) Measuring multi-disciplinarity;
3) Positioning indicators have challenged the traditional input-output measures, prioritizing volumes, market shares and productivity;
4) Capturing creativity and innovation;
5) Growth-diversity models; and
6) Data de-mining, knowledge, flow measurements and diversity issues.

**Conclusion**

The field of cybermetrics approaches the boundaries of bibliometrics, because some activities in cyberspace normally are not recorded, but communicated synchronously as in chat rooms. Cybermetric studies of such activities still fit in the generic field of Informetrics as the study of the quantitative aspects of information “in any form” and “in any social group” as stated by Tague-Sutcliffe (1992). The inclusion of webometrics expands the field of bibliometrics, as webometrics inevitably will contribute to further methodological developments of web-specific approaches. As ideas rooted in bibliometrics, scientometrics and Informetrics contributed to the emergence of webometrics, ideas in webometrics might also contribute to the development of these all-embracing fields.

Assessing Research and its Impacts: The *Generalized* Implementation Problem and a *Doubly-Conditional* Performance Evaluation Model

Cinzia Daraio

daraio@dis.uniroma1.it
Department of Computer, Control and Management Engineering “Antonio Ruberti” (DIAG), Sapienza University of Rome, Rome (Italy)

Abstract

This paper addresses the issue of designing relevant models of indicators to assess research and its impacts. The evaluation of research activities is a complex task for many reasons. There are no perfect indicators or metrics which fit for all purposes. In order to understand the appropriateness of the indicators to be used, we need to frame the problem taking into account the *systemic* nature of the phenomena and to develop *models* of metrics that are as close as possible to the reality being assessed. We show some examples of the usefulness of such a framework by discussing university rankings, the complexity of the assessment of research through the *generalized* implementation problem and presenting a *doubly conditional* performance evaluation model.

Conference Topic
Indicators, Science policy and research assessment, Science policy (on different levels)

Introduction: an overall framework for the assessment of Research and its Impacts

According to Daraio (2017a), each metric of research assessment (in this paper metrics and indicators are used as synonym) is based on a *model* that can be implicitly or explicitly defined and discussed. If the model underlying the metric is not described, this does not mean that the indicator is more robust to modelling choice. It simply means that you do not explicitly clarify and account for the underlying theoretical choices, methodological assumptions and data limits. Thus, as a consequence, if you do not specify your model of the metric, you may not check its robustness.

Developing models is important for two main reasons: i) to learn about the explicit consequences of assumptions, test the assumptions, highlight relevant relations; ii) to improve, to better operate, document/verify the assumptions, decompose analysis and synthesis, systematize the problem and the evaluation/choice done, explicit the dependence of the choice to the scenario. There are however several pitfalls and difficulties in modelling, which mainly relate to the possibility that the targets are not quantifiable; the complexity, uncertainty and changeability of the environment in which the controlled system works and, the limits in the decision context; the intrinsic complexity of calculation of the objective of the analysis.

Within this context, Daraio (2017a) proposes a *framework*, intended as a background which includes the main conditions, circumstances, ideas, and so on, to the realization of activities related to the assessment of research and its impacts. It is suggested as a reference to develop models of metrics accounting for the systemic nature of the research activity and its interrelations with teaching and innovation activities. See Figure 1 for an overall illustration.
Figure 1. A systemic framework for the development of models of metrics (source: Daraio 2017a)

Table 1 shows an outline of the definition of the different dimensions and components of the framework illustrated in Figure 1. The reader is referred to Daraio (2017a) for additional details and references. Daraio (2017a) states that “the ability to develop (and afterwards understand and use effectively) models for the assessment of research is linked and depends, among other factors, on the degree or depth of the conceptualization and formalization, in an unambiguous way, of the underlying idea of quality”.

The assessment of the research activity is also complicated by the quantification of data and its processing for their use in different contexts and for different purposes, including process monitoring, input-output monitoring, ex-ante and ex-post evaluation. In this case, according to Daraio and Glänzel (2016), there is a need to specify standards and rules for metadata definition and quantification (for additional details and references, see Daraio and Glänzel, 2016). Daraio (2017b) discusses the main challenges of econometric approaches to assess the productivity of research systems in this broader framework (characterized by Theory-Methodology and Data dimensions) and makes an attempt at standardization and harmonisation applied to the methodological dimension of the research assessment.

The main contribution of this paper is to show some examples of the usefulness of the framework introduced so far (Figure 1) for designing relevant models of indicators to assess research and its impacts. These examples include a discussion on

- university rankings,
- the complexity of the assessment of research through the generalized implementation problem,
- a doubly conditional performance evaluation model.

These issues are addressed in separate sections in the following. A final section summarizes and concludes the paper.
Table 1. Definition of the components of the framework

<table>
<thead>
<tr>
<th>Dimension component</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>1. Theory</strong></td>
<td>Identifies the conceptual content of the analysis, answering the question “what is the domain of interest” and delineating the boundary of the investigation. Education and Research are the main conceptual blocks of Theory. Their interrelations and their complementarities should be considered in a systematic way when assessing research.</td>
</tr>
<tr>
<td><strong>2. Methodology</strong></td>
<td>Identifies the range of methods, techniques and approaches that are relevant for the evaluation of research. It answers the question “how” the investigation is handled. Efficiency, Effectiveness and Impact are the subject of the assessment. They go from the output (baseline) that is the result of the transformation of inputs in outputs; to efficiency which relates output to inputs with respect to an estimated efficient frontier, effectiveness considers inputs, output and account for the aims of the activity, while impact refers to all contributions of research outside Academia.</td>
</tr>
<tr>
<td><strong>3. Data</strong></td>
<td>Data are a relevant dimension often neglected in modelling building. Data have a problematic definition because this depends on their use not on inherent characteristics of the data (Borgman, 2015, p. 74). Data are instances coming from the domain of interest and represent the means by which the analysis are carried out. Availability, Interoperability and “Unit-free” property refer to the usability of data, alternatives and choices that affect the data. This is the way in which heterogeneous data systems are able to exchange information in a meaningful way.</td>
</tr>
<tr>
<td><strong>Quality</strong></td>
<td>“Fitness for purpose”. It is the overarching concept of the framework. It is also an attribute of the different dimensions of the framework.</td>
</tr>
<tr>
<td><strong>Implementation factors</strong></td>
<td>Tailorability: Adaptability to the features of the problem at hand. Transparency: Description of the choices made and underlying hypothesis masked in the proposed/selected theory/method/data combination.</td>
</tr>
<tr>
<td><strong>Enabling conditions</strong></td>
<td>Openness: Accessibility to the main elements of the modelling. Convergence: Evolution of the transdisciplinary approach, which allows for overcoming the traditional paradigms, increasing the dimensional space of thinking. Mixed Methods: Intelligent combination of qualitative and quantitative approaches. Knowledge infrastructures: Networks of people that interacts with artifacts, tools and data infrastructures.</td>
</tr>

An illustration on university rankings

In this section we briefly describe how the framework introduced in the previous section could be applied for the interpretation of university rankings.

Let us consider the interpretation of the university rankings debate in Nordic countries. Piro and Sivertsen (2016) try to explain the differences in the scores of universities on the basis of the different assumptions made, while, Elken, Hovdhaugen, and Stensaker (2016) found that "rankings have a relatively modest impact on decision-making and strategic actions in the Nordic universities studied, and that there are few signs of rankings challenging the existing identities of the universities in this region". The latter seems to support an alternative role of rankings in the national context (see also Douglass, 2016). On the other hand, Daraio, Bonaccorsi and Simar (2015)¹ found that Nordic universities, taking into account their multidimensional activities, perform in line with the European reference standard. What can the present framework tell us about this rankings comparison? We can frame the comparison of ranking results according to the three dimensions (theory, methodology and data) and their constituent building blocks. See Table 2.

Gingras (2016) identifies three essential characteristics of a good indicator namely: adequacy, sensitivity and homogeneity and afterwards discusses why some rankings and indicators are invalid measures and nonetheless continue to be used.² Daraio and Bonaccorsi (2017) suggest that it would be possible to go beyond university rankings through the intelligent integration of existing data that may lead to an open-linked data platform that may permit the construction of new indicators without designing the indicators on a custom basis.

However, Moed (2017) argues that “current [ranking] systems are still one-dimensional in the sense that they provide finalized, seemingly unrelated indicator values rather than offering a dataset and tools to observe patterns in multifaceted data.”

The generalized implementation problem in Research Assessment

The operationalization of the general framework of Figure 1 needs the discussion and extension (along the three dimensions of the framework) of the implementation problem which is typical of quantitative methods (mostly mathematical models) in Operations Research and Management Science (Schultz and Slevin, 1975; Hildebrandt, 1977; Bryant, 1989; Keys, 1991; Mingers and Gill, 1997).

¹ Daraio, Bonaccorsi and Simar (2015) describe the main criticisms of rankings that their proposed approach (based on conditional directional distance functions) addressed, namely: 1. Monodimensionality (universities perform several missions: teaching, research, third mission) 2. Statistical robustness (multiple rankings, probabilistic rankings, robustness of rankings) 3. Dependence on university size and subject mix (rankings favour old and large universities where scientific, technical and medical disciplines prevail) 4. Lack of consideration of the input-output structure (ignore the amount of resources used). They propose a conditional directional distance approach as a fair comparison: a novel two-stage approach of conditional efficiency scores (nonparametric location scale model) allowed them to estimate the managerial efficiency scores as the residuals (what remains after having eliminated size and disciplinary specialization effects). They propose a bootstrap based approach for estimating error bounds for managerial efficiency scores and hence provide some statistical robustness.

² In reviewing Gingras (2016)'s book, Schubert (2017) points out that “Adequacy can, of course, be interpreted only with respect to a given question or task. Actually, this is the only criterion an indicator should fulfil. Sensitivity, homogeneity or whatever else are technicalities which are of secondary importance as long as the indicator is adequate to its task.” See also the discussion reported in Zitt (2015).

It is based on the application of methods developed as basic research to concrete organizations and contexts for specific problem-solving. We refer to the generalized problem because we consider i) the interaction of method development with its useful application; ii) that the implementation changes the unit of assessment; iii) that knowledge and technological innovation may be at place. Moreover, needless to say, the identification of the right problem and the development of an appropriate model are crucial determinants of success.

Figure 2 shows the extension of the implementation problem along the main dimensions of the Framework reported in Figure 1.

Along the Methodology dimension, we observe an evolution of the implementation theory, thanks to the introduction of the multi-methodology approach (Mingers and Gill, 1997; Mingers, 2006). In Figure 3 (Panel A), on the top-left side there is an illustration of three systems, which constitute the context of the intervention. According to Mingers (2006) who extended the Checkland (1981)'s two systems (problem solving and problem content systems), the three systems are the intervention system (agents undertaking the intervention), the problem content system (real-world situation of concern) and the intellectual resources system (available theories and methodologies).

A fruitful connection is the work on cognitive biases and their impact on decision-making introduced by Tversky and Kahneman (1974) which present three heuristics that are employed in taking decisions under uncertainty:
- representativeness, related to the use of categories to evaluate the probability that a given event belongs to a given class or a given process;
- availability of instances or scenarios, related to the evaluation of the frequency of a given class or the likelihood of a particular progress; and
- adjustment from an anchor, related to numerical prediction, when a pertinent value is available. These heuristics that are generally effective, lead to regular and expected biases that should be taken into account.

Intervention systems are made by agents (managers, decision makers...) who build models of problem content system (including inputs, organization, goals, criteria etc.) with the purpose of problem solving and obtaining outputs (activities, projects, solutions) which generate effects that interact and influence the previous systems. The analysis of the problem and context of intervention can be very difficult to address globally. This is due to the consideration of the two additional dimensions of Data and Theory. Here the approach of the Levels of Abstraction (LoA) proposed by Floridi (2002, 2008) could be helpful for our implementation problem to move from Data to information. Floridi’s (2002, 2008) method of abstraction relies on a method borrowed from a branch of theoretical computer science called Formal Methods, in which discrete mathematics is used to specify and analyse the behavior of information systems.

The idea behind the method of Levels of Abstraction (Floridi 2008) is quite simple and straightforward: reality can be viewed from different levels. Perhaps the most crucial feature of the method of LoA is that the identification relation between two observables is never absolute. Rather, the identification is always contextual and the context is a function of the level of abstraction chosen for the required analysis (Floridi and Sanders 2004). A LoA can be defined as a finite non-empty set of observables (which are interpreted typed variables, i.e. typed variables together with a statement of what features of the system under consideration they stand for) which are expected to be the components of a theory (this in our set-up, is given by the theory-method-data paradigm). A gradient of abstraction is made by a collection of LoAs and represents a kind of interface. It is used to analyse some systems from varying points of view or at different LoA. Hence, the method permits the analysis of systems by means of models developed at specific gradients of abstraction (interfaces). Figure 3 (Panel A) reports an illustration of the method adapted to our set-up. LoAs can be nested, disjointed and overlapping and do not need to be hierarchically related or ordered (as atomic components in a molecular). This method makes the ontological commitment of a theory (in our case of a configuration of theory-method-data) explicit as follows: A configuration of theory-method-data (theory in the original Floridi scheme) comprises at least one LoA and one model. The LoA allows the theory-method-data configuration to analyse the system under investigation and to elaborate a model that identifies some properties of the system (in our set up context of intervention systems) at the given LoA. The ontological commitment of a theory can be recovered by distinguishing between a committing and a committed component, within the scheme (see Figure 3, Panel A). By making the ontological commitment of a theory-method-data configuration explicit, the method of abstraction plays a crucial role in any context in which we acquire and process information. The resulting model, then, consists of informational objects and processes.

This is the implementation problem along the Data dimension. It has to be noted (along the Methodology dimension) that in this framework, multi-methodology refers also to empirical model building in Statistics, Econometrics and Information Theory (Box and Draper, 1987; Golan, 2008; Judge and Mittelhammer, 2011). On the other hand, the Theory dimension refers to people (and organizations of people) which are involved in the research activities. How translations occur in such a way that processes of abstraction (from the local to the global) and of instantiation (from the global to the local) modify the actors involved in the translation process (Callon and Latour, 1981; Callon, 1986a,b; Latour, 1993). This is what we learn from sociology, to complete our generalized implementation problem, whose main references are summarized in Figure 2. See Figure 3 Panel B for an illustration: It highlights the translation and the relative configurations and reconfigurations of mediations originated by the movements of the instantiation and abstraction that transform the actors involved in the process. This is why it is so difficult to trace the social (Latour, 2005).
Figure 2 An Application of the framework presented in Figure 1 to address the problem of Implementation in Research Assessment.

The doubly conditional performance evaluation model and its components

We introduce now a doubly conditional performance evaluation model which is one possible model for the assessment of research coherent with the framework outlined in Figure 1. It is illustrated in Figure 4. The performance evaluation model unfolds mainly along the methodological dimension, while Theory and Data dimensions are specific to the problem content and application context.

Performance measurement in public management is a challenged subject (Johnsen, 2005). Woelert (2015) identifies a proliferation of performance indicators in a kind of technical and quantitative escalation. Lewis (2015) highlights the almost neglected consideration of the consequences of performance measurement in evaluation of public policies. As we have seen in the previous section, the output of the research activity has some features that include complexity, uncertainty and indeterminacy. Among the challenges of their assessment, there are: 1) to bring about communication and debate about assumptions, choices and uncertainties, and about the limits of scientific knowledge; 2) to allow for articulation of different types of (scientific, local, indigenous, political, moral and institutional) knowledge; 3) to provide room for a transparent negotiation among standpoints (participatory processes)(van den Hove, 2007, see p. 815 for more normative requirements for science-policy interface).

This performance evaluation model can be helpful in combining the advantages of the partial convergence indicators approach (Martin and Irvine, 1983; Martin, 1996) mainly measurability and possibility of calculating the indices of performance, with a need for a multidimensional approach to the assessment of research and its impact (Moed and Halevi, 2015).

Martin and Irvine (1983) introduce the idea of converging partial indicators approach for assessing scientific performance, based on the multidimensional nature of research and its...
outputs: “All quantitative measures of research are, at best, only partial indicators influenced partly by the magnitude of the contribution to scientific progress and partly by other factors. Nevertheless, selective and careful use of such indicators is surely better than none at all. Furthermore, the most fruitful approach is likely to involve the combined use of multiple indicators. However, because each is influenced by a number of other factors, one needs to try and control for those by matching the groups to be compared and assessed as closely as one can” (Martin, 1996, p. 351). Hence, given the partial character of indicators, it is only possible to draw reliable conclusions in those cases in which the indicators provide convergent results,
Keeping the influence of non-relevant factors low. Moed and Halevi (2015) rather than focusing on a single output dimension and underlining the need to obtain convergence among a set of different indicators in order to produce valid and useful outcomes, they aimed at proposing “a consolidated multidimensional methodological approach addressing the various user needs, interests and purposes, based on the notion that indicators designed to meet a particular objective or inform one target group may not be adequate for other purposes or target groups.” Diverse institutional missions, and different policy environments and objectives, require different assessment processes and indicators. They focus on the purpose, objectives, and policy context of research assessments, and demonstrate how these characteristics determine the methodology and metrics to be applied.

For instance, publication counts are useful instruments to help in discriminating between those staff-members who are research active and those who are not, but are of little value if research active scientists are to be compared one with another according to their research performance. Moed and Halevi (2015) introduce the concept of a meta-analysis of the units under assessment in which metrics are not used as tools to evaluate individual units, but to reach policy decisions regarding the overall objective and general setup of an assessment process. Their base underlying assumption, that we share here, is that “the future of research assessment exercises lies in the intelligent combination of metrics and peer review. A necessary condition is a thorough awareness of the potentialities and limitations of each method.”

Figure 4 provides a qualitative illustration of the main component of the doubly conditional performance evaluation model that we propose here. It is based on a combination and extension of Johnsen (2005); van den Hove (2007) and Lewis (2015). It is “doubly conditional” because the evaluation is conditioned two times: on the information we consider and on that we do not consider.

In Figure 4, the different types of arrows and the different types of boxes simply illustrate heterogeneous influences and contents respectively. The elements filled with gray represent the main items on which the conditioning could be done.

We distinguish two kinds of conditioning. Conditioning on the items reported in the bottom of the Figure 4 (policy, objectives, actors, processes and results) means to compare comparable entities, setting appropriate reference sets. We call this internal conditioning or normalization. On the other hand, conditioning on the items reported in the top of the Figure 4 means to account for heterogeneity factors that we call external conditioning or contextualization. According to this model of performance evaluation, it is all a matter of appropriate normalization and contextualization.

This model:
1. Permits the identification of the components of the analysis (in terms of theory-method-data characterization) that are excluded (what remains outside) in the specific context of the evaluation;
2. Gives interpretative value of the measure (or metrics) of research assessment calculated, that has to be considered as a residual, i.e. what remains after the consideration of the dimensions we pursued, that is due to other factors/components not accounted for;
3. Represents a step toward the democratization of the evaluation practice, able to balance the opposite views of external accountability and internal improvement (Ewell, 2009), composing contrasting trends towards competition and cooperation through cohesion.

This performance evaluation model might be helpful to identify constitutive effects of indicators (Dahler-Larsen, 2014) and perhaps also their “unintended consequences”. This model is useful for the interpretation of the results obtained from our assessment, and it is useful to identify discrepancies, and shows what the residual, our “ignorance” is. It is also helpful to identify the gap and which variables may be added to explain a part of these discrepancies. It is a kind of
contemporary revisiting and revalidation of the Leibnsteins *x-inefficiency* concept (Leibenstein 1966, 1975, 1978a,b; see also Leibenstein and Maital, 1992).

Figure 4. Another application of the framework of Figure 1: A “doubly conditional” performance evaluation model

The indicators empirically calculated are interpreted as the *residual or our ignorance* on the phenomenon and it is possible to identify the neglected aspects of the analysis carried out. The neglected components can be useful for suggesting alternative or additional dimensions of research assessment, of interest for the subjects of the assessment that are scholars, institutions and so on.

This doubly conditional performance evaluation model may be used for doing a *profiling* of the activities, sharing evaluation models, improving knowledge by learning. Within this context, *for each subject under assessment a dimension of performance along which the evaluated entity can outperform or do better than the others can be found.* The identification of the best performing dimension of each entity subjected to the evaluation is important for developing strategy for identifying and establishing sustainable and durable value creation, going beyond competitive advantages (Zenger, 2016), exploiting the existing information (Porter and Millar, 1985), and finding out for each entity its own specialty-role in the knowledge production system.

This *performance evaluation model* may be used as a *flexible evaluation tool* for “value creation” in a learning and participatory environment. It might be seen as a revisited version of Ricardo’s approach of *comparative advantages* (Ricardo, 1817) but within the context of the broader framework including theory, methodology and data dimensions introduced at the beginning of this paper.
Conclusion
In this paper we analysed the importance of designing models for the assessment of research and its impacts. We have illustrated the central role played by a comprehensive framework, which includes, in an original way, together with the Theory and Methodology dimensions, also the Data dimension. We described some limited examples of application of this framework, which refer to university rankings, the complexity of the assessment of research connected to the generalized implementation problem and the doubly conditional performance evaluation model. They show the potential of this approach and encourage to test and deepen its use in different research assessment contexts.

Methodological Challenges for the Comparison of Results of Topic Extraction from Scientific Literature

Theresa Velden
velden@ztg.tu-berlin.de
Technische Universität Berlin, Berlin (Germany)

Abstract
This paper discusses the specific challenges of comparing topic extraction approaches in scientometrics. The discussion is inspired by experiences made in the recent topic extraction comparison exercise documented in a special issue of the journal Scientometrics (Gläser et al., 2017). It reviews the related, ongoing debate in network science about the status of ground truth in benchmarking community detection algorithms and then moves on to discuss challenges when comparing topic extraction solutions without access to a ground truth data set. The paper concludes with a proposed way forward. This paper is intended to inform the discussion at the special session on ‘Comparing Topic Extraction Approaches’ at the upcoming ISSI 2017 conference in Wuhan, China.

Conference Topic
Methods and techniques

Introduction
In a recent comparison exercise (Gläser et al. 2017, Velden et al. 2017b), several groups active in bibliometrics have conducted a systematic comparison of their respective topic extraction approaches and the results they generate. Specifically, they applied their approaches to a shared data set of bibliographic information of articles published in Astronomy and Astrophysics journals between 2003 and 2011 as indexed by the Web of Science (called the Astro Data Set). Since then, and courtesy of a license agreement provided by Clarivate Analytics, this initiative has been opened up to broad participation through the launch of a topic extraction challenge (see www.topic-challenge.info) that makes the Astro Data Set available to the community to test their approaches and conduct further comparisons. Against this background, this article discusses the various methodological challenges encountered when we seek to compare and evaluate top extraction approaches in bibliometrics in an effort to help move the field forward towards developing standards for the systematic evaluation of data analysis methods that seek to operationalize and delineate entities such as 'research topics' that are of fundamental importance to scientometric research.

For the purpose of this article, we define a topic extraction solution as a grouping of scientific papers (such as the papers in the Astro Data Set), allowing for multiple and weighted assignments of individual papers to such groups. In the simplest case, topic extraction solution is defined by a disjoint grouping of documents into clusters and fixed membership strength of documents in clusters with either 0 or 1. In more complex cases, solutions are defined as overlapping clusters and a variable strength of membership for documents within a cluster.

The motivation for comparing topic extraction approaches and solutions is to improve our systematic knowledge about methods, their appropriateness and shortcomings, specifically in the domain of scientometrics. In particular, we want to raise awareness of a problem called

1558
‘performativity fallacy’, namely the failure to consider the extent to which empirical phenomena that we observe are products of and expose features that are specific to the methods we employ (Law 2009). In the scientometrics literature, the empirical phenomenon of a topic is frequently defined ‘operationally’ as the outcome that an algorithm produces, without a careful assessment of the assumptions build into the data model and algorithm used and reflection on how those assumptions construct what is then taken as representing a topic and assessment of how topics world look differently if different choices were made in the construction process (Gläser et al. 2017). For example, after clustering a citation network of publications from a field of research, the clusters of documents we retrieve become ‘the topics’ that constitute the field. Topic extraction approaches produce the reality of topics, however due to lack of systematic investigation and comparison of our methods, we have a hard time to ascertain what properties of the topics we obtain are artifacts of our methods rather than properties of the genuine empirical manifestation of a theoretical well-defined object (‘research topic’).

To shed light on the performative nature of topic extraction algorithms, the comparison exercise mentioned above explored how much and in what ways solutions differ and how decisions that we take in the process of constructing a topic extraction solution, including data selection, data modeling, and the choice and application of an algorithm, generate solutions with distinct properties. In this article we will embed the observations made during this specific comparison exercise in a discussion of the increasing level of complexity of the challenges encountered when we seek to systematically compare and evaluate topic extraction approaches in bibliometrics.

Beyond benchmarking

At first sight, a systematic comparison of topic extraction approaches in scientometrics may seem like an obvious replication of a fairly established practice in computer science, namely to benchmark algorithms by comparing their performance when applied to the same data set. Benchmarking in computer science typically aims at evaluating the performance of a newly developed algorithm relative to existing ones with regard to speed and accuracy. For example, the development of new clustering algorithms for community detection in complex networks, routinely involves the comparison of a new community detection algorithm to other community detection algorithms (Lancichinetti et al. 2008). A popular benchmark data set for community detection algorithms that claim any relevance to social network analysis is the Zachary (1977) karate club network. This is a network of 34 nodes representing individual club members and weighted links between nodes representing the intensity of their social ties outside of the karate club. Importantly, these benchmark data sets are usually ‘labeled’, i.e. they come along with a ground truth, a specification of the true membership of each network node in a cluster stemming from direct observation rather than indirect inference. In the case of the karate club network the ground truth is based on a 3-year ethnographic observation of the club and its membership, and specifies the fission of the club membership into two separate sub networks in the course of an escalating dispute over a raise in fees for karate lessons. The accuracy of results delivered by a clustering algorithm is then measured in terms of agreement of the result with this ground truth (for which various different quantitative measures can be devised), and a popular test for community detection algorithms is whether it replicates the fission of the karate club network documented by Zachary (1977). Alternatively, one may fall back on or complement the external ground truth measures with internal quality measures that in some way assess the separation between clusters versus the internal coherence of clusters. For example see the systematic evaluation of clustering algorithms in the biomedical domain by Wiwie et al. (2015) that comprises an online evaluation service provided at https://clusteval.sdu.dk/1/mains). However it has been found that the agreement between such
internal measures and external measures of accuracy can be tenuous and what structural quality of a cluster is most relevant may well depend on the application domain, i.e. the entity that a community or cluster extracted by a method actually stands for (a scientific topic, a social group, a protein family, etc.).

The comparison exercise of topic extraction approaches in scientometrics that we discuss here differs in two important aspects. First, the approaches that we compare consist of an algorithm (typically a community detection algorithm) in combination with a bibliometric data model. This increases the complexity of the exercise, as approaches vary with regard to how the data is modeled (e.g. a direct citation network versus a similarity matrix based on word co-occurrence) and the community detection algorithm used. Second, there is no agreement on what would represent a correct topic extraction result. To the contrary, the suggestion is that when it comes to scientific topic structures there exist multiple equally valid topical perspectives onto a knowledge domain (Gläser et al. 2017). This implies that we are not looking for the one best method of topic extraction, but for guidance on what method may be best suited for a given purpose and the topical perspective that aligns with that purpose. To complicate matters further, as of now there exist no well established typology of topical perspectives nor corresponding ground truth data sets such that we are faced with the challenge to learn from direct comparisons of approaches and their results without reference to a given (set of) ground truth(s).

But let us take a step back and consider the methodological challenges of comparing and evaluating topic extraction approaches systematically, starting with comparisons that reference a ground truth data set, before discussing comparisons without reference to a ground truth data set.

**Comparison with a ground truth data set**

*The operationalization of communities in community detection algorithms*

The way a ground truth data set such as the Zachary karate club network has been used hitherto in network science took for granted that the structure of the network indeed foreshadowed and is causally linked to the eventual fission of the network that is specified by the ground truth data. Hence an algorithm that splits the network structure and separates the nodes in accordance with a given ground truth is seen as performing adequately, and the relationship between the data model (the network structure) and the ground truth is seen as unproblematic. Under these assumptions, the comparison of the results of algorithms with a given ground truth would serve to weed out algorithms that suffer from algorithmic shortcomings or biases in analyzing network structure that lead to deviations from the expected ground truth results. Aside from technical shortcomings, failures of algorithms to reproduce the ground truth communities point to a mismatch between theoretical properties of the object of study (assumed to be truthfully represented in the ground truth data) and the specific operationalization by the algorithm of communities as groupings of nodes in the network structure. A case in point is the work by Yang and Leskovec (2014, 2015) who compare communities detected in large real-world networks with ground truth communities (indicated by node labels). They suggest that many of the current community detection algorithms that allow for community overlap make the false assumption that nodes in overlap areas are weakly connected rather than strongly connected to each other. This misassumption makes those algorithms prone to misidentify overlap regions as communities in their own right.
The relationship between data model and ground truth

The question how to explain failure of community detection algorithms when compared with ground truth data sets has experienced an interesting twist recently. In a series of experiments with classical and more recent large-scale networks that have ground truth labels, Hric et al. (2014) find that none of the current community detection algorithms (overlapping and non-overlapping) performed satisfactory when compared against those ground truth data sets, leading the authors to question the relationship between data model (the given network structure) and ground truth (Hric et al. 2014). They raise the question whether the network structure adequately models the phenomenon of interest that is represented by the ground truth. They suggest that to recover the ground truth groupings one may need to enrich the data model by other than structural information and they point to respective recent efforts by computer scientists. Peel et al. (2016) go one step further, and question the readiness with which node metadata is commonly given the status of ground truth representing the study object of interest. They suggest that the node labels may refer to some other aspect or dimension of the empirical phenomenon of interest that may not bear a causal relationship with the network ties. They argue that a typical benchmark exercise simultaneously tests the performance of the algorithm as well as the correspondence of the ground truth data set to the phenomenon of interest without being able to distinguish between the two.

Applied to Zachary karate network the question is threefold: First, does the way a selected community detection algorithm operationalizes communities fit well with the theoretical model of the object of interest, e.g. the karate club network exposes features that could be exploited to discover a leader-follower partition as well as the social group fission partition, depending on algorithmic predispositions (see Fig. 1 in Peel et al 2016.) Second, does the data model capture information that is causally related to the generative process of the object of interest, so is the social fission in membership that eventually occurred have anything to do with the social ties outside the karate club between the individual club members that defined the structure of the network? In the case of the karate network, ground truth data and network structure stemmed from multi-year ethnographic observation, and the likelihood of a causal connection between data model and and object of interest is high: informed by social theory about fission in small groups it rested on the hypothesis that differential flow of information and sentiment due to the topology of the social network determine the eventual partition of the network. Third, are the ground truth labels for each club member that specify his or her membership into the old or new club after the fission appropriate to represent the object of interest? For the karate club network the ground truth data is closely tied to the object of interest, as it constitutes and describes the phenomenon to be explained, the fission of the original club membership into two factions. In other cases, especially for large networks, where ground truth labels are derived e.g. from declared group memberships in social networks or publication venues in a co-authorship network, the proposition of a strong causal link would seem to deserve further scrutiny.

Figure 1 serves to summarize this discussion. At the center of the endeavor we would expect a well articulated theoretical definition of a community (or topic) that would guide the operationalization of the respective phenomenon when modeling the data and implementing (or choosing) an algorithm to analyze this structure, as well as when generating the ground truth data set. When ground truth data is used to evaluate the performance of community detection algorithms, what is compared are the results of a data modeling and algorithmic analysis process on the one hand, with a constructed ground truth data set on the other hand. Too often in the community detection literature, the relationship of the theoretical concept of study to the data model and the ground truth is taken as unproblematic and remains exempt from scrutiny. However, in any of these steps,
problematic decisions can be taken that veer the results of the community detection approach and the results suggested by the benchmark away from the actual phenomenon of scientific interest. So what we can take away from this discussion is that when we interpret the benchmarking results of a community or topic detection algorithm vis a vis a ground truth data set, we need to exercise extreme caution in drawing conclusions whether or not an approach is suitable to detect the kind of objects we are interested in.

Fig. 1: Diagram depicting the various 'performative' steps undertaken, before a community detection result (or topic extraction result) is compared to and evaluated against a ground truth data set. In any of these steps decisions are taken that need to scrutinized with regard to their correspondence to the theoretical properties of the object of study.

Comparison without a ground truth data set
As mentioned above, there is no agreement on a single topical perspective that would prescribe a correct partition of a set of documents in the scientific literature. Topical structures are seen as multidimensional, as commonalities between research contributions may arise along different dimensions such as research objects versus research methods (see for example discussions in Wen et al 2017, Glänzel & Thijs 2017, Palchykov et al. 2016, and Newman & Girvan 2002) however as of now no consolidated theoretical knowledge exists that would allow us to specify these different topical perspectives. For the time being this renders the respective multiple ground truths
inaccessible. Under these circumstances, the question of how to conduct a comparison without reference to a ground truth and what to learn from it about the suitability of different becomes a research question in its own right.

We have seen scientometricians take different approaches to this question, as exemplified in the recent literature by Klavans & Boyack (2016), Subelj et al. (2016), and Velden et al. (2017).

**Ad-hoc yardstick**

Ad-hoc yardsticks take on the role of a ground truth data set. Where classical ground truth data sets ideally hail from independent observation, ad-hoc yardsticks are constructed on the spot, from the available data. For example, Klavans & Boyack (2016) investigate the influence of different citation based data models (co-citation versus direct citation versus bibliographic coupling) on topic detection results using the same community detection algorithm. As a yardstick for comparing and assessing the ‘accuracy’ of the different solutions they use overlap with the grouping of references by review articles (articles with > 100 references), and conclude that the direct citation data model performs best with regard to this yardstick. What Klavans’s and Boyack’s yardstick definition has going for it is that it is informed by domain knowledge developed over a career of doing scientometric research on the science system. They distinguish between scientific topic perspectives with different characteristics (research fronts, a topic of an earlier comparative study using a different yardstick (Boyack & Klavans, 2010), versus taxonomic topic classification) and seek to design their yard sticks to match those distinct perspectives. Whether such a yardstick would be appropriate to compare and evaluate a wider range of data models (including those that do not use citation as a feature) is doubtful, since the yardstick seems to be too closely related to citation based data models and is likely biased towards it.

**Statistical properties**

Subelj et al. (2016) compare a large range of different clustering algorithms by applying them to direct citation networks from different domains. The specific purpose that results would be used for is not elaborated beyond a general description of the task as “grouping scientific publications into clusters.“ In their comparison they focus on structural properties of solutions, complemented by their own expert review for one of the domains they can have expertise in (scientometrics). They find that the different approaches can be subdivided into a small set of families yielding similar results based on a metric of pairwise clustering differences. Those different families of algorithms tend to generate distinct size distributions which in turn a related to some distinct properties of linking patterns found with regard to internal and external linking, as well as further metrics relating to range of cluster sizes and cluster diameters. The authors suggest that reviewing such statistical properties provides insights that allow to discriminate between algorithms more suitable for the task.

---

1 Interestingly, the lack of ground truth data implies that no preferred level of resolution is defined anymore. As a community we have not yet developed a consistent way for how to deal with and think about different resolution levels in the extraction of scientific topics from the literature and their comparison. Velden et al. (2017b) attempted comparisons across widely differing resolution levels (ranging across approaches from 11 to 555 topics retrieved) that were in several cases decided ad-hoc rather than based on some theoretical justification. Subelj et al. (2016) in their comparison of community detection algorithms simply accepted the default setting provided by most algorithms, also resulting in a variety of different resolution levels to compare across. For comparison purposes one might tune algorithms to deliver very similar numbers of topics, and scan a range of such levels. Or one might search for resolution levels that seem the most natural for a given combination of data model and algorithm, based on some internal quality criterion, as discussed by Wiwie et al (2016).

2 Whether many current ground data sets for large data sets (such as social networks where the data model are friendship links between users and ground truth data are simply the group memberships declared by users using a respective feature of the same social network site) actually fulfill this requirement can be debated.
or less suitable. They develop a number of intuitive and practical criteria such as robustness of results, avoidance of excessive run times, a minimal proportion of publications being assigned to clusters of insignificant size, and a preference for cluster sizes ideally to not vary by more than one order of magnitude. However, they suggest that the ultimate criterion should be expert review of the topics obtained. Based on these criteria along with a favorable assessment of topic content by their own expert review, they conclude that infomap (or alternatively Metimap for very large networks) is the most suitable method to use on direct citation networks.

Embracing variation

Rather than looking to determine the most accurate or suitable approach by one measure or another, two recent works embrace variation and start from the assumption that a multiplicity of legitimate topical perspectives exist. Wen et al. (2017) triangulate three different bibliometric mappings of topics in the field of water research to demonstrate the complementarity of information gained by different approaches, journal to journal citation, author keyword overlap, and title word + reference overlap. They suggest that those complementary methods identify fields, topics and methods used within the field of water research.

Velden et al. (2017b) come up with various ways to determine and visualize differences between the topical structures produced by various approaches when applied to the same data set (Astro Data Set) and attempt to determine how choices made in the design of an approach produce specific outcomes. The latter goal of tracing back features of solutions to specific decisions in the design of an approach is challenging, as the multiplicity of data models and algorithms generates a large space configurations, and one would ideally compare solutions by varying only one aspect at a time, and addition scan a range of different levels of resolution to facilitate direct comparison. Based on their sample of approaches, Velden et al. (2017b) were dealing with a 5 by 5 matrix of potential combinations of data models and algorithms (see Figure 2), however only had resources to investigate and compare 8 out of the 25 possible combinations. Note that this matrix does not consider investigations of the same approach at various levels of resolution. Resolution levels varied widely across the sample, making direct comparisons problematic for many pairs of solutions.

Velden et al. find that all solutions in their sample agree in grouping together certain sets of documents, suggesting the existence of topical ‘cores’ of very densely connected documents by various types of community measures and represented by various data models. Solutions differ across a range of structural features, such as concentration of topic sizes and coverage of the data set, the latter ranging between 93% and 100%. Interestingly, one approach (Koopman et al. 2017) produces a major topic with a large proportion coming from those remaining 7% of publications missing as a distinct topic from the solutions delivered by those latter approaches.

These are still rather formal structural properties, observed without reference to specific topic contents or interpretation of the topical structure of the Astro Data Set that the different solutions construct. The authors further employ a number of visualization and labeling techniques (Koopman & Wang 2017, Velden et al. 2017) to explore the topical structures generated by the various approaches. Based on their analysis, three distinct perspectives onto the Astronomy and Astrophysics field can be distinguished:
**Fig. 2:** Potential configuration space of approaches compared in original topic extraction exercise using the Astro Data Set. Of 25 possible configurations, only 8 were compared. The number of configurations to compare is multiplied when systematically scanning different levels of resolution (number of topics).

**External:** This perspective is generated by considering the linking of documents in the Astro Data Set into the wider literature (Boyack, 2017). It is a view onto the field when considering the ‘external pull’ by documents published in other disciplines. It depicts the field as highly concentrated within some core domains (Gravitation and Cosmology, Astrophysics, and Solar Physics) where almost all documents combine into one or two large topics, plus other domains (such as Planetary Science or Astroparticle Physics) that are characterized by a wide scatter of documents into many smaller topics. This topical perspective accentuates interdisciplinary links and identifies subdomains within the field of Astronomy and Astrophysics with strong links to other disciplines.

**Internal & Global:** This perspective is internal, as seen from within the field as it only considers information within the Astro Data set. The results of four of the eight approaches in the sample (by Velden et al. 2017, van Eck & Waltman 2017, and Koopman et al. 2017) show great similarity although they use a set of different data models and algorithms. Their representations as topic affinity networks map the field as an elongated structure, organized by research objects from large-scale objects distant in space-time (cosmology) to objects in the local neighborhood of Earth (solar physics, planetary science, space science). The core of the field (with research on galaxies and stars) is resolved at a much higher level of granularity than by the external perspective.

**Internal & Local:** This perspective is generated using a community detection algorithm that produces overlapping communities and only evaluates the local neighborhood of a seed of documents, i.e. not taking the complete network information of documents in the Astro Data set into account (Havemann et al. 2017). It produces topics at a large variety of sizes. As Velden et al observe, they tend to reproduce the main topics found by the internal and global approaches in the sample, but also some distinct topics that are not identified by the latter approaches. By allowing for overlap, this approach may be more suitable to detect ‘bridging’ or ‘emerging’ topics at the interfaces of larger established topics that may get suppressed by approaches that only allow for disjunct topics constructed from a global analysis of network structure.

These distinctions underline how the suitability of approaches is dependent on purpose and intended use of the results of a topic extraction. They are first indication of what one might consider as topical perspectives, but fall short of a well-founded theoretical typology.

The Way Forward
It seems obvious at this point, that topic extraction approaches and their results need to be considered relative to their purpose and intended use, and in particular relative to the topical perspective that an approach is intended to evoke from the data. So one important line of research is to develop a typology of topical perspectives and corresponding theoretical definitions of topics that would need to inform their operationalization in form of data models and algorithms. One way would be to design an empirical study to engage with practitioners (scientists within the field, from neighboring fields, consultants, funding agencies, information services) to try disentangle distinct topical perspectives that are relevant in specific contexts for distinct purposes. How do these topical perspectives differ, and what are the implications for the theoretical conception of topics and their operationalization in the form of data models and algorithms?

Then, for a given purpose and topical perspective of interest, we would like to compare and evaluate different approaches. What is a good modeling and algorithmic approach to construct the relevant topical structure given theoretical insights into the nature of the topical perspective and the implied requirements for their operationalization? How can we resolve the problem that many popular data models (such as citation based models) likely mix different topical perspectives, as highlighted by Palchykov et al. (2016)? What can serve as a yardstick or ground truth to compare and assess the suitability of competing approaches for the respective purpose? How do we map and compare results that deliver overlapping topics, given that many of the standard metrics and mapping techniques assume a disjoint construction of topics?

At this point, I would like to highlight the opportunity to join the topic extraction challenge (www.topic-challenge.info) that makes available the Astro Data Set: to take advantage of a shared data set to learn about your own approach and how the solutions it produces compares to the solutions of other approaches; to participate in the discussion of what are relevant alternative topical perspectives, what could a yardstick to represent a ground truth look like in each case, and what are useful tools for the comparison of topical structures? The originators of the topic extraction challenge (Boyack et al. 2017) hope to establish the Astro Data set as a benchmark data set to test approaches and to grow the collection of solutions into a valuable open resource for further study as we hope to generate interest in improving collectively our systematic knowledge about methods, their suitability, strengths and limitations.

While it may seem as if we are going in a circle, I suggest we are making progress by having advanced our understanding of the various layers of performativity of topic extraction approaches, and by having identified avenues for further progress.

"We have learned a lot, Siddhartha, there is still much to learn. We are not going around in circles, we are moving up, the circle is a spiral, we have already ascended many a level."
(Hermann Hesse, Siddhartha, Chapter 2, 1922)

Abstract
We have proposed a method of detecting research fronts based on LDA. LDA can realize the extraction of topics from corpus accurately. Many current methods of detecting research fronts are lack of the indicators to identify research fronts. For the problem, we construct the indicators-strength and novelty. In the empirical study, we detect the research fronts of medical informatics, and the results shows that there are 19 research front, beside 17 of them have been approved by experts.

Knowledge discovery and data mining

Introduction
Research fronts present the focus and difficulty domain of scientific research. Obtaining the research fronts timely and accurately is of great significance for the country, institutions and researchers. Countries all around world give high attention on the study of the research fronts. Research fronts is critical with future of the development of scientific and technology, hence identifying the research fronts timely and accurately is of great importance. What’s more, academic resources are increasing day by day. Researchers are faced with great challenges in understanding the development trend of the field and obtaining research fronts. In addition, there are still some problems of research fronts identification (Leydesdorff, 2011).

1.1 Literature Review of Research Fronts
Price (1965) proposed the concept of research fronts. Afterwards researchers conduct abundant researches on it. Research defined the meaning of research fronts in different perspectives, and it can be classified into four categories: ①define as a collection of high cited papers, eg. Price (1965); ②define as a collection of co-cited papers, eg. Garfield (1994); ③define as a collection of bibliographic coupling papers, eg. Morris (2003); ④ defined as an emergent and transient grouping of concepts and underlying research issues, eg. Chen (2006).

There are various methods of detecting research fronts, which can be summarized from the qualitative and quantitative perspective. In the qualitative, literature review and brain storm are commonly used and authoritative methods. However, researchers are with different capabilities, so the result is obviously subjective and inconsistent. In the quantitative, it can be combed into citation analysis method and content analysis method, which are the focus of method studies.

With ample research results, citation analysis method started early, which can be concluded into co-citation analysis, bibliographic coupling, and direct citation. Recent years, co-citation analysis and bibliographic coupling are widely applied in detecting research fronts. Lee (2015) identifying the research fronts in Korean library and information science by document co-citation analysis. Liu (2016) conducted the study which applies a network clustering method to group the literature through a citation network established from the data envelopment analysis (DEA) literature over the period 2000 to 2014. Each research front is
then examined with key-route main path analysis to uncover the elements in its core. Due to the citation delay and it can’t reveal the content of paper, many researchers attempt to detect research fronts by content analysis method.

Content analysis method includes term frequency analysis, burst term analysis, and co-word analysis. The objects of term frequency analysis are keywords or subject headings mostly. Chu (2014) and Qin (2016) detected the research fronts based on term frequency analysis. However, this method has a drawback of the threshold need to be set manually, which may lead to the subjective results. In 2006, CM Chen embed Kleinberg’s (2003) burst detection algorithm into CiteSpace II, which is adapted to identify emergent research-front concepts. Compared with the terms analysis, co-word analysis emphatically measures the relationship between terms. Han (2015) adopted co-word analysis method to detect the hotspot domains and knowledge base in the research of special education teachers. The keywords, subject headings, burst items, and couples of co-words are condenses of the content of paper, which can represent the core meanings and research directions. Muñoz-Écija (2017) identified their origins of nanoscience and nanotechnology (NST) and the seminal papers through direct author citation of these works, and extracted from the titles and abstracts through word co-occurrence, the main lines of research were identified.

Through the literature review, there are two main problems in the research of front identification:

1. It’s lack of recognizing indexes of research fronts.
   The existing methods of detecting research fronts depend on the accumulation of terms or citation, though it’s lack of recognizing indexes.

2. The existing methods neglect the semantic information between texts.
   Citation analysis and content analysis method can’t detect the research fronts semantically, and they neglect the semantic information between texts.

With the development of text mining technology and semantic analysis, it is the research focus and future trends that detecting the research fronts accurately and semantically.

1.2 Literature Review of Topic Model

In the scientific researches, topics generally mean the main content in the paper. Under the topic model, topics are represented by a series of probability allocation. Topic model is a latent modelling method which can extract the topics from text. What’s more, the topics can be used to analyse the corpus preliminary. Up to date, many researches demonstrate that topic model can extract topic from massive text in the era of big time. In addition, one of the most important reasons of the prevalent is that the topic model is not so complicated and more explainable compared to other text mining methods.

Among the massive topic models, Latent Dirichlet Allocation(LDA) is a complete Bayesian model with a solid theoretical foundation. Due to the characters of flexible and expendable, it is widely used in emotional analysis, social media analysis, academic corpus analysis, and network structure data. The paper proposed the method of detecting research fronts based on LDA, and emphasized the application in the academic corpus analysis.

The earliest used in the academic corpus analysis of LDA is Grittith (2004). He used LDA model and showed that the extracted topics capture meaningful structure in the data, consistent with the class designations provided by the authors of the articles, and outline further applications of this analysis, including identifying “hot topics” by examining temporal dynamics and tagging extracts to illustrate semantic content. Hall (2008) apply unsupervised topic modelling to the ACL Anthology to analyse historical trends in the field of Computational Linguistics from 1978 to 2006. He induced topic clusters using LDA, and examined the strength of each topic over time. Zhou (2006) proposed a method for discovering the dependency relationships between the topics of documents shared in social
networks using the latent social interactions and trained a LDA model over our entire sample collection of CiteSeer, attempting to answer the question: given a seemingly new topic, from where does this topic evolve? Gideon (2006) extends journal bibliometric to topics (Citation Count, Impact Factor, Diffusion, Half-Life) and introduces three new topic impact measures: Topical Diversity, Topical Transfer, and Topical Precedence.

In the domestic, researchers mainly apply LDA to detect emerging topics. Fan (2014) attempted to detect the emerging topics from documents based on LDA. Wu (2012) proposed ATNLDA model to mine the topics evolution, which based on the methodology of co-occurrence and cluster. Lee (2015) used LDA and sparse representation classifier to categorize new topics. Ye and Leng (2013) combined the LDA and co-occurrence.

The studies of researchers demonstrate that LDA performed well in the topic extraction based on the academic corpus. The paper proposed the method of detecting the research fronts which is extracting the topics by LDA and identifies the front topics by research front indicators. We conduct empirical study with the example of medical informatics discipline, and access the results by experts.

2 Methodology

2.1 LDA

LDA is a three-level hierarchical Bayesian model, in which each item of a collection is modelled as a finite mixture over an underlying set of topics. Each topic is, in turn, modeled as an infinite mixture over an underlying set of topic probabilities. In the context of text modelling, the topic probabilities provide an explicit representation of a document.

Latent Dirichlet allocation (LDA) is a generative probabilistic model of a corpus. The basic idea is that documents are represented as random mixtures over latent topics, where each topic is characterized by a distribution over words.

LDA assumes the following generative process for each document \( \mathbf{w} \) in a corpus \( D \):

1. Choose \( N \sim \text{Poisson}(\xi) \).
2. Choose \( \theta \sim \text{Dir}(\alpha) \).
3. For each of the \( N \) words \( w_n \):
   
   a) Choose a topic \( z_n \sim \text{Multinomial}(\theta) \).
   
   b) Choose a word \( w_n \) from \( p(w_n | z_n, \beta) \), a multinomial probability conditioned on the topic \( z_n \).

The LDA model is represented as a probabilistic graphical model in Figure 1. As the figure makes clear, there are three levels to the LDA representation. The parameters \( \alpha \) and \( \beta \) are corpus-level parameters, assumed to be sampled once in the process of generating a corpus. The variables \( \theta_d \) are document-level variables, sampled once per document. Finally, the variables \( z_{dn} \) and \( w_{dn} \) are word-level variables and are sampled once for each word in each document.

![Figure 1: Graphical model representation of LDA. The boxes are “plates” representing replicates. The outer plate represents documents, while the inner plate represents the repeated choice of topics and words within a document.](image-url)
We can view LDA as a dimensionality reduction technique, but with proper underlying generative probabilistic semantics that make sense for the type of data that it models.

2.2 Indicators of Identifying the Research Fronts

LDA can extract the latent topics from big amount corpus which contains many research front topics. So how can we detect them accurately and quickly? We try to structure the indicators to identify them. The paper proposed the strength and novelty of topics as the indicators. Strength can reflect the high attention by researchers, and novelty can reflect the latest studies. To illustrate the strength and novelty of topics, we introduce the concept of topic firstly.

Topic is a series of items \(w_i\) with its weight \(p(w_i|z)\) which can reveal the semantic meaning of topic. It represents in means of vector:

\[
\text{z} = ((w_1, p(w_1|z)), (w_2, p(w_2|z)), \ldots (w_n, p(w_n|z))) \quad \text{Formula (1)}
\]

Figure 2 is the text expression of topic:

\[
\begin{pmatrix}
T_{t_1} & T_{t_2} & \ldots & T_{t_n} \\
\begin{pmatrix} p_{t_1} & p_{t_2} & \ldots & p_{t_{n+1}} & p_{t_{t_n}} \end{pmatrix} & \begin{pmatrix} p_{t_2} & p_{t_2} & \ldots & p_{t_{2n+1}} & p_{t_{2n}} \end{pmatrix} \\
\ldots & \ldots & \ldots & \ldots & \ldots \\
\begin{pmatrix} p_{t_{k-1}} & p_{t_{k-1}} & \ldots & p_{t_{k(n-1)}} & p_{t_{k-1n}} \end{pmatrix} & \begin{pmatrix} p_{t_k} & p_{t_k} & \ldots & p_{t_{kn-1}} & p_{t_{kn}} \end{pmatrix}
\end{pmatrix}
\]

Figure 2: Text expression of topic.

Strength of topic is the indicator to access the topics whether it can be hot topics. In general, strength is the ratio of the overall document amounts to the amounts of one topic involves. The formula is following:

\[
\theta_j = \frac{\Sigma_d \theta_j^{(d)}}{M} \quad \text{Formula (2)}
\]

\(\theta_j\) is the value of strength of one some topic. \(M\) represents the total amount of documents. \(\theta_j^{(d)}\) represents the weight of topic \(j\) in the document \(d\). The weights are more high, the more important. Hence, we can calculate the strength of the topic and plot the trends to illustrate the topic.

Novelty of topics can reflect the average publication time. If one topic publishes more recently, the higher degree of the novelty. Research fronts are the latest scientific findings and research issues, so they are more novel than other topics. In this paper, we calculate the novelty by counting the average publish time.

2.3 Workflow of Detection of Research Fronts

Figure 3 is the workflow of the detecting of research fronts based on LDA. It includes three periods, which are data pre-processing, extracting the topics based on LDA, and identifying the research fronts.

In the data pre-processing period, we collect data by specific retrieval strategy from literature database. Then remove the duplicate records, delete incomplete records, and extract “Abstract” field. Abstracts are the source of corpus. At last, remove stopwords and do lemmatization, so the corpus can be constructed.

In the period of extracting the topics based on LDA, it focuses on the three parameters estimation: the Dirichlet hyperparameters \(\alpha\) and \(\beta\), and the number of topics \(K\). In this paper, \(K\) is set by the Perplexity of topic model, and when the value of Perplexity is smallest, \(K\) is
the optimal value. For the hyperparameters $\alpha$ and $\beta$, they are set as $\alpha = 50/K$, $\beta = 200/W$ (W is number of words in the vocabulary).

In the period of identifying the research fronts, it needs to calculate the strength and novelty of each topic. When the strength and novelty of one topic reach the threshold, it can be identified as research front.

Figure 3: The workflow of the detecting of research fronts based on LDA.

3 Empirical Study

3.1 Data Pre-processing

We choose Web of Science$^{\text{TM}}$ as the data source and adopt “subject categories” to retrieval the documents of the discipline of medical informatics. Web of Science$^{\text{TM}}$ contains 252 subject categories, and “medical informatics” is one of them. From 2007 to 2016, there are 35981 records under the subject categories of medical informatics (Retrieved on January 3, 2017).

In this paper, the corpus need to include title, keyword, abstract, and year. Therefore, we adopt the Article, Proceedings Paper, Review, and Reprint, which amounts 33870 records and accounts for 94.13% of total number.
3.2 Results

We perform parameter estimation using collapsed Gibbs sampling (Griffiths and Steyvers, 2004). This study uses the R language to achieve topic extraction based on LDA. Figure 4 is K selection results, showing the Perplexity of the corpus for different settings of the number of topics. With the increase of number of topic, the Perplexity of the model gradually decreases. When the number of topic is 62, the model has the lowest Perplexity, which is the best fitting result. Furthermore,

![Figure 4: Trendline of Perplexity](image)

After extracting 62 topics, we calculate the strength of topic, the result is shown in figure 5.

![Figure 5: strength of topics](image)

In figure 5, the height of bar represents the value of strength, and the dotted line is the average of strength of 62 topics. The average of strength is 2.17. Topic 4 is the “Medical text knowledge extraction” with the highest strength. Topic 1, 3, 4, 9, 19, 21, 31, 41, 48, 54, and 57 are with higher strength. There are 22 topics which strength is higher than average.

In the aspect of novelty of topics, we adopt boxplot to visualize. In figure 5.5, the boxplot contains one rectangle, dotted line, and the tow borderlines. The spacing between the different parts of the box indicate the degree of dispersion spread and skewness in the data. In addition to the points themselves, they allow one to visually estimate various L-estimators, notably the interquartile range, midhinge, range, mid-range, and trimean.
To calculate the novelty of the 22 topics which strength is higher than average, figure 6 shows that the average public time of 22 topics is 2012. The public time of topic 3, 8, 19, 22, 31, 34, 53, 54, and 58 is 2013. In the view of novelty, topic 3, 4, 8, 19, 20, and 34 is more novelty than others, which active around in 2015.

Combine the strength and novelty, we set the research fronts as its strength is higher than average and public time is 5 recent years. Hence the paper identifies 19 research fronts in medical informatics shown in table 2. Due to the limited space, we cannot present all the automatically extracted top words for all topics. Instead, we manually tag all the topics with labels by summarizing the ranked words.

To access the results, the paper adopts expert consult. We invite 7 experts in medical informatics to score the result by Likter five scores. The experts are mainly professors who engaged in medical informatics research many years, respectively from Peking University, JiLin University, ZhongNan University, China Medical University, and Institute of Medical Information, CAMS&PUMC. The result of accessing shows that 17 research fronts have been approved by experts.

4 Conclusion

We have proposed a method of detecting research fronts based on LDA. LDA can realize the extraction of topics from corpus accurately. Many current methods of detecting research fronts are lack of the indicators to identify research fronts. For the problem, we construct the indicators-strength and novelty. In the empirical study, we detect the research fronts of medical informatics, and the results shows that there are 19 research fronts, beside 17 of them have been approved by experts.

However, this method has some limitation. One is the threshold of the strength and novelty, which settings need to be manually involved. Anther limitation is that the corpus is only form literature database. Granted, using one or another data source may condition the results of the study. Database coverage is determinant for obtaining more or less comprehensive results. Due to the research fronts exist in many carriers, such as patent, tender and even scientific blog on the web. Future studies may therefore lead us to integrate multiple text sources to detect research fronts, so as to arrive at comparative results. In addition, some future research based on the method could be incorporated and some potential applications.

Abstract
This study presents an attempt to systematically integrate domain knowledge into the algorithmic classification of large text corpora. Taking the societal problem of ‘obesity’ as case study, we build an ontology for obesity and integrate this ontology into topic modelling algorithms. The idea is that for the purpose of mapping a given societal issue with a large collection of scientific texts, the combination of a domain ontology and topic modelling may facilitate the tasks of delineating the relevant corpus, classifying it into topics and interpreting the resulting topics. Preliminary results show that the topics obtained adding an ontology to topic modelling are more meaningful. Considering the need of aligning the research with societal needs, our work goes into the direction of providing a tool to map the topics research outputs in mapping categories that are easier to interpret from a user’s perspective.

Introduction
The issue of mapping science and having a bird’s eye view of scientific production is one of the core problems of scientometrics (e.g. Börner, Chaomei & Boyack, 2003). Yet the increasing policy demands for aligning scientific endeavors with societal needs (Cassi et al. 2017) requires methods that allow policymakers to analyse research corpora with a societal problem perspective (Wallace & Rafols, 2015).

Recently, several techniques have been proposed to coarse grain the outputs of scientific production, by obtaining both maps of words (Van Eck & Waltman, 2010) and by using statistical methods to retrieve topics in large datasets (Griffiths & Steyvers, 2004). Albeit useful, these methods do not use available human knowledge in their algorithms. It is therefore poorly understood how their results differ from expert-informed classifications of scientific documents into clusters of research topics.

In the last years, preliminary steps have been made towards the integration of semantic technologies (e.g. human-based ontologies) and algorithmic clustering (e.g. machine learning methods) for the classification of large datasets (Andrzejewski, Zhu & Craven, 2009; Chhatbar, 2010). However, the applicability of the aforementioned methods is still limited, mainly because of three factors: i) domain knowledge is not usually embedded in a systematic way, so that expert knowledge is enforced locally only for a subset of concepts in the corpora; ii) models developed so far assume in general that there exist only one ‘best’ representation of knowledge, without taking into account that experts with diverse background may have different descriptions of the same domain; and finally iii.) the performance of those methods against the array of possible unsupervised alternatives is yet to be proven.

A representation of knowledge that aims at capturing a comprehensive view of scientific production must leverage on plural representations of a scientific domain, which means taking into account a variety of views. Comprehensiveness and pluralism become especially regarding
topic mapping tools for policy, given that interpretation of knowledge landscapes are dependent on the framing of the topic.

In this case study of obesity, the challenges above are tackled by, firstly, gathering the knowledge of heterogeneous experts through direct interviews; secondly, by formalising the knowledge from interviews into an ontology centred on the concept of ‘obesity’; and finally, by embedding such ontology into topic modelling algorithms, in order to produce an automated topic mapping.

Methods
The present work aims at incorporating a domain ontology into topic modelling (TM) algorithms, for the case of ‘obesity’. Let us first introduce the concepts of ontology and TM.

An ontology is a formal description of the concepts in a certain domain (where a domain is the given fragment of reality that the ontology aims to represent), the relationships between them and the properties of each of the concepts. An ontology also allows representing particular instances of a concept (i.e. individual cases??) and the relationships between them. For example, in the obesity ontology, Disease is a concept, and Obesity is an instance of Disease. A disease may be treated following a certain treatment: Treatment is another concept in the ontology, related to the Disease concept, through relationship canBeTreated. The ontology also allows us to represent that Obesity may be treated by following a VeryLowCalorieDiet, where VeryLowCalorieDiet is an instance of Treatment.

However, ontologies go further than just carrying out the descriptions listed above. On the one hand, given an ontology, it is possible to infer new knowledge by using a reasoner. On the other hand, it is possible to define axioms (i.e. restrictions) in the manner how the concepts and relationships relate to each other, so as to obtain more accurate representations. An ontology can be formalised and visualised as a graph, where nodes are concepts and edges are the logical relationships that link those concepts.

Topic Modelling (TM) is a field of machine learning that aims at ‘discovering’ the unknown topics to which a collection of texts belongs to (Steyvers & Griffiths, 2007). Generally, the topics are stacks of tightly related words that co-appear consistently in the observed texts. Several techniques have been proposed to detect the topics, but all share the idea that the texts were produced by a stochastic generative model, and aim at recovering the parameters of the model that best explain the observed data. In our work, we use Latent Dirichlet Allocation (LDA) (Blei, Ng & Jordan, 2003), which assumes a text generative model that has a Dirichlet distribution for the probability of linking topics to documents and words to topics.

The steps outlined below describe the tasks of building an ontology dealing with the theme of obesity, embedding it into LDA and retrieving domain-knowledge informed topics.

Step 1: Identification of the corpus
We used in our study the obesity corpus identified in Cassi et al. (2017) which was delineated with the following procedure. Firstly, publications with MeSH term matching the search obes* in MEDLINE/PubMed during the 2000-2013 period were retrieved. Secondly, the same search directly on the WoS Core Collection was performed. Finally, from all micro-clusters based on direct-citation paper clustering of all WoS for 2000-2013, those clusters where at least a 10% of papers tagged as obesity (according to MeSH or WoS Topic) were retained.
Step 2: Creation of an ontology around the concept of Obesity

To create the obesity ontology, two main sources were used. On the one hand, we used the information obtained by checking relevant literature, ranging from Wikipedia to scientific publications, including medical websites and World Health Organization (WHO) documents. On the other hand, we interviewed four experts to obtain their specific input on the topic. These experts came from four different fields of expertise: nutrition, medicine, biology and health policy.

All the interviewees agreed that obesity is a multifactorial disease and that it needs to be tackled with diverse approaches. Therefore, the ontology is not limited to the medical perspective: it has been informed by articles on marketing and its impact on food consumption, lifestyle, psychological, and nutritional perspectives, among others, in order to capture a comprehensive and plural view on. The graph of the resulting ontology is shown in Figure 1.

Step 3: Integration of the domain ontology with topic modelling

Previous works have focused on the effort of integrating some expert knowledge onto topic modelling. Logic LDA for instance is aimed at incorporating first order logic into topic modelling based on LDA (Andrzejewski, Zhu, Craven, & Recht, 2011). However, the task of injecting a whole ontology onto some topic modelling algorithm remains unaccomplished so far. Here, we address this challenge by decomposing the ontology built in Step 2 into modules that are fed to Logic LDA in the form of its native rules (i.e., . . . ), by adopting the following approach. As outlined previously, an ontology can be encoded in a graph, where nodes are
concepts and links are logical relations among those concepts. In turn, the resulting graph can be analyzed by means of the tools of network theory, such as, for instance, community detection algorithms. We thus partitioned the ontology graph into communities of closely related concepts by using the Infomap clustering algorithm (Rosvall & Bergstrom, 2008). We then used the resulting clusters to build rules aimed at guiding LogicLDA topic discovery. Specifically, we retrieved 33 clusters of highly connected concepts and, for each of these clusters, we enforced a LogicLDA ‘seed’ rule that enhanced the retrieval into the same topic of groups of words in the same ‘conceptual community’.

Step 4: Analysis of topics

Last, we analyzed and ‘annotated’ by hand the topics produced by blind LDA and its semantically (i.e. ontology) enhanced version through LogicLDA, respectively. TM performed via LDA (both in its blind form or in the semantically enhanced one) identifies topics that are simply a collection of words. The task of linking such lists of words to a specific theme is left to the user/interpreter. Our work aims precisely at facilitating this task, by devising a method that produces topics already aligned with the knowledge encoded in an ontology. Our analysis verified that the topics retrieved via the semantically enhanced LDA were easier to categorise.

Results and discussion

Figure 2 shows a summary of the topics extracted with blind LDA (left) and its ontology semantically enhanced version (right). In both cases, we chose to detect 33 topics, corresponding to the number of tightly linked clusters in the ontology. The first result to highlight concerns the overall structure of the topic map. Indeed, the inclusion of the ontology substantially changes the structure of the topics retrieved. In Figure 3 we show a matrix reproducing the pattern of word pairs co-occurrence within topics: each row/column of the matrix is a word, darker elements of the matrix imply a more frequent co-occurrence in the topics of the row/column word pair. The matrix on the left shows the results of standard LDA, while the matrix on the right those of the ontology enhanced one. The order of words in the two matrices is preserved. As it can be observed, the co-occurrence patterns visibly vary between the two cases, with the ontology-enhanced LDA showing higher word co-occurrence.

The second result to stress is connected to the content of single topics. When the number of topics exceeds the heterogeneity of the corpus, LDA has the shortcoming of yielding some transversal topics that gather all texts which are difficult to classify. These transversal topics do not focus on some specific theme and are hard to interpret. We show in Figure 2 those transversal as uncoloured circles. The ontology enforces a given scientific perspective and reduces the number of ‘transversal’ topics that are retrieved by LDA. Since the ontology forces LDA to find topics related with the themes treated in the ontology, the number of transversal topics decreases from 5 to 3 when using the ontology.

The third notable result has to do with the focus of the topics: the introduction of the concept dealt with by the ontology forces some macro-themes uncovered by blind LDA to become much more defined. This is the case, for instance, of the topic dealing with policies, that becomes specifically an education policy topic when introducing the ontology.
Figure 2 The topics extracted with blind LDA (left) and the semantically enhanced version of LDA (right). For each topic, we show the first five characteristic words. The size of the dots is proportional to the topic incidence in the corpus, transversal topics have no filling.

Figure 3 Matrix of word cooccurrence in topics, for the blind LDA (left) and semantically enhanced LDA (right). The matrix shows co-occurrence for all pairs of words: darker tones of blue imply a more frequent occurrence of the word pair across topics. Since the sequence of words in the matrices is the same, comparing the two matrices allows to appreciate the difference between the overall structure of the topics in the blind LDA case and in the ontology enhanced one.

Conclusions
We presented in this paper a first attempt at integrating a domain ontology into LDA topic modelling. We did so by focusing on the issue of “obesity”, by building our own ontology on the theme and by leveraging on LogicLDA to enforce the logical constraints encoded in the ontology.

Our preliminary results suggest that incorporating domain knowledge into topic modelling is indeed viable and that the results obtained via standard LDA and its ontology informed variant do differ. Furthermore, we found that the classification of texts obtained with an ontology is
easier to understand (since they are classified according to scientific perspectives) and that the selection of the logical clusters in the ontology enhanced the retrieval of some specific subtopics of interest (since the ontology encompasses a plurality of views).

In the light of these promising preliminary results, our goal is now to fine tune and systematise the method devised, in order to offer a tool to categorise scientific research in a way that is easier to interpret according to the specific societal needs represented by the ontology.

Abstract
Big data has been attracting wide attention due to its great importance. The rapid development of big data in recent years has led to a large amount of publications containing the achieved knowledge of this area. To study the intellectual structure of the related research about big data, a retrospective bibliometric analysis is conducted based on the Web of Science databases. 13673 papers and 8016 citation links are collected. The LDA topic model are used to detect the topic distribution of big data research area. 11 topics about big data technology, application and security are found. Island algorithm is applied to find the most influential 28 research communities from citation network, and these communicates are labelled through topic distribution rather than traditional way of single tag. Labelling each cluster by topic distribution can reveal the research content for sub-structures, which reflects a much more comprehensive picture of big data research area and provide a valuable reference for researchers to understand the overview and present situations in this field.

Introduction
Structured and unstructured data is produced massively in scale under the constant development of information technology and internet environment. Relevant statistics show that a social networking site, Twitter, has a record 500 million pieces of daily new Tweets (Singh et al., 2015). Those data, large scaled in various types and updated very frequently, can no longer be explained by traditional definition of data, which results in the birth of ‘big data’ at the right moment. As early as 2001, Laney, an analyst at Gartner,
a US information technology consultancy, analyzed the characteristics of massive
growth data from three perspectives: volume, velocity and variety (Laney, 2012). Since
then, big data’s value density (LaValle et al., 2011), authenticity (Raghupathi et al.,
2014), complexity (Fan et al., 2013) and other features are further explained, and the
value of large data has been constantly recognized. The United Nations Global Pulse,
in a 2011 report, points out that big data has greatly improved the efficiency of decision-
making in key areas of social development such as health care, employment, and
economics, but the challenges that it brought with are not to be overlooked (UN Global
Pulse, 2012). At present, the government, academia and the business community
maintain an intensively increased attention to big data. Big data has become a new
research area which develops rapidly and produces results fruitfully.

In this study, a bibliometric analysis on big data research area is to be made based on
big data research papers retrieved from Web of Science database without timespan
settings which enables to explore initiating papers with big data concept. The analysis
methods mainly include LDA topic model and citation network analysis. LDA topic
model is used to extract the topic distribution of the whole research area; meanwhile,
citation network analysis is used to detect highly attractive communities of big data
research. This study also proposes a new method to integrate the topic model analysis
results and structural analysis results of citation networks. This method can effectively
reveal the communities which attract widely concern.

This paper is organized as follows: the literature review part introduces big data
research and related methods, such as citation network analysis and content based
citation analysis; Methodology explains data source, retrieval strategy, LDA topic
model, communities detection algorithm and a proposed method that integrates topic
model and citation network analysis; Results shows the topic distribution of big data
research area, as well as the topic distribution of highly impact communities which are
detected. Conclusion sum up the whole study and discussion presents views to future
related research.

Literature Review

Brandl, a scholar of University of Vienna, in his early paper on big data published in
2004, proposed to use knowledge mining to find economic data and forecast the trend
of macroeconomics (Brandl B., 2004). In September 2008, Nature published a special
research theme on big data, and a number of articles discussed the influence of big data
on modern life and scientific research (Lynch, 2008). In 2012, many international
organizations and government departments issued initiatives and reports related to big
data, such as ‘big data, big impact’ report released the Davos Economic Forum (World
Economic Forum, 2012) and ‘Big Data Research and Development Initiative’ issued by
The Obama Administration (Executive Office of the President, 2012). These initiatives
and reports have aroused widespread concern in society and have produced a great deal
of research findings. Singh et al. (2015) once used scientometric method to analyze big
data studies in terms of major countries, institutions, authors, grow of output, authorship
and country-level collaboration patterns and top publication sources. They used the
distribution of papers’ classification and some selected control terms to analyze the
subjects of big data research area. Singh’s study retrieved and analyzed only 1416 papers in WOS and 6810 papers in Scopus from 2010 to 2014. But papers related to big data have rapidly increased to more than 10,000 by the year of 2016. Fig. 1 shows the time distribution of published research papers on big data. It is found that research papers on big data begin to grow rapidly since year 2012. Thus, this paper aims to update the previous research study and to effectively reveal the current situation of big data research area.

Citation networks are sequentially dependent: more recent publications can only cite older ones. Citing behavior among scientific publications can reveal dynamic knowledge flows. So the complex and inter-connected structure of the citation networks has been utilized for studying the knowledge structure of a given research field. Using citation based approaches to analyze the intellectual structure of science has a long history. Some outstanding former studies used clusters of highly-cited papers to represent the scientific specialties and explored the entire specialty structure of science (Small and Upham, 2009) and research fronts (Aris et al. 2009). Other approaches include co-citation analysis among highly cited authors, journals, or keywords. Mapping all the scientific literature, sometimes so called knowledge domain visualization has gained increased attention in recent years (Chen 2003). Meanwhile, with the fast development of social network analysis, more and more approaches for whole network analysis have been employed (Snir & Ravid 2016; Tang & Tsai 2016; Tang et al. 2016). Since Ding et al.(2014) introduced the content based citation analysis, text mining methods has been widely used in citation network analysis (Chen 2017; Jha et al. 2017; Kim et al. 2016).

**Methodology**

*Data pre-processing*

The data for the present study were acquired from the on-line edition of the science citation index-expanded (SCI-E), social science citation index (SSCI), and conference
proceedings citation index (CPCI) database published by Thomson Reuters. A set of publications (articles, reviews, proceedings papers and software reviews) related to big data were generated by searching the term ‘bigdata’ or ‘big data’ in the bibliographic field “TS” of the ISI Web of Science database. Papers about large scale data array and large scale data analysis were also included, but the meaning of big data mentioned in these papers was far way different from those in current researches. After repetitious papers eliminated, 13673 papers were collected from 4958 journals, proceedings, and books. The data were retrieved on March 25, 2017.

To detect the topics of big data research area, title, abstract, keywords and keywords plus are used. Citations among the 13673 papers are also cleaned for analysis. Citation network is acyclic because a paper can only cite early published papers. As a result, all arcs in the citation network point backwards in time. However, it was found that there were two exceptions: some papers published earlier cite papers published later; also, some papers are of self-cited. The reasons for the former exception have been discussed by Rousseau and Small (2005), who gave an extreme case which is called Escher Staircase phenomenon. The later exception is caused by the mistakes from Web of Science or by authors who have made papers self-cited. In this study, citations of the former exception were re-arranged so that they are chronically in order according to the publication time; citations of the later exception were removed. Finally, 8016 citations were collected for the generation of citation network.

Research methods

**LDA topic model.** The topic extraction of the text content is to select the appropriate text content topics and characteristic vocabulary in order to describe characteristics of the text content. Topic model, a probability generation or production model of text content, such as latent semantic analysis (LSA) (Deerwester et al., 1990), probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) and LDA (Blei et al., 2003), which can express the meaning of the text to an extreme and solve semantic relevance problems among vocabularies, topics and text by simulating human thinking process, is the most commonly used text topic extraction method. LDA topic model adopts Dirichlet distribution, simplifies the derivation of the model and avoids the over-fitting problem of the LSA and PLSA models (Hofmann, T., 2001). Therefore, it has a good priori probability hypothesis that the number of parameters does not grow linearly with the increase of the number of texts with a strong generalization ability and excellent performance in algorithm complexity algorithm complexity and exhibition effect, the derivative model is widely used in the fields of topic mining, classification clustering, retrieval and topic evolution of text analysis (Yang et al., 2016; Tan et al., 2016; Morchid et al., 2017). This study uses the Incremental Hierarchical Dirichlet Processes to realize topic detection (Gao et al., 2011).

**Highly impact communities detection from citation network.** Island algorithm is applied to detect communities (clusters) from citation network in this study. According to Nooy et al. (2011), an island cluster is a maximal sub-network of vertices connected directly or indirectly by lines with the value of vertices in the cluster greater than those outside
the cluster. Island algorithm has its advantage in mining the cluster in network without basing on one single standard. It concerns not only the size of sub-network, but also vertices of greater importance than those around communities. This is helpful when to detect topics that are not so hot but has formed to a large scale, especially when to analyze exceptionally large-scale connected component.

For example, in a citation network composed by research papers on information retrieval, these papers form a large connected component which are about algorithms and user behavior. In this largely connected component, all papers about algorithms are highly cited (e.g. all of their citation scores are larger than 100), whereas those on user behavior are lower cited (e.g. the largest citation score is 50). To detect communities in such a big component, if a standard threshold of citation count is set at 70, community of user behavior will be ignored; whereas, if the standard threshold is lowered at 30, though the community about user behavior shows up, the community of algorithms will be severely expanded to such an extent that many non-essential research papers will be flooded into the network. Fortunately, island algorithm can solve this problem. It can hold many highly impact communities at the same time, and each of them has similar size and is formed by research papers with higher citation scores than those papers who around the communities. In this paper, vertex island algorithm will be used (Nooy et al., 2011).

**Topic distribution of Clusters.** The LDA topic model can be used to find the distribution of words in topics and the distribution of topics in documents, that is, it can extract topic from words and documents respectively. In a literature cluster, the weight of each document is different (e.g. they have different betweenness centrality), so the weights of topics in each cluster cannot simply be the sum of weights of each topic, but need to be converted at first. Suppose that cluster C contains n documents, i.e. C=(d₁, d₂, ..., dᵢ), and these documents are represented by m topics, let the weight of the document dᵢ is wᵢ, and the weight of dᵢ for topic k is pᵢk. Let Xₖᵢ as weight for topic k after the document dᵢ is converted, then we get

\[
\begin{bmatrix}
X_{11} & X_{12} & \cdots & X_{1m} \\
X_{21} & X_{22} & \cdots & X_{2m} \\
\vdots & \vdots & \cdots & \vdots \\
X_{n1} & X_{n2} & \cdots & X_{nm}
\end{bmatrix}
\begin{bmatrix}
w_1 \\
w_2 \\
\vdots \\
w_n
\end{bmatrix}
= 
\begin{bmatrix}
p_{11} & p_{12} & \cdots & p_{1m} \\
p_{21} & p_{22} & \cdots & p_{2m} \\
\vdots & \vdots & \cdots & \vdots \\
p_{n1} & p_{n2} & \cdots & p_{nm}
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
\vdots \\
x_n
\end{bmatrix}
\]

Besides, the calculation of the weight Yᵢ of cluster C in topic i is as the following:

\[
Y_i = \sum_{k=1}^{n} X_{ik}
\]

Traditionally, analyst always gave each cluster only one label of its content. For example, in Citespace, 4 algorithms such as LIS, TF*IDF, LLR and MI are used for labelling one tag (Chen 2017). Actually, one cluster is a sub-field of a research area. One tag labelling can help to filter out unnecessary information and find out main subject of a cluster. But one cluster, i.e. one sub-field always cover more than one subject. This study tries to use more tags to show the topic distribution of every cluster, which can attribute to a comprehensive analysis.
Result.

**Topic distribution**

11 topics were selected finally after a number of trials. As higher-frequency keywords in each topic were given in the result of LDA model analysis, the topics can be named according to these keywords as it is shown in Table.1. In general, current research on big data mainly focuses on three categories- core technology of big data, application of big data in many areas, and personal privacy protection in big data environment. In the category of core technology, the main research topics at present include Distributed System, Algorithms, Database, Semantic web and knowledge discovery, and Machine learning. In the category of big data application, the related topics include Smart city, Medical science, Social media and mobility network, Remote sensing and other applications area such as business, education and manufacturing. Scholars mostly concerned about the security issues in the big data environment focus on the protection of personal privacy.

The distribution of each topic in the dataset is shown in Figure 2. The length of the bar represents the cumulative frequency of the keywords in the topics. It can be found in Figure 2 that the topic related to technology accounts for the majority of the current research on big data, and the topics of Distributed System, Algorithms, and Database are the largest in numbers.

Figure 2. The distribution of each topic in the dataset

To the topics related to technologies: (1) Distributed system. MapReduce is an important program for big data concurrent applications and is a core component of Hadoop. Distributed computing programming can be implemented rapidly on Hadoop platform through MapReduce, so the research in the topic of Distributed System is closely related to MapReduce and Hadoop. (2) Algorithms. As there are more information dimension in big data, a large number of papers focused on high-dimensional data processing in the topic on Algorithms. For example, there are many papers on implementation of efficient cluster in big data. (3) Database. The traditional database cannot meet the demand of storage and processing of large scale data in big data environment. Therefore, big data solutions based on NewSQL and NoSQL database received wide attention and scholars studied on big data storage and analysis through new database platforms. (4) Semantic web and knowledge discovery. In traditional information environment, the level of collaboration between Semantic web, Linked data communities and the Applied Ontology community has been much less than expected whereas big data can well connected these communities and provide opportunity for the development of Semantic web. So the topic related to Semantic web becomes an important domain among current big data research. (5) Machine learning. The core of big data is to use the value of data. Machine learning is key technology of using data value and is thus indispensable for big data. For machine learning, the more the data is, the more chances are to improve the accuracy of the model. Big data provides new experimental environment for machine learning. At the same time, machine learning, as important data analysis technology, has attracted attention by
To the topics related to application: (1) Smart city. The infrastructure including smart grid, urban energy management, real-time monitoring and forecasting of urban traffic flow needs the strong support from big data. Big data application in Smart city is most prominent. (2) Medical science. There are many fruits of big data application in the field of Medical science. At present related big data case sets on diseases have been established, which can support dealing with emergency situations and improvement of nursing quality during the patient care process. (3) Social media and mobility network. A large amount of data produced during the wide application of social media meets the core features of big data such as large volume, rich variety, low value density, and fast processing speed. As digital footprint in human life and communication, social media and mobility data have become an important kind of big data. Social media data can provide data basis for research on human behavior, policy influence and economic development. (4) Remote sensing. The data produced in remote sensing activities is rich and typical characteristics of big data. Big data technology provides important solutions for complex remote sensing data processing in the fields of weather forecasting, water resources monitoring, and environmental protection. (5) Other application areas. Big data can be also used in business and education. Big data and business intelligence is paid more attention to improve strategic decision making efficiency in the business field. How to use big data to improve higher education quality and student information literacy is hot spot in the field of education. 

To the topic about security issues. The information and privacy risks generated with the continuous development of big data are rising. Research on risk control is significant. At present, privacy protection in the big data environment is in initial stage. The related research focused on specific technical means and tools.

**Communities in Citation network**

![Figure 3. Mapping the clusters in citation network](image)

Here we use the betweenness centrality scores for island cluster detection. The betweenness centrality of a node in the network measures the importance of the position...
of the node in the network. Those paper that highly connected to other nodes such as hubs or positioned between different groups of nodes may have high betweenness centrality scores (Chen 2017).

Figure. 3 is the mapping of the whole network and island clusters. 8635 papers are not cited by other papers, in other words, only 5058 pieces of papers are paid by researchers’ attention and cited. There are 300 connected components with size >2, and the largest component is constructed by 4334 papers. 28 clusters are extracted by using island algorithm as it is shown in the right part of Figure 3. Size of each cluster is set in a range from 5 to 15. These 28 extracted island clusters are 28 communities that attract more attention than other communities. Labeling these clusters is next step for analysis.

**Figure 4. Topic distribution of 28 communities**

The topic distribution of communities as it is shown in Figure 4. All the communities can be classified into 3 types. All the papers of the first type are focused on one single topic. For example, community 17 in Figure 4 which consists of 12 papers only focused on medical science. Papers belonged to this cluster discussed how to use big data to improve Emergency Care, cardiovascular care, in the Care of Children, big data application in European health systems and databases are diverse and fragmented. Technologies are scarcely mentioned or discussed.

To the second type, such as community 1 in Figure 4, mainly focus on a few topics. Though the weight of the topic “medical science” is the largest, unlike cluster 17, papers of this cluster are more concerned on how to obtain information from Internet and social media to improve medical research and healthcare. For example, MacFadden et al. (2016) developed a Web-based/mobile platform for aggregating, analyzing, and disseminating regional antimicrobial resistance information. Lee (2016) Harnessing Spatial Big Data for Infectious Disease Surveillance and Inference.

To the third type, such as community 27, the research contents nearly relate to all topics. Community 27 includes 11 papers which have high scores to all the topics. It is found that most of them are researches at a macro level which mainly focus on the technological changes by big data environment and its future, framework of
This study explores the intellectual structure of the big data research through examining papers indexed by Web of Science. 13673 papers and 8016 citation links among them are collected to build a citation network. This study use LDA topic model to analyze the topic distribution of the dataset, and classify different topics into three categories: core technology, application and security issues. The core technology in big data research mainly focus on Distributed system, Semantic web and knowledge discovery, Machine learning, Algorithm and Database. Application areas include Smart city, Social media and mobility network, Remote sensing, Medical Science and other application areas such as business, education, and so on. Besides, security issue is mainly about privacy security.

Through island algorithm, 28 island clusters are detected from the citation network. These clusters are communities who attracted higher attention in some sub-fields and form connected components at large scales. Then by using topic model, topic distribution of each cluster is attained. Though some cluster has papers on single one topic, most clusters cover more than one topics. Compared with the traditional way of using one tag for cluster labelling, more tags result in showing a comprehensive picture as well as the diversity feature of big data research.

**Discussion**

LDA topic model can detect the topic distribution of a research area, but how these detected topics are linked to each other? To tackle this question, citation network analysis can be adopted to integrate with LDA topic model. Citation network reflects real connection in the knowledge diffusion process. If to put focus on topic co-occurrence in island clusters, a much more specific and real connection among topics will be reflected. Take researches on technological application of a field for example,
if all the topics are classified into two categories: one is technology and the other is application (privacy security is also included), topic co-occurrence will be detected, as it is shown in Figure 5. It is found that those technologies are widely used in different areas.

![Figure 5. the bipartite graph of topic co-occurrence](image)

LDA topic model which is able to detect the distribution of dataset, but it fails to determine the existence of real relationship among papers. The same word or topic can only mean the similarity may exist between different papers, but can never testify knowledge exchanges happen in real world. Citation reflects real research communication but analysis based on citation network does not take research content into account. Thus, if to combine LDA topic model and citation network analysis, a better analysis result can be yielded. However, interpreting the results requires circumspectness due to some limitations of this study. In addition to datasets from Web of Science, open access journals and online publications are also can be considered to reflect the true structure of big data research field better. Also, the number of topics and island clusters depends on pre-set parameters. Proper number of topics and island clusters needs to be determined by repetitious trials, which will influence the research efficiency.

Introduction

Citation analysis is a bibliometric analysis method which reveals the quantitative characteristics and laws of scholarly publications. It involves the use of mathematical and statistical methods to analyse citations within journals, papers, authors, and other references. Citation analysis has seen substantial theoretical and practical progress over several decades of development, and has been widely applied to evaluate scientific knowledge, identify scientific models and detect new frontiers which being explored by the scientific community.

Traditional citation analysis methods and tools are overly dependent on citation databases, which have the following drawbacks:
1. All citation acts are treated as equally important;
2. All kinds of statistical indicators are based on specific instances of reference, which are annotated only by the author;
3. Citation databases can only be used to reveal citation relation between different papers, but fail to reflect any deeper relationships among them.

Motivations and behaviours related to citation have been analysed by researchers from various angles. Content-based citation analysis method has also been proposed by Ding et al. (2014). In this paper, we propose a new citation analysis framework based on ontology and linked data; our goal is to enhance the efficacy of citation analysis via semantic web technology.

Related work

In recent years, researchers have begun to introduce semantic web technology to citation analysis in effort to exploit ontology, linked data, and other technologies to improve the description of citation behaviours and motivations. The most representative example is the Semantic Publishing and Referencing (SPAR) Ontologies created by Shotton, Portwin, Klyne, and Miles (2009). CiTO ( Citation Typing Ontology) is the ontology which SPAR uses to describe the relationship between citing papers and cited papers; it provides reference information such as background, method, citation type (e.g., journals, books, reports), peer review, and so on.

Other researchers, for example, Ding, Konidena, Sun, and Chen (2009), have explored the idea of semantic citation to suggest that individuals can use ontology and linked data to describe bibliographic data and publish it to RDF triples. Mahmood, Qadir, and Afzal (2013) combined semantic web technology with credible citation analysis to establish a framework that provides openness and reliability validation for all stages of the citation behaviour lifecycle. The framework makes author, publisher, database vendor work together, thus building a set of reliable reference information while eliminating any false or misleading citation actions in the literature.

Method and process

Any citation analysis method based on ontology and linked data mainly includes the following three steps: First, building citation ontology. Then, using the citation ontology to normalize the reference information and publishing the citation data to citation linked data. Finally, writing specific SPARQL search queries to extract the data needed for citation analysis.

Citation ontology construction

From the perspective of citation analysis, bibliographic citation information and full-text citation information are two independent parts but also two important sources of data that are both necessary for citation analysis. So, we construct the Bibliographic Citation Ontology (BCO) and Full-text Citation Ontology (FCO) based on the bibliographic citation information and the full-text citation information, respectively. This allows us to achieve comprehensive semantic annotation of the citation information at hand.

From the list of references, information such as the author, periodical, document type, year, volume period, and page number are extracted as the classes and properties of BCO. On the other hand, the construction of FCO begins with three aspects: citation function, citation sentiment and citation position. Citation function represents the role of cited work to citing work, such as background development, data support, methodology support, extension, refutation and so on. Citation sentiment express the emotion attitude from citing work to cited work, such as positive, neutral, and negative. Citation position indicates the location of the paragraph where the reference behaviour occurs, such as the "Introduction" or "Conclusion" part of the paper.

An example of the FCO ontology’s classes and properties is shown in Figure 1.
Publishing citation linked data

Then, we can convert citation information to citation linked data according to citation ontology. We recommend D2R as the linked data conversion tool for this purpose. D2R is a very popular tool for linked data publication which serves to convert the massive, relational database format data into linked data RDF triples. After that, we need a database to store citation linked data. Both OpenLink Virtuoso and Apache Jena Fuseki are very good choices.

Citation analysis method implementation

The essence of the new citation analysis is to write the corresponding SPARQL queries, which can be used to extract the citation information of specific dimensions. The search results are then calculated and visualized to analyse the citations per different dimension. For example, co-citation analysis, bibliographic coupling analysis, citation language analysis, citation country analysis, citation age analysis, citation journal analysis, and so on are based on the bibliographic data of traditional citation analysis, while citation function analysis, citation sentiment analysis and citation position analysis are based on a full-text citation analysis perspective.

We write SPARQL queries to extract specific citation information, which is shown in Figure 2. The first SPARQL query is used to retrieve all the publication year information for the references cited by paper A, and the second query to retrieve all references to reference 4, which extends the function of document 4. The search results are then calculated and displayed as the final results. Visualization software (e.g., Graphviz, Relfinder) could also be applied to simplify the display of results. Other dimensions of citation analysis can be implemented according to the same principle. As the quality of data is continually improved, more dimensions of citation analysis can also be achieved in follow-up experiments.

Conclusion

In this paper, we proposed a new citation analysis framework based on ontology and linked data. By combining these technologies into a new semantic web with citation analysis method, we hope to improve the traditional citation analysis method (which relies heavily on citation databases). With the rapid development of semantic publishing and projects like the Open Citation Corpus (OCC), it is possible to mark massive amounts of citation information as machine-readable RDF triples. In the future, we plan to design further experiments to verify the feasibility of the proposed method. We hope that introducing ontology and linked data into citation analysis will yield optimal results while facilitating new technological development and innovations.

Introduction

Many public departments produce or collect a broad range of different types of data during the process of performing their tasks (Zhou & Ma, 2016). The large quantity and centrality of data collected by governments make these data particularly significant as an important information resource for the public (Cai & Xia, 2015). Since 2009, lots of movements have pushed governments to publish relating policies and principles to guarantee the constant development of open government data (OGD) (Ubaldi, 2013). In 2015, State Council of the P.R. China has published a policy for the promotion of the development of big data, which became the guideline for OGD development in China. Under its influence, a lot of local OGD platforms are built. How to get a thorough understanding of the present development of OGD in China has become a focus. Though researchers in China have made efforts to evaluate OGD websites, little attention has been paid to the context and impact of OGD. Thus, this study aims to build a reasonable model that fits the assessment of OGD development in local area level. So that we could get a thorough view of the strength and weakness in the present development of OGD in different areas in China.

Method

The evaluation framework

In order to build such an evaluation framework, we first investigated into the evaluation systems worldwide for their structures and variable selections. We selected 8 evaluation systems as samples: Open Data Census, Open Data Index, Open Data Barometer, Open Government Index, Open Data Readiness Assessment, OUR Data Index, Open Government Budgetary Data in Brazil, Open Data Monitor. These systems are: Firstly, complete and systematic, having a frame for the OGD evaluation. Secondly, they have been applied to OGD evaluations for many years, thus they are practical. Based on the investigation of eight OGD evaluation systems, we proposed a three-layer framework as the basic of the assessing model which was shown in Table 1. The first layer listed three main aspects of the evaluation, while the second and third layers contain specific variables. Readiness focused on the conditions for OGD development from the view of local government. Dataset focused on the nature and qualities of open datasets, including the openness of data, issues of data quality and quantity. Impact focused on the benefits to be gained from the OGD.

Analytic Hierarchy Process

The Analytic Hierarchy Process (AHP) is a general theory of measurement through pairwise comparisons and relies on the judgements of experts to derive priority scales (Saaty, 2008). It was developed by T.L. Saaty in 1971-1975. The study used AHP to get the priorities of all the elements in the above evaluation framework, and used Yet Another AHP Software (Yaahp 10.5) as an important aid to AHP analyses.

Procedure

First, we transferred the evaluation framework into the hierarchic structure in AHP, as was shown in Figure 1. Secondly, we created the expert questionnaire for the pairwise comparisons of the importance of elements that belong to each of the upper level elements in the hierarchy. We chose 10 experts in the area of OGD research in China to fill in the questionnaires. They ranked the importance of each pair elements from 1 to 9. After we collected expert questionnaires, we first examined the consistency of each of the comparison matrices. We abandoned those matrices with the consistency ratio (C.R.) over 0.10, and then calculated the weighted geometric mean of the values in each matrices given by different experts to form the final matrices for

1600
calculating the priorities. After that, we derived the local scale of priorities by solving for the principal eigenvector of the matrix and then normalizing the result. We continued this process of weighing until the final priorities of the alternatives in the bottom most level are obtained. After weighting by the priority of its parent criterion (which for the second-level elements is always equal to unity, the weight of the focus), we finally got the global derived scale for each variables in the model. Yaahp 10.5 was used to make these calculations and guided us to improve the inconsistency if needed.

Figure 1. Hierarchy with weights

Results

Following the above procedure, we first got the final matrices after calculating the weighted geometric mean of values in the same pairwise comparison matrix graded by different experts. We also examined the C.R. in each matrix to make sure of its consistency. Then we derived the local scale of priorities (W_i). After that, we weighted the local scale by the priority of its parent criterion, and got the global derived scale of each of the elements (Marked in Figure 1).

An Initial Evaluation

In order to test and verify the performance of the evaluation model, we selected Shanghai’s OGD platform to carry out the initial evaluation. Table 2 listed the value of each elements in the evaluation model as well as its weight derived from the AHP process. We could find that Shanghai got a good performance in their data access and data quality. But the government in Shanghai need to pay more attention to the support of business utilization of OGD, as well as the protection of personal data. The evaluation also shows that the OGD did not have a great impact on the economy development as well as improving government efficiency.

Discussion

The assessing model has an advantage of analysing the strength and weakness of the OGD development in China. The model could also become a good aid for setting goals or making plans before and during the development. Another advantage of this evaluation model is that it covers the whole developing process, from preparing the overall environment to the impact of OGD on different aspects. Thus, it guaranteed a relatively long period of validity for this model.

We also noticed that the quantity variables have a great influence on the final accessing grade because their values are too large compared with other variables. Thus, in future evaluation process, it is better to find a possible solution to reduce the numerical disparity between quantity variables and quality variables.

Introduction
Bibliometric analysis is a method that is used to describe patterns of publication and national and international strengths and biases in areas of research within a given field or body of literature such as library and information science (LIS) (Aharony, 2011). Johnson (2011) explained that many bibliometric studies enumerate the extent and scope of scientific communication amongst scholars/researchers. According to Ocholla and Ocholla (2007), bibliometric studies are widely used to inform policies and decisions in political, economic, social and technological domains affecting information flow and use pattern within, between and outside institutions and countries. Thus, bibliometric studies are essentially used in evaluation of research and publications in all areas of human endeavors to support decision making by policy makers in governments, organizations/institutions (universities), academic departments and individual scholars/researchers. Furthermore, bibliometric analysis is significantly used in the ranking of research and publications (Meho and Spurgin, 2005) and this has become popular especially in the universities and other academic and research institutes with emergence of different rankings organizations within the past one or two decades (Ani, 2015). Barik and Jena (2016) opined that bibliometric study is focus on evaluation of research performance of authors, institutions/universities, countries or regions in variety of disciplines. Publications counts and citation analysis are two major methods that are used in bibliometric studies. Ocholla and Ocholla (2007) described citation analysis as a tool that is used as quantitative measure of the quality of research and publications.

LIS is a discipline that is fast growing in terms of research and publication globally. Although bibliometric analysis and ranking studies in LIS have a long history in developed countries (Meho & Spurgin, 2005); in Africa, bibliometric studies are limited and insignificant in Africa in spite of the widely applications of these studies by policy makers to support research and publications in line with the emerging global rankings of universities (Ocholla & Ocholla, 2007). Onyancha (2007) vividly captured the poor state of LIS research in Africa by expressing the fear that there is general concern among LIS scholars concerning the growth and development of LIS research in Africa in relation to global perspective. Thus, this present study is intended to fill the knowledge gap in bibliometric studies and would therefore expand the scope of literature in LIS in Africa.

Objectives of the Study
The study was guided by the following objectives:
1. To rank LIS research and publications in African countries in global perspective;
2. To rank LIS research and publications in Africa by country, and
3. To determine trends in LIS research and publications in Africa.

Research Method
The Web of Science databases published by Thomson Reuters were used for the study. The study was limited to the used of Social Science Citation Index (SSCI) and Arts and Humanities Citation Index (A&HCI). The data for the study were obtained by conducting an advanced search using Web of Science Category, WC=Information Science and Library Science, with articles as the document types, and all languages in terms of selection of language of publication of the journal articles. The period of the study was limited to 2010-2016 to depict current state of research globally and in Africa in particular. The data obtained were analyzed globally and by African countries based on the objectives of the study.

Results and Discussion
The results of the study are presented and discussed in this section based on the objectives of the study.

Ranking of LIS research and publications in Africa in global perspective
The results of the study showing ranking of LIS research and publications in Africa in global perspective are presented in table 1. The results revealed that Africa is not represented among the top 10 countries globally in LIS research and publication in all bibliometric indicators that are used in this study (publication counts and citation...
The results of the study showed that South Africa and Nigeria are the foremost countries in LIS research in term of publication counts. The findings of the study are consistent with previous studies that affirmed South Africa and Nigeria as the leading countries in LIS research in Africa (Aharony, 2011; Onyancha, 2007).

### Ranking of LIS research and publication in Africa by country

The results of the study showing the rankings of LIS research by publication counts in Africa are shown in table 2. The results in table 2 revealed that South Africa and Nigeria are the foremost countries in LIS research in term of publication counts. The findings of the study are consistent with previous studies that affirmed South Africa and Nigeria as the leading countries in LIS research in Africa (Aharony, 2011; Onyancha, 2007).

### Ranking of African countries by citation analysis

In table 3, African countries are ranked by citation analysis and the results revealed that South Africa is significantly leading other countries in the number of total citations (1006), followed by Nigeria (229), Kenya (106), Ghana (90) and Uganda (90). South Africa (15) is again leading in h-index, followed by Nigeria (7), while Tunisia (7.58) is the most ranked African country in terms of citations per article and is followed by Ethiopia (7.00).

Trends in LIS research and publications in Africa, 2010-2016

The growth, progress and development of different fields of knowledge are usually determined by annual publication outputs in a given field (discipline) over a period of time. It was therefore pertinent to examine the trends in LIS research and publication in the study. The results of the study are presented in figure 1. The results showed an increasing trend in general or overall annual publication outputs in LIS research in Africa; but analysis by individual country using the three most ranked countries (South Africa, Nigeria and Ghana), showed declining and fluctuating trends. In South Africa, there was an increased in annual publication output until a decline was set in 2015-2016. The declining and fluctuating trend in annual publication outputs was apparent in Nigeria. Similar declining and fluctuating trend was also observed in annual publication output in Ghana. In the case of Nigeria, a recent study by Ani, Ngulube and Onyancha (2017) affirmed fluctuating and unpredictable trend in the annual publication output in LIS research in Nigeria.

Introduction

A plethora of bibliometric indices have been proposed to quantify scientific output. To deal with this storm of valuable indicators, the need arises for a classification scheme of scientists according to multiple evaluation metrics. In this work, we expand upon the concept of the skyline operator (Sidiropoulos, Gogoglou, Katsaros, & Manolopoulos, 2016), and introduce a new indicator, namely the Rainbow Ranking. For this study, we collected data from Microsoft Academic Search (MAS), and extracted full citation data starting from year 1950 up to 2015 for computer science scientists.

Rainbow-Ranking (RR-index)

The Rainbow-Ranking applies the skyline operator iteratively until all scientists are classified into a skyline level. Figure 1 shows a graphical representation of the skyline levels with two dimensions: citations per publication and the h-index. Every point in Figure 1 corresponds to a scientist. Each line connecting the points corresponds to a different skyline level. The x-axis represents ranking positions of each scientist according to their h-index, whereas on the y-axis the respective ranking positions according to citations per publication. Since this iterative procedure results into a plot with grouped curves as shown, we have named in the Rainbow Ranking.

For the rest of our experiments we select as dimensions of the skyline operator the h-index (Hirsch, 2005), the Perfectionism Index (Sidiropoulos, Katsaros, & Manolopoulos, 2015), and the A-index (Jin, Liang, Rousseau, & Egghe, 2007). Given a set of scientists A=X₁, the first call of skyline produces the first skyline level. We denote this first set of scientists as set S₁. Next, we compute set X₂=X₁-S₁, which contains the scientists that were not classified in the first skyline set S₁. For the set X₂ the skyline operator is applied once more and the result is the second skyline level (S₂). The process continues until all the scientists of the dataset are assigned a value.

To summarize the ranking levels into a single number metric, given a set of scientists A and a set of dimensions dims, we define the RR-index of a scientist a based on dims as follows:

\[
RR(dims) = \frac{\left| \text{levels}(a, dims) \right| + \left| \text{ties}(a, dims) \right|}{2|A|}
\]

|A| is the total number of scientists, |levels(a,dims)| is the number of scientists ranked at higher skyline levels than scientist a based on dimensions dims. Level 1 is considered higher than level 2. |ties(a,dims)| is the number of scientists who are ranked at the same level with scientist a, excluding scientist a. Thus, the following holds for the RR-index: 0 < RR(dims) ≤ 100.

Results

The following table illustrates the RR-based ranking. The first skyline level is occupied by scientists who can be grouped into two groups; one group (in italics) are those who have worked in core computer science (e.g., networking, compilers, databases), and the second group are those who have worked in computational biology. In the second skyline level, we mainly encounter core computer scientists (in italics), but also a political scientist and economist (Simon Herbert); the others are computational biologists.

### Summary

This article addresses the following problem: “Given a set of bibliometric indicators, selected in any algorithmic way, can we successively rank scientists into layers based on these indicators, such that the scientists in each layer outperform those of the lower layers according to (at least one) indicator?” We employed the skyline and iteratively applied it to scientists, thus designing the **Rainbow Ranking** indicator. We evaluated it against computer scientists and showed intuitive results.

Introduction

The rapid development of information technology has driven the media dissemination of information on the speed and scope, so the frequent exposure of the academic misconduct caused great concern for research integrity in today's society and seriously damaged the public trust in science. Since 1952, The Integrity of Science published in Nature anonymously, The research integrity has received widespread concern around the world. At least four thousand related papers from China have been published in academic journals. The number of papers in recent years is growing fast and the problem of research integrity has become a focus of academic circles.

From the perspective of the development of science and technology, and on the basis of the development and evolution of the concept of research integrity, the paper applies bibliometric, policy text analysis and content analysis methods, aiming at providing a reference for understanding the evolution of research research in China.

Data and Methods

Data collection

WOS was used as the foreign source of data analysis. With "TI=("research integrity") or ("scien* integrity") or ("academic* integrity") or ("research misconduct") or ("scien* misconduct") or ("academic* dishonest") or ("academic* anomie") or ("research morality") "for the search strategies. processed a total of 1019 related documents. This part of the documents are used as a sample of research direction content analysis.

CNKI was used as the domestic source of the data analysis. With "TI=科研诚信 or 学术诚信 or 科研不端 or 学术不端 or 科研道德 or 学术道德 or 科研失范 or 学术失范 or 科研腐败 or 学术腐败 or 科研造假 or 学术造假 or 学术抄袭 or 学术剽窃" for the search strategies. finally received 1070 related literature.

The study collected 37 relevant policy texts published on 19 government or research agency websites in 12 countries This part of the data were used as a sample of the policy text analysis.

Data analysis

In the study, the paper mainly adopted the standardized processing technology of the literature title data, standardly processed the proposed keyword field, economically analyzed these fields to obtain frequency or co-occurrence of the frequency of statistical data, then applied Ucinet social network analysis tools for keyword co-occurrence analysis and keyword center degree analysis, and finally used Netdraw for visualization. The specific research hotspot analysis process shown in Figure 1.

Figure 1. The Division process of Research integrity's hotspots

Results and discussion

An overview

The distribution of the literature can reflect the level of academic research in a certain extent (Sun Yusheng et al. 2013), The speed of development and the degree of attention, revealing the longitudinal law of the study (Liu Guifeng, 2011). Prior to 2016, a total of 2089 articles were published in the core journals of WOS and CNKI. Figure 1 shows the number of articles in WOS and CNKI for each period. As shown in Figure 1, the X-axis represents the age distribution, and the Y-axis represents the number of documents. The two columns in each period show the number of WOS and CNKI articles.

Figure 2. Distribution of the number of articles in domestic and foreign

From Figure 1 we can found that the scientific integrity at home and abroad is in a upward trend on the whole. As for the research of scientific integrity, foreign research started earlier, and the number of research results were more than that of...
China. However, after 2007, the research results in China started to overnumber those in foreign countries.

**The evolution of policy and conceptual terms**

In 1942 the American sociologist RK Merton first proposed the concept and basic scientific norms of modern science in On Science and Democracy, and in the 1980s it began to evolve from academic issues to social and government public policies. By the end of the 1980s, the "Schoen case" of USA, "Huang Yuxi paper fraud" of South Korea and other international scientific misconduct occurred frequently. The scientific integrity issue has upgraded to the focus of the international community. This reflects the evolutionary path of scientific integrity from the bud, start to the development and internationalization.

In 1990s, China really began to pay attention to scientific integrity. Over the past three years, about 100 theoretical research literature can be retrieved each year through the application of "scientific integrity" as the keyword to search article from CNKI. In particular, in 2011, the China Association for Science and Technology, the Ministry of Education jointly launched the postgraduate scientific morality and style of study to promote educational activities, academic ethics and scientific integrity education work to a new height.

![Figure 3. development memorabilia of Research Integrity](image)

**Figure 3. development memorabilia of Research Integrity**

![Figure 4. The first occurrence of the concept of research integrity in academic papers](image)

**Figure 4. The first occurrence of the concept of research integrity in academic papers**

**Combing the evolution of research focus**

Keywords can summarize the core content of the paper. In order to explore the research content of scientific integrity, this paper extracted all the keywords of the research literature, pre-processed with Bibstats, and sorted the word frequency of the keywords. Research integrity's hotspots development evolution is divided into the following three stages:
- Research on the Construction of Academic Moral Spirit;
- Research on Academic evaluation and academic management;
- Research on research integrity education in colleges and universities

**Conclusion**

Through the above analysis, it is found that the progress of scientific integrity research in China has lagged far behind the developed countries. The initial research of integrity research mainly focused on the explanatory study of the academic moral. The number of research papers is small and the content is limited to criticizing academic moral misconduct or cultivating the importance of academic ethics and other surface level. After the 2000, research in the mid-term research inclined to descriptive research. It began to explore based on the case and gradually conducted in-depth, systematic research on the theme of integrity research, meanwhile discussing the problems and governance methods as well as researching the governance of all aspects of the research misconduct. The paper from 2008 to now is more inclined to exploratory research, and the direction of research is more in-depth, concerned with the guidance research of the policy establishment, and more focused on academic management research. Management of research integrity transforms from "the problem re-governance" into predictive "take precautions". In the past two years, the research on the field of scientific integrity has been carried out from the perspective of reality and theory.

Do under-cited influential sleeping beauties exist?

Xiaojun Hu\textsuperscript{1} Ronald Rousseau\textsuperscript{2}

Abstract
In this study we investigate if sleeping beauties, also known as articles suffering delayed recognition, can at the same time be under-cited influential articles. Theoretically these two types of articles are independent, in the sense that being a sleeping beauty depends on the number and time distribution of received citations, while being an under-cited influential article depends only partially on the number of received (first generation) citations, and much more on second and third citation generations. Among 49 sleeping beauties we found 13 that are also under-cited influential.

Conference Topic
Citation Analysis

Introduction
In diachronous studies and depending on their citation curves or ageing profiles articles can be categorized in different ways. In (Smith Aversa, 1985) the author makes, for highly cited papers, a distinction between delayed rise in received citations combined with a slow decline, on the one hand, and early rise combined with a rapid decline, on the other. More recently, Costas et al. (2010) classify documents into three general types: delayed documents, which receive the main part of their citations later than normal documents; flashes-in-the-pan (van Dalen \& Henkens, 2005), which receive citations immediately after their publication but are not cited or influential in the long term; and normal documents, documents with a typical distribution of citations over time. The delayed documents include articles known as sleeping beauties (van Raan, 2004), articles suffering from delayed or late recognition, being premature discoveries, being ahead of one's time, suffering from Mendel's syndrome or being late bloomers (all synonyms or near-synonyms, describing the same phenomenon).

Recently, and especially in China, sleeping beauties attracted a lot of attention (Ke et al., 2015; Li, 2014; Li \& Shi, 2016; Li \& Ye, 2016; Du \& Wu, 2016), leading among others to “all-elements-sleeping-beauties” (Li \& Ye, 2012), i.e. articles that at first receive some attention, then go through a period in which they are hardly noticed, followed by a period of being highly cited, awakened by a prince, so to speak. Figure 1 shows the citation curve of (Romans, 1986), a typical sleeping beauty studied by van Raan (2004). It received no citations for nine years and then received more than 100 citations over the next six years. After a peak (it received 32 citations in the year 1999) its citation curve shows a gradual and irregular decline similar to that of ‘normally cited’ articles.
A different type of articles: under-cited influential articles

All the types of articles mentioned above were based on the – direct – citation distribution. Yet, recently Hu and Rousseau (2016, 2017) introduced another type of articles in which first, second and third generation citations play a role, leading to the sparking index (Hu & Rousseau, 2017). These articles are referred to as under-cited influential articles. Such articles are characterized by three properties: (1) they are reasonably well-cited (a basic requirement to be influential); (2) citations of citations (second generation citations) are rather high, so that the original one is influential in an indirect way (a more refined token of influence); (3) given condition two, these articles received fewer citations than expected (being under-cited). Each of these three requirements is operationalized leading to a two formulae referred to as sparking indices. There are two types of sparking indices depending on the number of received citations: a sparking index on the 1% level, denoted as S1 (for articles that are cited at least 201 times) and a sparking index on the 10% level, denoted as S10 (for articles that are cited at least 21 times but less than 201). Details are provided in (Hu & Rousseau, 2016, 2017). These two articles also show that such under-cited influential articles are neither common, nor extremely rare. Many articles written by Nobel Prize winners, but also other, including recent articles, fall into the group of under-cited influential articles.

Before continuing our investigation we want to clarify the terminology of under-cited influential articles. It is clear that these articles are influential: they are reasonably well cited and, through citing articles, their influence on the development of the ideas that started with them is even higher. Many of them, like the Nobel prize winning articles studied in (Hu & Rousseau, 2017), can even be described as foundational articles. These articles are also referred to as under-cited. By this we do not mean that they are treated unfairly. We just want to stress that many articles that built on them received more citations. One reason could be that these articles added new results that incorporated the results of the ‘under-cited’ one, so that later investigators do not feel the need to refer to the original.

Clearly sleeping beauties and under-cited influential articles differ in many aspects except that in short-term evaluations based on bibliometric indicators, they both are under-valued. Sleeping beauties usually begin with a long period of few citations and then direct citations (first generation) go up. Under-cited influential articles usually are rather well-cited but
thenumber of received citations does not fully reflect their influence on their field. Probably only expert peer reviewers can see their importance. These considerations led us to the following research question.

**Are there sleeping beauties which are also under-cited influential articles?**

We looked through a set of articles dealing with delayed recognition or sleeping beauties and determined 49 articles considered to be sleeping beauties, restricting then to 1950 or later and included in the SCI-E. As a universally accepted, precise definition of a sleeping beauty does not exist, we do not discuss if these articles are really sleeping beauties. We just accept the opinion of the authors who studied these articles. For all these sleeping beauties we checked if they are also under-cited influential articles. Citations were collected and calculations made in February 2017. Bibliographic information on these sleeping beauties is given in Table 2 (Appendix), while the articles discussing these sleeping beauties can be found in Table 3 (Appendix). Results of our investigations are shown in Table 1. We found 13 sleeping beauties of the 49 checked that are also under-cited influential articles. This is 27%. Of course numbers are too small to accord any meaning to this percentage.

**Characteristics of articles which are sleeping beauties as well as under-cited influential**

The article by Romans (1986) turned out to be also under-cited influential according to our definition. This is illustrated in Figures 2-3 where, besides the original citation curve we also show the curve of the citing curves with the second most citations (in yearly distribution and in cumulative number). As the top 1% (rounded up) citing articles consists of four articles we show the second one among these (referred to as the median citing article). This median citing article, published in 1999, received already in the year 2000 more citations that Romans’ (Figure 2) and the next year its cumulative total citations was higher than Romans’ (Figure 3). This is just an illustration as such an intersection is neither necessary nor sufficient to be an under-cited influential article.
Discussions and conclusions

We note the following caveat: the definitions of sleeping beauties and under-cited influential articles depend on some ad hoc rules. This leads to the question: do these 13 articles, or most of these, really belong to the two types mentioned, or would a slight change in definition to one of the two types make a consequential difference?

Assume that we have a strict definition of a sleeping beauty, then we wonder after how many years is it clear that an article is a sleeping beauty? Is it, at that moment, also possible to say that this sleeping beauty is moreover under-cited influential (for which a strict definition exists), or is it then usually too early, as one needs three generations of citing articles and it took quite some time before the first generation was ‘large enough’ and hence does not easily leads to many second and third generation citations. Assuming that a ‘recent’ sleeping beauty is not under-cited influential is it then possibly to predict (i.e., determine a probability) if it will ever be?
We conclude that we have shown that there do exist articles that are sleeping beauties and are at the same time under-cited influential, Romans’ (1986) being a case in point.

Which Drives Which? The Causal Relationship between Number of Editorial Board Members and Scientific Output of Universities in the Chemistry Field: a Granger Causality Test

Xing Wang\textsuperscript{1,2}

\textsuperscript{1} wangxing@sjtu.edu.cn
Shanxi University of Finance & Economics, Information Management School, 696 Wucheng Road, 030006 Taiyuan (China)

\textsuperscript{2} wangxing830914@gmail.com
Shanghai Jiao Tong University, Graduate School of Education, 800 Dongchuan Road, 200240 Shanghai (China)

Introduction
Editorial boards of scholarly journals are important to the entire academic world, and there may be some relationship between the number of editorial board members and the scientific output of universities. Several studies have examined the correlation between the number of editorial board members and scientific output of universities in some subjects (Braun, Dióspatonyi, Zádor, & Zsindely, 2007; Burgess & Shaw, 2010; Frey & Rost, 2010). However, there has been a lack of study about the causality in this relationship. It may be more interesting to determine whether such a causal relationship exists between the number of editorial board members and the scientific output of universities and, if so, which drives which.

In this study, we used time-series data and the Granger causality test to explore the causal relationship between the number of editorial board members and the number of articles of top 14 universities in the chemistry field.

Data and Method
We collected time-series data for the Granger causality test using two variables: the number of editorial board members and the number of articles published per university. We selected the following nine top journals as sample journals for this analysis: Journal of the American Chemical Society, Angewandte Chemie International Edition, Chemical Reviews, Accounts of Chemical Research, Analytical Chemistry, Biochemistry, Chemistry of Materials, Inorganic Chemistry, and Journal of Organic Chemistry. We chose the period from 1998 to 2014.

We used the Shanghai ranking’s top 20 universities in chemistry as our sample universities for the Granger causality test. First, we recorded and calculated the number of editorial board members over the years of 20 universities from 1998 to 2014 at the nine journals. Next, we artificially set a threshold: only universities with no less than five editorial board members for at least one year were considered qualified for our Granger causality test. Fourteen universities constituted the final sample for this analysis.

Using the advanced search function of Web of Science, we obtained the number of articles published in the nine journals each year from 1998 to 2014 at 14 universities. The main statistical technique used in this study was Granger causality test model which can be written as follows:

\[
Y_t = \alpha_0 + \sum_{i=1}^{m} \alpha_i Y_{t-i} + \mu_t \tag{1}
\]

\[
Y_t = \alpha_0 + \sum_{i=1}^{m} \alpha_i Y_{t-i} + \sum_{j=1}^{m} \beta_j X_{t-j} + \mu_t \tag{2}
\]

Results
The Granger cause test results showed that there was unidirectional causality for only three universities which are UCLA, ETH-Zurich, and University of Pennsylvania. However, there was no significant causal relationship in either direction for the other eleven universities (Table 1). The regression equations of UCLA, ETH-Zurich, and the University of Pennsylvania based on the Granger causality test model (2) are shown in Table 2.

Although the Granger causality test results suggested unidirectional causality in the above three universities, the established regression equations of these three universities based on the Granger causality test model were contradictory with respect to meaning. For example, the coefficient of $X_{t-1}$ was significantly negative ($p < 0.05$) in the equation of lag phase 1 of UCLA, and the coefficient of $X_{t-1}$ was also significantly negative ($p < 0.05$) in the equation of the lag phase 2 of UCLA. Similar issues occurred in the situation of ETH-Zurich and the University of Pennsylvania.
Based on the above results, the causal relationship between the number of editorial board members and the number of articles of top 14 universities in chemistry was not obvious overall.

Table 1. Granger cause test between the number of editorial board members and the number of articles of universities (1998-2014).

Note. EB, PUB represents respectively the number of editorial board members and the number of articles. Column 1 is the 2014 Shanghai ranking of the selected universities in chemistry. Column 5 is the lag phase. For the three universities that had a significant causal relationship between the two variables, the lag phases having a significant causal relationship were all provided. For universities with no detected causal relations during lag phase 1 to 4, we only present an optimal lag phase based on the Akaike Information Criterion. "**"] indicate that the EB and Pub series are not stationary or not co-integrated.

Conclusion

Our Granger causality test results suggest that the causal relationship between the number of editorial board members and the number of articles of top 14 universities in chemistry is not obvious overall. Combining with the interviews of some editorial board members from the above nine journals, we consider that the causal relationship between the number of editorial board members and the number of articles of universities may not be ‘rigid’.

Abstract
The vector representation of documents is important for literature aggregation, clustering and classification. Co-occurrence latent semantic vector space model (CLSVSM) based on the binary co-occurrence information, exploited the latent semantic relations between terms and documents. Comparing with the vector space model (VSM), it can improve the accuracy of text clustering. To better utilize the latent semantic information through CLSVSM, this paper introduces the ternary co-occurrence information. Our goal in this survey is to offers a ternary co-occurrence layer matrix representation, to give a calculation method of ternary co-occurrence frequency and relative strength and to show the effect of the binary and ternary weighted CLSVSM. Finally, we use Chinese data sets and English data sets respectively to compare the two models. The results show that the new model is equal to binary CLSVSM in English data sets, but has an outstanding performance in Chinese data sets.

Introduction
In the era of big data, literature resources are very rich, but the resource overload tends to bring some questions, such as declining of the retrieval accuracy and increasing of the cost. Resource aggregation is an effective way to solve the question of too many resources. Literature aggregation can be realized by the clustering of the feature vector of literature; its result is related to whether the semantic information is fully extracted, whether the vector representation is reasonable, and whether the clustering method is effective, etc. It is very important to use the semantic information to express the vector fully. Literature representation is derived from the research of the text representation. The text representation methods include set theory, algebra, probability statistics, graph theory and so on. The most basic representation is the vector space model (VSM) (Salton, 1997), this model assumes independency between the vocabulary terms and ignores all the conceptual relations between terms that potentially exist; The Generalized vector space model (GVSM) (Wong, Ziarko&Wong, 1985) excavates the co-occurrence information of words, but it cannot extract the semantic information fully. The semantic vector space model [4] (SVSM) (Song, Liang&Soon, 2014), excessive relies on ontology or the language database. The co-occurrence latent semantic vector space model based on the binary information (CLSVSM) (Niu&Qiu, 2014) is used to proceed literature aggregation. The result shows that the model is better than the VSM. But we find that researching the binary information only is not comprehensive. In this paper, we introduce the ternary information.

In CLSVSM, the extraction of latent semantic information is based on co-occurrence analysis. Co-occurrence analysis is a method to quantify the co-occurrence information in various
information carriers. Its methods include co-cited analysis, bibliographic coupling analysis and co-word analysis (Pang, Fang & Yang, 2012). The research of this paper mainly starts from the co-word analysis, and digs the latent semantic information between the terms in the digital literature. The co-word analysis was proposed by Callon, Courtial and Turner et al (1983). It is a method of content analysis, and it is mainly used to analyze the phenomenon of professional terms that can reveal a subject or a research direction in a field occurring in one document. Take the frequency of a group of terms in one document as the foundation for hierarchical clustering and find the relationship between terms (Feng & Leng, 2006; Lu, Jing & Fan, 2016; Chen, Chen & Wu, 2016). Co-word analysis can be widely used in hot-spot analysis researching (Xie, Liang & Wang, 2005; Ma & Wang, 2007; Su, 2009; Li & Dong, 2010), discipline structure revealed (Li & Wang, 2011; Yang & Cui, 2011), information retrieval (Rokaya, Atlam & Fuketa, 2011) and other fields.

At present, there is less research of ternary relations. Dong, Liu and Jiang discussed the principle of the triad census method and applied it in the research on the structure of citation network (2010). Li proposed the concept of three-word sequential co-occurrence pair and the application of reflected terms and tight ring (2013). Hu and Chen proposed that the conceptual knowledge network based on keyword co-occurrence can be divided into different layers in terms of the k-core value of nodes, and introduced the theory of triadic closure as the basic unit of network structure analyses (2014). In the research of co-word, Leng, Wang and Li (2011) used the bit vector orthogonal method of DLG (direct large item-set generation) to give the co-word operation method, calculated the stability of ternary co-occurrence and its influence of the results, and gave the results comparison of binary and ternary co-word. Lastly, the author came to a conclusion: The binary co-word results reflected the relationship between research topics, which mainly including the keywords, and the result of the ternary co-word reflected the research area and questions of the phrase collocation. This study found the result of ternary word has some practical significance and it is very important to research the ternary information.

In this paper, the co-occurrence model is based on the co-word analysis, but it can apply for all co-occurrence analysis. This article is uniformly referred to as co-occurrence, for example, we present the co-occurrence of two (three) characteristic terms as binary (ternary) co-occurrence. The organization of the paper is as follows: In section 2, a brief review of the co-occurrence latent semantic vector space model based on binary information is given. The ternary co-occurrence layer matrix representation, ternary co-occurrence frequency, relative strength of ternary co-occurrence calculation and the weighted CLSVSM formation are presented in section 3. Further, experimental results and discussions to support the algorithm can be seen in section 4. Conclusions are derived in section 5.

**Co-occurrence latent semantic vector space model based on the binary information**

Let $A$ be a document - term matrix. Suppose our document collection contains $n$ documents and $m$ unique terms. The matrix $A$ will have $n$ rows (one row for each document) and $m$ columns (one column for each unique term in the vocabulary). Let $t_j$ be the $j$-th term in the vocabulary and let $d_i$ be the $i$-th document in the collection. The $i$-th row in $A$ is the row vector $a_i$, and the $j$-th column in is the column vector $a_j$. The row vector $a_i$ contains $m$ elements, one element for each term, and the column vector $a_j$ contains $n$ elements, one element for each document. Suppose $A$ is a simple matrix of frequencies. The element $a_{ij}$ in $A$ is the frequency of the $j$-th term in the $i$-th document. If the $j$-th term is
belong to the document $d_i$, then $a_{ij}$ is equal to 1, otherwise it is 0. The matrix is sparse and we define this matrix as Boolean document-term matrix.

Let $C$ be the co-occurrence matrix and let $B$ be the co-occurrence relative strength between terms. They are expressed as follow:

$$C = A^T \cdot A = \left(c_{ij}\right)_{m \times m}$$

$$B = \left(b_{ij}\right)_{m \times m} = \text{diag}\left(\frac{1}{\sqrt{c_{11}}}, \frac{1}{\sqrt{c_{22}}}, \ldots, \frac{1}{\sqrt{c_{mm}}}\right)A^T \cdot \text{diag}\left(\frac{1}{\sqrt{c_{11}}}, \frac{1}{\sqrt{c_{22}}}, \ldots, \frac{1}{\sqrt{c_{mm}}}\right)$$

$$b_{ij} = \frac{c_{ij}}{\sqrt{c_{ii}c_{jj}}}, i, j = 1, 2, \ldots, m$$

The CLSVSM is defined as follow:

$$\phi: d_i \rightarrow \phi(d_i) = (q_{i1}, q_{i2}, q_{i3}, \ldots, q_{im})^T \in R^D$$

$$q_{ij} = \begin{cases} 
1, & a_{ij} = 1 \\
\max_{l \in I_{l1}} \{b_{lj}\}, & a_{ij} = 0, \max_{l \in I_{l1}} \{b_{lj}\} \neq 0 \\
0, & \text{others.}
\end{cases}$$

Where $I_{l1} = \{j | a_{ij} = 1\}$ and $q_{ij} \in [0,1]$

The new document-term matrix is defined as:

$$Q = \begin{pmatrix}
q_{11} & q_{12} & \cdots & q_{1m-1} & q_{1m} \\
q_{21} & q_{22} & \cdots & q_{2m-1} & q_{2m} \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
q_{n-1,1} & q_{n-1,2} & \cdots & q_{n-1,m-1} & q_{n-1,m} \\
q_{n,1} & q_{n,2} & \cdots & q_{n,m-1} & q_{n,m}
\end{pmatrix} \begin{pmatrix}
\phi^T(d_1) \\
\phi^T(d_2) \\
\vdots \\
\phi^T(d_{n-1}) \\
\phi^T(d_n)
\end{pmatrix}$$

The author uses the maximum co-occurrence strength between terms to add the semantic information in the traditional high-dimensional vector space model (only 0,1 weight), that is, if the weight value is 0 then give a new value between 0 and 1.

**Ternary CLSVSM**

In the literature [1], the author has proved that the CLSVSM based on the binary information can extract the latent semantic information, but only researching the binary information is not enough, and we need to extract the co-occurrence information beyond binary.

**The Representation of Ternary Co-occurrence Layer Matrix**

The primary question of ternary co-occurrence is how to represent the co-occurrence information. In this passage, we present a ternary co-occurrence layer matrix with algebraic method.
Definition 1: Given documents sets $D$ and its document-term matrix $A$, let $t_j$ be the j-th column of the matrix, we define co-occurrence of the j-th term $t_j$ and all term pairs $(t_i, t_k)$ $(i,k=1,2,\cdots,m)$ is the j-th layer of ternary co-occurrence as follow:

$$C_j^{(3)} = C_t^{(3)}(t_j) = (\text{diag}(t_j)A)^T \cdot (\text{diag}(t_j)A)$$

where $\text{diag}(t_j)$ is a diagonal matrix and its diagonal element is the component of $t_j$.

Firstly we calculate $\text{diag}(t_j)A$. In calculation, we use $\text{diag}(t_j)$ to modify the document-term matrix $A$ and constitute a new matrix, the modification method is as follow: If the diagonal elements of matrix $\text{diag}(t_j)$ contain 0, that is, the term $t_j$ at least in one document (the document set is $d$) does not appear, at this time the k-th row and the k-th column elements are 0. According to the matrix multiplication, the kth row the elements of the $\text{diag}(t_j)A$ are all 0. If the diagonal elements of $\text{diag}(t_j)$ are all 1, that is, the term $t_j$ appears in all documents, the result of $\text{diag}(t_j)A$ is $A$. Then we calculate the $(\text{diag}(t_j)A)^T \cdot (\text{diag}(t_j)A)$, and the form is similar to the binary co-occurrence matrix.

For example:

$$A = (t_1, t_2, t_3, t_4, t_5) = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{bmatrix}$$

$$\text{diag}(t_1)A = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{bmatrix}$$

$$C_1^{(3)} = C^{(3)}(t_1) = (\text{diag}(t_1)A)^T \cdot (\text{diag}(t_1)A) = \begin{bmatrix} 4 & 3 & 2 & 2 & 3 \\ 3 & 3 & 2 & 2 & 2 \\ 2 & 2 & 2 & 1 & 1 \\ 2 & 2 & 1 & 2 & 1 \\ 3 & 2 & 1 & 1 & 3 \end{bmatrix}$$
In this calculation, we find that the diagonal elements of \( \text{diag}(t_j) \) contains 0, that is, the elements of the second row and the second column are all 0, namely the first term is not belong to the second document, therefore the second row of \( \text{diag}(t_j)A \) is 0. \( C_1^{(3)} \) is the co-occurrence frequency matrix of the first term \( t_1 \) with other terms. Obviously, the matrix is a symmetric matrix. The second row third column \( C_1^{(3)}(2,3) = 2 \) is the co-occurrence frequency of the terms \( t_1, t_2 \) and \( t_3 \). It is easy to verify that the matrix is correct, and the three words appear simultaneously in the first line and the fifth line.

The Relative Strength of Ternary Co-occurrence

It is not difficult to extract the ternary co-occurrence frequency through the program and even the frequency that more than ternary can be obtained. This paper mainly studies the calculation method of ternary co-occurrence frequency.

Firstly, we calculate the ternary co-occurrence frequency, let \( C_i, C_j, C_k \) respectively be the frequency of terms \( t_i, t_j, t_k \) and let \( C_{ij}, C_{jk}, C_{ik} \) be the frequency of the binary co-occurrence. \( C_{ijk} \) is the frequency of the ternary co-occurrence. Let \( c_{i\cup j\cup k} \) be the number of documents that including at least one of the three terms. Contrasting the promotion of the addition formula in the probability theory, for the three events A, B, C, let \( P \) be the probability of occurrence of events, then we define \( P(A\cup B\cup C) \) as follow:

\[
P(A\cup B\cup C) = P(A) + P(B) + P(C) - P(A\cap B) - P(A\cap C) - P(B\cap C) + P(A\cap B\cap C)
\]

We can infer:

\[
C_{i\cup j\cup k} = C_i + C_j + C_k - C_{ij} - C_{jk} - C_{ik} + C_{ijk}
\]

\[
C_{ijk} = C_{i\cup j\cup k} - (C_i + C_j + C_k) + (C_{ij} + C_{jk} + C_{ik})
\]

In this formula, \( C_{i\cup j\cup k} \) can be obtained from the document-term matrix, \( C_i, C_j, C_k, C_{ij}, C_{jk}, C_{ik} \) can be obtained by the co-occurrence matrix between terms, and then we can calculate the ternary co-occurrence frequencies.

Definition 2: given the set of documents \( D \) and its document-term matrix \( A \) and binary co-occurrence matrix \( C \), we can define the relative strength of ternary co-occurrence \( b_{ijk} \) of any three terms \( (t_i, t_j, t_k) \) as follow:

\[
b_{ijk} = \frac{C_{ijk}}{\sqrt[3]{|C_{ij}C_{jk}C_{ik}|}}, i, j, k = 1, 2, \ldots, m
\]

The Weighted CLSVSM Based on Binary and Ternary

In the new CLSVSM, we consider combining with binary and ternary co-occurrence information, and give the ternary greater weight.

Definition 3: Given the set of documents \( D \) and its document-term matrix \( A \), the binary co-occurrence relative strength matrix \( B \), the ternary co-occurrence matrix \( C^{(3)} \), the j-th floor
ternary co-occurrence matrix $C_{j}^{(3)}$, the j-th floor ternary co-occurrence relative strength matrix $B_{j}^{(3)} = (b_{ijk})_{m \times m}$. We define the new co-occurrence latent semantic vector space model based on binary and ternary as follow:

$$
\varphi(d_{i}) = \tilde{d}_{i} = (q_{i1}, q_{i2}, \ldots, q_{im}) \in \mathbb{R}^{m}
$$

$$
q_{ij} = \begin{cases}
1, & a_{ij} = 1 \\
\max_{rel_{i}} \{b_{ij}\}, & a_{ij} = 0, \max_{rel_{i}} \{b_{ij}\} \neq 0, \max_{rel_{i}} \{b_{ij}\} = 0 \\
\frac{1}{3} \max_{rel_{i}} \{b_{ij}\} + \frac{2}{3} \max_{rel_{i}, rel_{j}} \{b_{ij}\}, & a_{ij} = 0, \max_{rel_{i}} \{b_{ij}\} \neq 0, \max_{rel_{i}} \{b_{ij}\} = 0 \\
0, & \text{others}
\end{cases}
$$

Where, $I_{i} = \{ j | a_{ij} = 1 \}$ is the indicator sets of $j$.

The new “document - term” model is defined as:

$$
Q = \begin{pmatrix}
q_{11} & q_{12} & \cdots & q_{1m-1} & q_{1m} \\
q_{21} & q_{22} & \cdots & q_{2m-1} & q_{2m} \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
q_{n-1,1} & q_{n-1,2} & \cdots & q_{n-1,m-1} & q_{n-1,m} \\
q_{n,1} & q_{n,2} & \cdots & q_{n,m-1} & q_{n,m}
\end{pmatrix}
= \begin{pmatrix}
\varphi^{T}(d_{1}) \\
\varphi^{T}(d_{2}) \\
\vdots \\
\varphi^{T}(d_{n-1}) \\
\varphi^{T}(d_{n})
\end{pmatrix}
$$

Experiment and result analysis

Experimental Data

In this experiment, we use the Chinese and English data to compare the binary CLSVSM and the weighted CLSVSM results respectively.

The Chinese data sets were collected in disciplines under three categories of information science in CNKI. After getting rid of non keyword documents, we get a total of 896 documents, which includes 299 "published", 298 "Library and Information and Digital Library", and 299 "archives and museums". The number of key words is 2509 (without repetition).

The English data sets used in the experiment are from "web of science". Firstly, we retrieve the first 1500 articles in the information science and library science according to the cited frequency in descending order, if the frequency is the same, we choose according to the system automatic sort. After getting rid of non keyword documents, we get a total of 411 documents, which includes 234 "Computer Science Information System", 123 "Management", and 54 "Computer Science Interdisciplinary Applications". The number of key words is 1661 (without repetition).

Experimental Process

This paper compares the two models according to the following steps:

Step 1: Pre-process the data and extract the terms of each document;
Step 2: Calculate the frequency of each term, list the terms in descending order and construct the co-occurrence matrix;
Step 3: Construct the vector space model and establish the document-term matrix of the literature;
Step 4: Calculate the co-word matrix according to the document-term matrix, get the frequency of the keywords, the binary co-occurrence, and the ternary co-occurrence;
Step 5: Calculate the relative strength of the binary and ternary co-occurrence, calculate the binary CLSVSM and the weighted CLSVSM, there will be two new document-term matrix;
Step 6: Use CLUTO software for clustering and it mainly uses the two new matrix;
Step 7: Record the experimental data, compare the experimental result, and come to the conclusion;

In this paper, 50 experiments were carried out on Chinese and English data respectively. The number of clusters was 3, and the cosine similarity was used. The number of iterations was 10 times for each experiment. From solution 1 to solution 50, we all use D-I2 program. That is, the clustering algorithm is Direct K-means, and the criterion function is I2. In each experiment, we have to record the value of purity and entropy, after the experiment, we also need to calculate the BF value. Finally, we also need to calculate the mean and standard deviation of purity, entropy, BF value and compare the results of the two models.

If the experimental subjects are divided into \( k \) classes, defined as \( L_j (1 \leq j \leq k) \). They can be clustered into \( k \) clusters, wrote as \( S_r (1 \leq r \leq k) \). The number of articles in the literature is \( n \), \( S_r \) and \( L_j \) contain \( n_r \) and \( n_j \) documents respectively. There are \( r_j \) identical documents.

Purity and entropy can be defined as follow:

\[
Purity = \sum_{r=1}^{k} \frac{1}{n} \max_{1 \leq j \leq k} n_{rj} = \frac{1}{n} \sum_{r=1}^{k} \max_{1 \leq j \leq k} n_{rj}
\]

\[
Entropy = \sum_{r=1}^{k} \frac{n_{rj}}{n} \left( -\frac{1}{\log k} \sum_{j=1}^{k} \frac{n_{rj}}{n_r} \log \frac{n_{rj}}{n_r} \right)
\]

B-Cubed method is the evaluation index of information retrieval, the main idea is to calculate the accuracy of each class (Precision) and recall (Recall), then calculate the weighted average sum and get the overall precision and recall rate. Precision and recall are defined as follows:

\[
BP_r = \text{precision}(r, j) = \frac{n_{rj}}{n_r}
\]

\[
BR_j = \text{recall}(r, j) = \frac{n_{rj}}{n_j}
\]

And the total precision and recall are:

\[
BP = \frac{1}{n} \sum_{r=1}^{k} n_r \times BP_r
\]

\[
BR = \frac{1}{n} \sum_{j=1}^{k} n_j \times BR_j
\]

BF value can be defined as follow:

\[
BF = \frac{2 \times BP \times BR}{BP + BR}
\]
Experimental Results

In this paper, the weighted CLSVSM experiment is compared with the binary experiment. The results of the Chinese data sets and the English data sets are shown in Table 4.1 and Table 4.2.

### Table 4.1 Comparison of two models (Chinese data)

<table>
<thead>
<tr>
<th></th>
<th>Entropy</th>
<th>Purity</th>
<th>BF Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Weighted CLSVSM</td>
<td>0.579±0.029</td>
<td>0.784±0.016</td>
<td>0.791±0.013</td>
</tr>
<tr>
<td>Binary CLSVSM</td>
<td>0.596±0.039</td>
<td>0.768±0.037</td>
<td>0.776±0.034</td>
</tr>
</tbody>
</table>

Note: The data in the table are mean ± standard deviation

In the three clustering indicators, the closer the purity and BF values are to 1 and the entropy is to 0, the better the clustering effect. That is, the clustering effect will increase with the enlargement of purity and F value, and decrease with the enlargement of entropy. In the table 4.1, we first analyze the value of mean, it can be clearly seen that purity and BF value of the weighted model are higher than the binary experiment; the entropy is lower than the binary experiment. And then analyze the value of mean ± standard deviation, according to the basic knowledge of the statistics; we can see the value within the range of mean ± standard deviation, which is a large probability. We take the BF value as an example, in the weighted model, the value falls in [0.778, 0.804] is a high probability event, and the binary CLSVSM experiment is a large probability event in the range of [0.742, 0.8]. Relatively speaking, the value in the weighted model is bigger. In general, the clustering effect of the weighted model is better than binary model.

### Table 4.2 Comparison of two models (English)

<table>
<thead>
<tr>
<th></th>
<th>Entropy</th>
<th>Purity</th>
<th>BF Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Weighted CLSVSM</td>
<td>0.552±0.011</td>
<td>0.729±0.004</td>
<td>0.681±0.015</td>
</tr>
<tr>
<td>Binary CLSVSM</td>
<td>0.545±0.004</td>
<td>0.718±0.005</td>
<td>0.682±0.012</td>
</tr>
</tbody>
</table>

In the table 4.2, the result of the weighted CLSVSM model is closer to the binary model, which is due to the diversity of the documents we choose. The possible reason is that there is a phenomenon of polysemy in English term, but we ignored it.

In the CLSVSM, the weighted CLSVSM experiment effect is better than the binary experiment in the Chinese literature. For the English literature, because the choice of literature and the processing of the terms are not perfect, the clustering results of the two models are similar in this experiment.

Conclusions

This paper mainly extended the binary co-occurrence model; we researched the representation of ternary co-occurrence, the calculation of ternary co-occurrence frequency and the relative strength, and formation of the weighted CLSVSM, and gave the experimental design. We showed that, in the Chinese literature, the clustering effect of the weighted model was better but in the English literature, the two clustering effects were equivalent. In this paper, the representation of the ternary co-occurrence layer matrix can be extended to the multiple co-occurrences, but it should be noted that in general the frequency of the multiple co-occurrence will decrease rapidly with the increase of multiple numbers. The multiple co-occurrence phrases are also rapidly decreasing. In the subsequent study, we will try to find a way to directly represent the ternary information and explore the scope of the model.

In addition, in the weighted CLSVSM model, we haven’t considered whether the weight value is the most appropriate value. And another question I want to say is that whether the
choice of terms in this paper (keywords) is enough. The terms extracted from references or the title of each document can also reveal the relations of the documents.

References
**Introduction**

Cancer, brain cancer as subtype, more threatening than of “AIDS, malaria and tuberculosis combined”, revealed and predicted its alarming signs to increase 80% in 2030. In concepts mapping for medical fields, various data mining techniques have been used, although mutual interaction and dynamics of those concepts are still unclear (Kostoff 2014). Such interational studies could track the behavioural dynamics of such concepts/factors to identify and understand the emerging technologies and drifts in concepts.

To face this challenge, we tried to develop a system, Hybrid Relation Analysis (HRA) for concept mapping in connections with relations, where we used topic modelling and variant of references. In Bibliometrics, Latent Dirichlet Allocation (Blei, Ng et al. 2003), is a classical choice regarding its efficacy and practical implication (Blei 2011) and has been utilized for various localized purposes. Bibliographic coupling is way of indirect relation and rated better performance than citations and co-citations (Boyack and Klavans 2010).

Our objective is to develop a system to identify and detect the drift of emerging technologies and understand the concepts of resultant innovation, where mechanism, extent, dominance and temporal trend of technological concepts and their interaction can be measured. We used technological literatures of brain cancer that can be valuable to comprehend the commercial perception of cause and treatment relationships as well as its commercial insight.

**Method**

We used Derwent Innovation Index, a precise, integrated, value added with originality, competitive and opportunity oriented patent database to get patents records for the disease brain cancer from years 1987 to 2016.

Latest machine learning, text mining, bibliometrics, data visualization and higher programing language-based approaches, are applied for the analysing the various databases. We based our experiment on optimizing conjugate gradient and Gibbs sampling. All the experiments have been performed on Intel Core i5 with 2.9 GHz and 16 GB main memory.

The search strategy, Huang (Huang, Schuehle et al. 2015) is applied with customization to ensure maximum recall and precision rates using patents classification codes relating to brain (G01N-033/574) and cancer (G01N-033/574).

After applying various pre and post data processing techniques, topic modeling, classical Latent Dirichlet Allocation method (Blei, Ng et al. 2003) is preferred for its reliability, multi-labeling and generative characteristics.

Later, second phase utilize the references, where for optimum number of factors divergence measure (Kullback and Leibler 1951) for any two matrices is:

HRA, as variants to LDA, for two hypothetical factors Zk and Zk’ having same citation link, CM from M documents that are independent and not governed by the document-theme relatedness utilizing the value of Θ, which is probability of document d for given factors k (Fig 2).

**Figure 1. Framework**

**Figure 2. Plate Notation Difference between LDA and HRA**
**Case study**

The method, yet generative, aimed at patent database due to flexibility in citation manipulation and commercial implication, although our experience and domain knowledge can affect result insight.

**Results**

In Fig 3, shows the relations (shared references) among eight concepts (ball). Distance between the factors is semantic relevance i.e., a closer is the neighbour, related is the concepts. Size of the ball reflect total number of shared citations. Position is comparative place, and control by all the mentioned factors, and besides three highlights can be drawn:

- For eight hypothetical factors, 56 possible combinations ($N^2-N$, where $N$ = No. of factors) are presented with 28 unique combinations for distinctive mutual impacts;
- “T-2: Thyroid Gland”, “T-6: Indirect Diseases” and “T-5: Antibody” stand as effective influential factors;
- Shared citation, depict a distinct picture for technological concepts, and dynamics combined with concepts relatedness.

Moreover, Fig.4 depicts the comparison between the total references and respective sharing for all concepts.

![Figure 3. Visualization of HRA in the technological field, Brain Cancer](image)

![Figure 4. A comparison of total and shared references for each concept.](image)

**Discussion and Conclusion**

Our HRA scheme used topic modelling and shared citations as concerted approach for mutual interaction, and dependency of technological topics to detect and understand emerging technologies, as described by Kostoff et al. (Kostoff 2014) that how bibliographic coupling and shared text could serve the optimistically better role than solo impacts. This innovative approach could improve topic coherence, interaction and depict supplementary insight to understand emerging technologies, where cluster linkage improve the clarity of map (Boyack and Klavans 2010) better than some other measures like citations and co-citations. As it is mentioned, bibliographic coupling originally is a powerful tool to map the coherent themes and documents representing similar research focus. Beside the total number of references are low, their sharing is dramatically higher in number for any concepts (Fig 4.).

All possible combinations follow: $N^2-N$; $N>1$, $N$= No. of factors. The study depicts that regulatory chemicals, secondary disorders and natural defence mechanism are the dominant and emerging concepts in field of brain cancer. Future research could focus on more specific implication of these concepts like which hormones, distinctive various diseases and components blood cells (immune system) and as major determinants.

Abstract
Given that many frontiers and hotspots of science and technology are emerging from interdisciplines, the accurate identification and forecasting of interdisciplinary topics has become increasingly significant. Existing methods of interdisciplinary topic identification have their respective application fields, and each identification result can help researchers acquire partial characteristics of interdisciplinary topics. This paper offers an integrated method for identifying and predicting interdisciplinary topics from scientific literature. It integrates various methods, including co-occurrence networks analysis, high-TI terms analysis and burst detection, and offers an overall perspective into interdisciplinary topic identification. The results of the different methods are mutually confirmed and complemented, further overviewing the characteristics of the interdisciplinary field and highlighting the importance or potential of interdisciplinary topics. In this study, Information Science & Library Science is selected as a case study. The research has clearly shown that a more accurate and comprehensive results can be achieved for interdisciplinary topic identification and prediction by employing this integrated method. Further, the integration of different methods has promising potential for application in knowledge discovery and scientific measurement in the future.

Social network analysis
Introduction
With the development of science and technology, scientific research is no longer limited to the study of a single field, but extended to interdisciplinary research. Bioinformatics, an interdisciplinary between Molecular Biology and Computer Science, is an excellent example to show the interdisciplinary trend because it utilizes computer tools to store, retrieve, and analyze biological information. In fact, new theories of science or emergence of inventions often originate from the intersections of disciplines, and the emphasis on interdisciplinary studies will lead to more precise and comprehensive results for frontiers prediction of science and technology.

Scientific literature is an important data source for interdisciplinary research. It is significant to explore effective knowledge mining algorithms to identify interdisciplinary topics from mass scientific literature and to make predictions. Interdisciplinary topics identification is different from conventional hotspots and frontier topics recognition, which not only reflects the popularity and growth of disciplinary knowledge, but also reflects its intersectionality. Traditional interdisciplinary analysis, which is based on high frequency terms, has certain one-sided limitations that make it bound to miss some important information and fail to guarantee the accuracy of the results. Therefore, developing an integrated method that makes full use of the characteristics of multiple topic identification methods is a pre-requisite.

This paper recalls various methods of topic identification, clarifies the characteristics of different methods in interdisciplinary topics analysis, and then puts forward an integrated method for interdisciplinary topic identification and prediction, offering an overall perspective into interdisciplinary research.

The paper continues with the presentation of the literature review. After the research methodology, the subsequent section presents the results and discussion. Finally, the paper concludes with some positive effects and limitations of the method.

Literature review
Many methods for topic identification have been provided in existing research, which mainly used knowledge units as the database. Knowledge units consist of terms, phrases, sentences, paragraphs and the like, among which topic terms analysis has the widest range of application, and types of topic terms cover both keywords given by authors and terms abstracted from the text by natural language processing (NLP).

High-frequency term analysis is the most basic and important method in topic identification, which reveals the research focus through frequency statistics. It is considered that terms of higher frequency are more likely to represent the hotspots in the field (Chu et al. 2014). By using high-frequency term analysis, many researchers took the relationship between terms into consideration. Co-occurrence analysis of terms is a typical method to meter the co-present situation of two terms that appeared in the same document, and then reflect the special relationship among them using cluster analysis (Cui 2003). It can reveal the link of research topics represented by topic terms, analyze the topic structure, and indicate the field’s hotspots and trends (Garfield 2004; Rokaya 2008; Xie 2016). However, the vast majority of co-occurrence analysis was merely based on strong co-occurrence networks. It means that terms have relative low co-occurrence frequency will be ignored, which leads to the exclusion of some potential and important topics, especially interdisciplinary topics. Wei et al. (2015)
constructed several weak co-occurrence networks to analyze research topics and their intersectionality. According to the research, the less highlighted topics in the strong co-occurrence networks would become obvious in the weak co-occurrence networks, which may be the current or potential focus.

Burst detection is another effective method for topic identification, which has a unique advantage in revealing the dynamic trends of terms and topics. It is known as burst term if the term suddenly increases in a short time, and generally, it does not belong to high frequency terms (Hong 2010). Several scholars have applied burst detection in research frontier and future trends analysis (Mane 2004; Wang 2015). Kleinberg (2003) constructed a burst detection algorithm to discover burst phenomenon, which has been the most widely used algorithm in burst detection based on scientific literature. The algorithm focuses on the terms whose relative growth rates suddenly increase, and it has been applied in multiple studies to predict the evolution trend of specific research area (Zhou 2015; Li 2017) due to its scientificty and convenience.

Many authors investigate interdisciplinary topic identification based on the above methods (Li 2013; Min 2014). Meanwhile, new attempts are made by employing some indexes. Xu (2015) used a series of indexes for interdisciplinary topic mining called high-TI terms analysis, which consists of two main indexes. The first index is TI value, which can be calculated depending on the formula $TI = d \times \log tf$; $d$ is the number of disciplines covered by the term, and $tf$ is the term frequency. This method took the distribution of terms into consideration, and reflected the interdisciplinary impact between disciplines. The other index is “betweenness centrality” (BET), a common social network analysis indicator. It was proposed by Freeman (1977) and was considered as the “intermediate” level of a node to the whole network. It can be obtained from some social network analysis software, such as UCINET. For either of the indexes, the interdisciplinarity has a positive association with the value. However, unlike TI value, which focuses on cross points between disciplines, BET value mainly represents the hinge points inside disciplines. These indexes can be efficient indicators for interdisciplinary analysis when complemented with other methods.

Above all, high-frequency term analysis and strong co-occurrence networks analysis based on high frequency terms have the widest range of applications because they generalize the most useful information. At the same time, the growing trend of using the terms and other subtle but valuable information may be ignored. Burst detection, which successfully focuses on the term’s dynamic tendency, has superiority in predicting future interdisciplinary topic and its results are highly likely to be hot topics. Weak co-occurrence networks analysis can only reflect partial and inconspicuous characteristics of the research topics in the field, but they are important supplements for strong co-occurrence topics and are more likely to represent the intersection of different disciplines as away from the field’s core topics. High-TI terms analysis can directly and intuitively reveal the interdisciplinarity among topic terms despite the requirement that it must be combined with the co-occurrence networks analysis.

Given that the above analysis methods have their respective fields of application, it is difficult to determine the best method, which reflects that each method has its emphasis. Similarly, any identification result can help researchers to analyze only partial characteristics of interdisciplinary topics. It is only when identifying interdisciplinary topics from different perspectives that we can comprehensively reveal its overall characteristics.

In summary, this study aims to put forward an integrated method for interdisciplinary topic identification and prediction, which integrates various results obtained from different methods,
including co-occurrence networks analysis, high-TI terms analysis, and burst detection, to
identify interdisciplinary topics from different perspectives and make interdisciplinary topic
identification and prediction more comprehensive and precise.

Research methodology
The framework of the integrated method for interdisciplinary topic identification and
prediction is shown in Fig. 1, which includes four parts.

Data collection
Considering that Information Science & Library Science (LIS) is a typical interdisciplinary
discipline, LIS was chosen as a case study to show the application of the integrated method.
SCI-EXPANDED, SSCI, CPCI-S, CCR-EXPANDED, and IC databases of the Web of Science (WOS) were selected as the data sources. The search strategy was “WC=Information Science & Library Science”, and the publication type was limited to “Article”. Data from 2007 to 2016 were retrieved on 2nd January, and 35,270 items were finally accessed.

Data processing
For massive scientific literature, mining and cleaning of the terms are time-consuming and laborious. Thomson Data Analyzer (TDA) is powerful in data extraction and cleaning (TDA 2016), which we employ to process data with the advice of experts. First, the dataset was prepared by extracting the titles, abstracts and references, and other paragraphs in the first part of the literature data. Then, meaningful topic terms or phrases were extracted until a certain threshold was reached through text mining. Next, the terms were cleaned using the following steps, including cleaning based on general thesauri, depth cleaning based on fuzzy matching, terms merging, and terms clustering based on principal component analysis. The final topic terms were cleaned, and the dataset of topic terms was constructed.

Interdisciplinary topic identification
Interdisciplinary topic identification is at the core of the integrated method, comprises three procedures. First, the top 300 high frequency terms were selected as basic data, and TDA was utilized to obtain the co-occurrence 300 × 300 matrix. Then, the matrix was placed into Ucinet, and GN algorithm was selected to achieve the following co-occurrence networks by clustering and visualization: (1) Strong co-occurrence networks of high-frequency terms: in this network, the term was the only node, and the threshold value of co-occurrence frequency was set as 10. (2) Co-occurrence networks of high-frequency terms and disciplines: in this network, there are two types of nodes—terms and disciplines. The threshold value of co-occurrence frequency was set as 15. Next, the TI and BET values of every term were calculated in topic terms dataset, where each term was ordered in turn, and two lists were obtained. Then, the TI and BET values of every term were compared with the two co-occurrence networks mentioned previously. Terms were marked as square in strong co-occurrence networks of high-frequency terms and disciplines when their TI values were greater than 10. The terms were marked as a star in both networks when they show high TI value and high Bet value at the same time and appear simultaneously on both networks. Finally, the co-occurrence matrix obtained in the first step was imported into Gephi to obtain weak co-occurrence networks. To make it clearer, co-occurrence frequency ranged from 3 to 10, and the node degree was not less than 5.

The information above shows that three kinds of interdisciplinary topics can be obtained. Then, combining all the results and subtracting the significant ones enables the identification of interdisciplinary topics in a more systematic and wholesome manner.

Interdisciplinary topic predication
The prediction of interdisciplinary topics has two steps—time series analysis and burst detection. Time series analysis is based on the identification results in the previous part. We could determine the orientation of future evolution by analyzing the topics’ changing situations along a given timeline. In the study, the topics acquired through upper analysis would be lined up and the trends can be found in this process. Burst detection utilizes Sci2,
which is a knowledge discovery tool developed by Katy Börner (2009), a library and information expert at Indiana University, Bloomington. It could detect frontier terms in the field using Kleinberg's burst monitoring algorithm. In this research, we set the detection interval from 2007 to 2016 and took the burst terms as the representation of related topics. More efficient and accurate prediction results can be achieved by combining the two steps.

**Results and Discussion**

Considering the large amount of data, this study chose 2007, 2009, 2011, 2013, and 2015 as the target years and made a detailed analysis. Meanwhile, only visualization results of 2007 were presented owing to space constraints.

**Interdisciplinary topic identification in 2007**

Figure 2 shows a strong co-occurrence network of high-frequency terms, and it is divided into 14 sub-networks, including complex networks, technology application practice, open access, journal evaluation, digital libraries, document services, bibliometrics, information management, information technology, information retrieval, information science, citation analysis, user study, and knowledge management.

![Fig. 2. Strong co-occurrence network of high-frequency terms in 2007.](image)

Figure 3 presents the co-occurrence network of high-frequency terms and disciplines, which indicates that LIS mainly interacts with the History of Social Sciences, Computer Science, and Management in 2007. The high-TI and high-Bet terms appearing in two networks are found in information retrieval, information management, bibliometric analysis, information technology, information systems and empirical investigation. This implies that these topic terms are the key nodes when LIS interacts with other disciplines, and the meanings reflected by these terms are regarded as important hinges and cross nodes in interdisciplinary areas in 2007.
Figure 4 illustrates a weak co-occurrence network, which is broken down into four sub-networks—communication technologies, information science, digital libraries, and bibliometric analysis. All of these topics are also contained in the results of strong co-occurrence network of high-frequency terms, but the positions of bibliometric analysis, communication technologies, and digital libraries in the weak co-occurrence network are more prominent in proportion to their importance, manifesting that these interdisciplinary topics have the potential for further development and should not be underestimated. Moreover, the bibliometric analysis is also an important hinge and cross node in high-TI terms analysis,
indicating that the importance of some topics has been highlighted by the weak co-occurrence networks analysis. In addition, the results of weak co-occurrence network analysis are consistent with the results of strong co-occurrence networks analysis and high-TI terms analysis to some extent, which proves that weak co-occurrence networks analysis is a necessary complement to the other two methods.

**Interdisciplinary topic identification in 2009**

The strong co-occurrence network of high-frequency terms in 2009 can be divided into 17 sub-networks, which include user research, e-government, complex networks, technology application practice, open access, digital libraries, text classification, bibliometrics, information services, information management, information technology, information retrieval, information systems, information literacy education/train, academic libraries, citation analysis, and knowledge management. LIS mainly interacts with Computer Science and Management. Important hinges and cross nodes are found in subjects including user satisfaction, open access, information management, citation data, information technology, information systems, complex networks, communication technologies, classification technique, bibliometric analysis, and semantic relationships analysis. The weak co-occurrence network is clustered into five sub-networks, which are information management, information technology, user satisfaction, open access, and scientific communication. They are all included in the strong co-occurrence network at the same time; however, the position of scientific communication in the weak co-occurrence network is more salient than in the strong co-occurrence network. Meanwhile, information management, information technology, user satisfaction, and open access are important hinges and cross nodes.

**Interdisciplinary topic identification in 2011**

The strong co-occurrence network of high-frequency terms in 2011 involves 14 sub-networks that contain web 2.0 technologies, technology study, competitive intelligence, open access, scientific collaboration, journal evaluation, information services, information behavior research, information technology, information retrieval, academic evaluation, academic libraries, citation analysis, and knowledge management. LIS interacts with Arts & Humanities, Computer Science and Business & Economics mainly by the terms, such as information technology, user acceptance, and information systems in 2011. The weak co-occurrence network in 2011 has six sub-networks, including information science, information retrieval, social networks, information technology, digital libraries, and knowledge sharing. All of the sub-networks are included in the strong co-occurrence network except the digital libraries. In addition, the positions of nodes of information science, information retrieval, social networks, and digital libraries in the weak co-occurrence network are more important than in the strong co-occurrence network. “Digital libraries” is a significant interdisciplinary topic with great potential, to which more attention should be given. Meanwhile, information technology is an important hinge and cross node from the perspective of high-TI terms analysis.

**Interdisciplinary topic identification in 2013**

There are 15 sub-networks in the strong co-occurrence network of high-frequency terms of 2013, including competitive intelligence, open access, scientific collaboration, journal evaluation, social network research, web use, bibliometrics, information behavior research,
academic evaluation, academic libraries, user study, semantic analysis, knowledge management, public libraries, and information sources. Although information technology, information systems, digital libraries, information retrieval, information science, and social networks were not classified into any sub-networks, they are important hinge nodes in the network. LIS usually interacts with Computer Science, Business & Economics, Health Care Sciences & Services, and Medical Informatics using the terms, such as user acceptance, information technology, information retrieval, information systems, social networks, knowledge sharing, and social media, which are important hinges and cross nodes. The weak co-occurrence network in 2013 is clustered into five sub-networks, which consists of information science, knowledge management, user acceptance, citation analysis, and information need. These topics are all contained in the strong co-occurrence network as well. The difference lies in the fact that the positions of knowledge management, citation analysis, and information need are more conspicuous than in the strong co-occurrence network. In addition, user acceptance is the hinge and cross node in high-TI terms analysis.

Interdisciplinary topics identification in 2015
The strong co-occurrence network of high-frequency terms of 2015 is divided into 11 sub-networks covering academic libraries, technology application practice, information behavior research, knowledge sharing, information science, complex networks, bibliometric analysis, competitive intelligence, information technology, text analysis, and digital libraries. LIS mainly interacts with Computer Science and Management. At the same time, it has interaction with Health Care Sciences & Services, Medical Informatics, and Communication to some extent. The important hinges and cross nodes are knowledge sharing, information management, qualitative analysis, information systems, academic evaluation, citation analysis, information science, complex networks, information technology, social media, and health informatics. It implies that the interdisciplinary features of these terms are prominent. The weak co-occurrence network of 2015 is clustered into five sub-networks covering qualitative analysis, social media, information systems, information management, and citation analysis, which all belong to the strong co-occurrence network. The positions of qualitative analysis, social media, information systems, and information management are more obvious than in the strong co-occurrence network. Meanwhile, the core nodes of the five sub-networks are all important hinges and cross nodes according to the results of high-TI terms analysis.

Interdisciplinary topic prediction
(1) Time series analysis
The results of time series analysis can be concluded as follows: First, some topics, which have been around in the co-currency networks for more than four years, may be considered as the most constant and hot interdisciplinary topics in the area. These topics cover open access or knowledge sharing or scientific communication, information management or knowledge management, information technology or communication technology, information retrieval, citation analysis, information system, technical application practice, journal evaluation or academic evaluation, bibliometric analysis, information science, user study or user satisfaction or user needs or user acceptance. Second, a few topics have disappeared in recent years, signaling that the importance of these topics has somewhat reduced and probably will continue to show a downward trend in the future. These topics cover literature service or
information service, e-government, text classification or classification techniques, information literacy education, scientific communication and others. Third, many topics have always existed since it appeared in the last few years. Undoubtedly, this group reflects the major orientation of interdisciplinary evolution in the near future. Semantic relationships analysis, competitive advantage, information behavior, scientific collaboration, social networks, and social media all belong to this group.

(2) Burst detection

The original results of Sci2 consisted of 323 terms, which were further screened out by artificial interpretation based on the correlation with research objects, and then 55 terms were filtered. Table 1 lists the burst terms that appear from 2014 and still persist. “Weight” represents the degree of emergency. “Start” represents the start year when a term began to be a burst term, and in a similar way, “End” represents the end year when a term is no longer a burst term. “Length” is the time span from start to end.

</table>

Given that the end year of all terms in the table is 2017, it can indicate that any term should not be underestimated in the following years. From the view of weight, we can see that social media has the highest value, revealing its greater significance in future studies. Next is altmetrics, a new method of assessing the impact of published works. With the continuous development of social media, altmetrics will be widely used in the research. Besides, the weight of virtual communities, big data, social network, scientific collaboration, web 2.0, co-authorship networks all exceed five, demonstrating the good development prospect of these topics. From the perspective of length, terms have a higher value, possessing both abruptness and a certain continuity. These terms include social media, information overload,
organizational-behavior, societal impact, collaboration networks, and publication patterns, whose Length values are greater than four.

Discussion
Based on the above analysis, the key characteristics of the interdisciplinary situation in LIS can be outlined. First, the number of interdisciplines connected to LIS shows an increasing trend. Among them, Computer Science is an enduring discipline, which shows the greatest similarity in research content to LIS, and Management and Business & Economics come second in light of similarity in research content. Medical Informatics and Health Care Sciences & Services demonstrate an obvious trend to interact with LIS. Second, the most important interdisciplinary topics in LIS are not only core nodes of strong co-occurrence networks of high-frequency terms, but also sub-networks of weak co-occurrence network of high-frequency terms, as well as terms with high TI and high BET value. These topics include bibliometrics (2007), information management, information technology, user satisfaction, and open access (2009), information technology (2011), user acceptance (2013), qualitative analysis, social media, information systems, information management, and citation analysis (2015). Third, the major future interdisciplinary topics consist of semantic relationships analysis, competitive advantage, information behavior, scientific collaboration, social networks, social media, altmetrics, virtual communities, big data, web 2.0, and co-authorship networks, among which social media, social network and scientific collaboration are especially on the rise due to the continuous development of communication tools.

Conclusion
In this study, we constructed an integrated method for interdisciplinary topic identification and prediction. By employing the integrated method, more accurate and comprehensive results can be obtained for interdisciplinary topic identification and prediction. The results of the different methods are mutually confirmed and complemented, further overviewing the characteristics of the interdisciplinary field and highlighting the importance or potential of interdisciplinary topics.

However, this integrated method is limited to the fusion of analysis results, which is only the late fusion stage for integration. Beyond that, early fusion stage (data integration) and mid-fusion stage (fusion of data relations) are also available and valuable. Thus, in the future, we plan to consider deep integration from the early or middle stage. Moreover, it is necessary to expand the integrated method further by absorbing other good methods into its system and exploring more possibilities of integration.

The integration of different methods has promising potential for application in knowledge discovery and scientific measurement in the future. However, the kind of objects that can be integrated, the choice between data types or data relation, and their method of integration, which is either artificial or automatic, require us to conduct more in-depth and long-term exploration.

Abstract
Previous studies focused on the characteristics of elite scientists, or the early identification of high-potential scientists, but neglected career development research of ordinary young scientists. Using scientometrics and CV methods, the present study aims to establish statistic models in order to explore young scientists’ career development, and predict their future academic impact. Predictors at 2009 were divided into four categories: publication indicators, scholar relationship indicators, scholar relationship indicators and research theme indicators, and these indicators were used to predict $h$-index at 2014. Predictive models were established separately in each category using stepwise regression, and finally a comprehensive model was built. Our result shows that $h$-index and total number of paper published could significantly predict scientific impact in the future. To improve academic impact, young scientists need to carry out extensive cooperation and play a key role in the cooperation, need to have the research experience in developed countries, and to reduce their research specialization.

Conference Topic
Studies on the level of individual scientists

Introduction
Whether we can base on small number indicators to predicate a scientists’ future scientific impact? More practically, for making a wise choice, which part of applicants’ CV should be pay more attention to, when scientific institutes want to recruit a new researcher? Many researchers had tried to answer these questions. Using machine-learning approach, Acuna et al. (2012) collected 3085 neuroscientists’ CV data, and match them with publication data in Scopus. They tried to use scientometrics indicators to predict $h$-index of these neuroscientists in 1 year, 5 year, and 10 years later. In a better linear predictive model, the predictors are current $h$-index, number of article written, years since publishing first article, number of distinct journals published in, and number of articles in Nature, Science, Nature Neuroscience, PNAS and Neuron. These indicators can explain 67% variance of $h$-index in the 5-years later. The work of Dijk et al. (2014) is also valuable. They tried to predict who will become a PI in the future based on 25000 researcher’s publication information in PubMed. The conclusion was that number of publications, the impact factor (IF) of the journals in which those papers are published, and the number of the papers that receive more citations than average for the journal in which they were published (citation/IF) are three important predictors. Whether a scientist will become PI depends to a great extent on their publication, especially in their early career. More importantly, this study found some non-publication features, such as the range of university and gender, also significantly determine whether a scientist will become a PI. Scientists’ CVs provide more information beyond their publication. Generally, CV contains many information about educational experience, mobility experience, gender, occupation years, scientific cooperation, research theme, and so on. Beside these scientometrics indicators calculated from their publication, whether these non-publication features obtained from CV --
- personal characteristics, scholar cooperation relationship, research theme --- could play a statistically significant role in predict future scientific impact? The current study tries to consider both of publication features and non-publication features, and finds out which indicators are more sensitive in predicting the future scientific impact after parameter comparison.

The literature review revealed that mobility experience is benefit scientific career development (Filippo, Casado, Gómez, 2009; Yamashita & Yoshinaga, 2014; Cañibano, Otamendi, Andúja, 2008; Jonkers & Tijssen, 2008). And other studies supported the opinion that post-doc experience enriches the researchers’ human and social capital, and has a positive effect on future academic performance (Zubieta, 2009; Gaughan & Robin, 2004). So, personal characteristic features in current study contain some scientific mobility indicators and post-doc indicators. Furthermore, because the differences on gender and career age must make certain influence on academic achievement (Cole, 1984; Symonds, Gemmell, Braisher, et al., 2011; Bornmann, Mutz, & Daniel, 2007; Dickersin, Fredman, Flegal, et al., 1998). Gender and age were also included into personal characteristic features.

Many studies also provided a lot of evidences that the scientific cooperation is positively related with scientific productivity and impact (Price, 1963; Zuckerman, 1967; Tang & Shapiro, 2012; Katz & Hicks, 1997). Recent researches used social network method to qualify one researcher’s co-author network (Abbasi, Chung, & Hossain, 2012; Mccarty, Jawitz, Hopkins, et al., 2013). In present study, we will also consider the size of co-author network and position in the network as the scholar cooperation feature.

Meanwhile, each researcher has their own special research field. Researchers in different research field would be have different career development trajectories. Whether the researcher who focus on hot topic or rising topic has more developmental potential? Whether one researcher consistently focused on one research field will acquire better scientific impact in the future than those who are interested in different fields? These research theme related features involve in theme hotness, theme novelty and researcher’s specialization.

In present study, different types of indicators will be included in a comprehensive predictive model to build an optimizing model with predictors as little as possible, and try to figure out the most effective factors. We also pay main attention to young scientists who just start their career path.

**Methods**

**Sample:** This study will focus on young psychological researchers of 15 psychological research institutes from USA, Netherland and China. The sample procedure excluded adjunct professor, emeritus professor, affiliate professor, doctor students, post-doctor and technical staffs. Only the scientists who got their doctoral degree between 2004 and 2009 were selected. Their CVs were downloaded from their websites and LinkedIn, and decoded. Their publication data was downloaded from Web of Sciences (WOS). And according to these data, we counted each person’s $h$-index in 2009 and 2014. The period of data collection was Mar – May, 2015.

**Indicators:** The dependent factor is $h$-index at 2014, as the measurement of future academic impact. The predictive variables were divided into four categories: publication indicator, scholar experience indicator, scholar relationships indicator, and research theme indicator. Eight publication indicators calculated from publication data were selected. They are $h$-index, total number of papers published, total citation, citation per paper, $h$-index per year, paper number per year, number of journals, and average impact factor. Seven scholar experience indicators decoded from CV are gender, whether has post-doc experience, duration and times of post-doc, career age, mobility frequency, and whether has work experience at American
institutes. Two scholar relationship indicators are total number of co-author and betweenness centrality of co-author network. We used each young psychologist as core node to build ego network, and calculated the betweenness centrality of core node. The authors who has high betweenness centrality are more important for their co-author network, and have more control on cooperation relationship. Research theme indicators are theme hotness, theme novelty and specialization. Theme hotness of each author was defined as the average number of $h$-index of all author keywords. Theme novelty of each author was defined as the average number of time span of all author keywords since their first appearance in publication. Leahey (2006) define the Specialization as “a researcher focusing tightly on one or a few subfields, rather than spanning many”. Calculation of specialization refers to the formula of Porter, et al. (2007). Specialization ($S$):

$$S = \frac{\sum[(\text{# of papers published in } WC_1)^2 + \cdots + (\text{# of papers published in } WC_n)^2]}{\sum[(\text{# of papers published in } WC_1 + \cdots + (\text{# of papers published in } WC_n)]^2}$$

Where WC is the Web of Science Category in WOS.

All the predictors used in present study see Table 1.

**Procedure:** The retrospective analysis was used. The present study try to use the predictive variables in 2009 to predict academic impact of a specific scientist in 2014. Indicators in each category were used to find the most significant predictor in each model. Through stepwise regression, all predicative indicators were entered into formula one by one. According to Akaike Information Criterion, the non-significant variables were deleted, and the significant variables remained. The best fit model should satisfy the follow two conditions: all the variables in predictive model are significant, and number of predictors should keep as less as possible. Finally, using the same method, a comprehensive predictive model was built. R language were used to complete statistical analysis.

**Results and discussion**

**The predictive model of publication indicators:** Only two publication indicators can significantly predict the \( h \)-index in five years later. They are current \( h \)-index and number of publication. The R-squared for the obtained regression model is 69.83% (\( F=94.75, p<0.01 \)). There is no collinearity in this model. Variance Inflation Factor (VIF) is 3.82, below 10. The regression equation can be written as:

\[
H = 0.87 \, (H09) + 0.28 \, (Num.JP09) + 3.78
\]

This result is consistent with previous research conclusion that publication indicators could well predict academic impact in five years later (Acuna et al., 2012). What’s more, our result reveals that the model is also suitable for young scientists, even they just start their career development. Peterson, Jung, Yang, et al. (2011) developed a career progress model, and tested it on career of scientists and athletes. They found that cumulative advantage gained from past success will determine the future career development, an evidence of age-old Matthew “rich get richer” effect. Our model shows that for scientists, the Matthew effect appears very early. The tiny difference in \( h \)-index and number of publication between PhD graduates maybe became formidable lap in the later. Just as Peterson, Jung, Yang et al.’s study (2011), we also highlight the importance of early career development. Career competition started very early for scientists.

**The predictive model of scholar experience indicators:** In all seven variables, only the destination of mobility can significantly predict the \( h \) index in five years later. It means that the future scientific impact is not related with gender, post-doc experience, whether and number of scientific mobility, but the scholar experience in American institute seemly is important for future development, at least for psychologists. Meanwhile, its contribution is lower that current \( h \)-index and number of publication. The R-squared for the obtained regression model is only 16.32% (\( F=12.9, p<0.01 \)). The regression equation can be written as:

\[
H = 4.46 \, (Dest) + 7.26
\]
The predictive model of scholar relationship indicators: Both size and centrality of co-author network significantly predict h-index in five years later. The R-squared for the obtained regression model is 50.3% (F=40.98, p<0.01). There is no collinearity in this model. The regression equation can be written as:

\[ H = 0.19 \text{(Num.Co)} + 11.41 \text{(Betweenness)} + 4.41 \]

The size of co-author network reflects the wide cooperation relationship of scientist. McCarty, Jawitz, Hopkins, et al. (2013) found that the differences of h-index could be explained by number of co-authors. The current study confirms their conclusion, and further suggests that number of co-authors also can highly explain the variance of h-index in five years later. Moreover, the significant predictive effect of betweenness means that scientist should maintain the core position of their scholar network. The one who exhibits more control on cooperation network will have better career development in the future.

The predictive model of research theme indicators: Among three theme indicators, only specialization is the significant predictor of h-index in five years later. The contribution of specialization is 15.3% (F = 16.17, p< 0.01). The regression equation can be written as:

\[ H = -11.93 \text{(Specialization)} + 13.49 \]

The standard B value is negative. It means that if a scientist only focus on one research field, his/her scientific impact may become lower than his/her peers. This result seemingly violates common sense. But in practice, the scientist who only focus on certain scientific question indeed is difficult to publishing more research papers, and generally has small cooperation network.

The comprehensive full model: Based on four separate models, six significant variables were used to construct a multiple predictive model. Using the same lineal regression method, the comprehensive model was constructed. Three factors were eliminated, and other factors remain. H-index, number of publication and specialization still significantly predict h-index in the five years later. The final model is:

\[ H = 4.76 + 0.92 \text{(H09)} + 0.24 \text{(Num.JP09)} – 3.00 \text{(Specialization)} \]

The R-square of the model is 72.55% (F= 74.14, p<0.01).

We should not make causal interpretation of the relation between these predictors and future scientific impact. But empirically, just as the model shows, the young scientist who has higher h-index, published more papers, and has extensive research interest will have more potential in the future.

Conclusion
A empirical model was constructed. The model can use only three indictors --- h-index, total number of paper published, and specialization – to predict future research impact effectively. And the data also suggests early cumulative advantage is essential for future career development of young scientists. To improve academic impact, young scientists need to carry out extensive cooperation and play a key role in the cooperation, need to have the research experience in developed countries, and to reduce their research specialization.

Is the Gap in Scientific and Technological Strength Between G7 and BRICS Becoming Smaller or Larger?

Yuan Junpeng  Gao Jiping  Su Cheng  Zhai Lihua  Wang Haiyan  Pan Yuntao

junpengyu@gmail.com
Institute of Scientific and Technical Information of China, Beijing (China)

Introduction
Science and technology in emerging economies is undergoing rapid development. As a result, the question arises of whether the gap in scientific and technological strength between emerging economies and developed countries is becoming smaller or larger. Although there are many ways of studying scientific activity systematically, scientometric analysis provides a well-proven means of achieving this goal (Garfield E. 1979). Although numerous lists of highly cited articles have been compiled across a variety of scientific fields, few have included articles from all fields (van Raan 2017, Siddiqi and Usman 2017, Terekhov 2017). The present study was an in-depth scientometric analysis of data. It aimed to identify and analyse the 1000 most highly cited articles and evaluate the research performance of the G7 and BRICS countries. It is hoped that this study will stimulate useful discussion among scientists and research managers about research directions and provide insight for policy and funding decisions.

Dataset and methods
Since the reformation and opening up of its economy in 1978, China has undergone rapid development. The Web of Science (WoS) database was used to compile a citation history of papers for the period 1978–2008. Based on these articles and citations, the top 1000 highest-impact articles in every discipline were selected as the dataset. To measure scientific output, we adopted as indicators the total number of articles, total citation rates, citations per article, and numbers of domestic and international articles. To examine collaboration, we chose the index of international articles, the international cooperation rate to assess the role of international collaboration in high-impact articles.

Analyses and results
We consider whether a country’s stage of economic development and its S&T level can affect the production of its highly cited papers. Do S&T levels lead to or result from numbers of highly cited papers?

Characteristics of G7 countries’ highly cited papers
Domestic articles are taken to be highly cited papers that were written entirely by authors of one particular country. Analysis of the G7's domestic papers in 22 disciplines can be used as an indicator of the S&T capability and impact of the G7 countries in various disciplines. It can be seen that domestic papers of the G7 accounted for the majority of the papers in all the disciplines: except for the fields of space science, clinical medicine, agricultural sciences, and mathematics, those proportions were greater than 70%. The proportion of G7 domestic papers to all domestic papers in the discipline of general social sciences was more than 90%.

Because it provides access to a wider range of facilities and resources, collaboration is encouraged at a policy level. It enables researchers to participate in networks of cutting-edge and innovative activity. The international cooperation rate can reflect the G7 countries’ status of participation in international scientific and technological cooperation. The international cooperation rate of G7 countries in the 22 disciplines is shown in Figure 1.

Fig 1a. The international cooperation rate among the G7 countries in 22 disciplines

Fig 1b. The international cooperation rate among the G7 countries in 22 disciplines

The present study divided the years between 1979 and 2008 into three decades (1979–88, 1989–98, and 1999–2008) to compare the number of domestic articles in G7 countries in 22 disciplines. Analysis showed that the number of highly cited papers from 1979 to 1988 and from 1989 to 1998 was far greater
than the number of such papers from 1999 to 2008. This is in keeping with the principle that in the G7 countries papers published earlier tend to be cited more often.

**Characteristics of BRICS countries’ highly cited papers**

In terms of the number of papers in the various disciplines, there was a large gap between the rankings of the five BRICS countries and the G7 countries. Table 1 lists the total number of articles and the ranking by discipline of the BRICS countries. Table 1. The total number of articles and ranking by discipline of the BRICS countries (1979–2008)

The economic strength and S&T capacity of the BRICS countries made substantial progress over the period from 1979 to 2008, and the number of SCI papers of the five countries also increased rapidly. It is evident that the highly cited papers in the BRICS countries were mainly the result of international cooperation. In terms of the average international cooperation rate among the BRICS countries, chemistry was the discipline with the lowest rate; the average rate amounted only to 16.67%. The next lowest were pharmacology & toxicology and mathematics. The other disciplines showed an average rate of greater than 50%. Notable was the rate of 100% in economics & business, immunology, and multidisciplinary, which indicates that the highly cited papers produced by BRICS countries in these three disciplines were entirely the result of international cooperation. Compared with the figures for the G7 countries, the average rate for chemistry and pharmacology & toxicology was also low among the BRICS countries.

**Conclusion and discussion**

The present study was designed to analyze the published articles that attracted the most citations in the G7 and BRICS countries. Some valuable insights can be gained through this restricted approach.

1) The United States was the world leader, followed by the United Kingdom, Germany, and Japan. There was a significant gap between Italy and the other G7 countries.

2) In terms of the number of papers in the various disciplines, there was a large gap between the rankings of the BRICS countries and the G7 countries.

3) There was a world trend toward domestic research in terms of highly cited papers. The papers in the majority of disciplines in the United States were based on independent domestic research. The United Kingdom, France, Germany, and Italy placed greater emphasis on international cooperation, and Japan and Canada had different tendencies toward international cooperation in different disciplines.

4) The highly cited papers among BRICS countries in economics & business, immunology, and multidisciplinary were produced entirely by international cooperation.

5) The growth rates were high in 13 disciplines in Germany and 12 disciplines in Japan. In the United Kingdom and France, the growth rates were high in eight disciplines. Finally, the United States had high growth rates in five disciplines, and in Canada and Italy growth rates were high in four disciplines.

Introduction
When it comes to possible benefit of linguistic complexity to scientific impact, opinions are split in communities (e.g., Gopen & Swan, 1990; O’Conner, 2010). To be or not to be complex? This is a worthy question for us to investigate—whether linguistic complexity is crucial to scientific writing so that impact can be expanded. Can scholars succeed when they write pleasant English, usually accompanied with complexity to some extent? Or they just employ writing as a tool to report their findings and ignore the beauty of language. After all, publishing papers of high impact as many as possible is one of scholars’ genuine concerns. This preliminary study is to dig this controversial questions based on large-scale fulltext and citation data of academic articles using regression analysis.

Methodology
Data
We collected 170,000 fulltext journal articles with publishing history (the dates when the paper is received, revised, accepted, and published) detailed in dates from 2006-2015 published in PLoS* and their corresponding citation data harvested from Scopus between 2016 February 3-6, a very short time period, so that we can neglect the potential error in citation data caused by different harvest timelines. We only kept all the articles in Biology by retrieving the assigned disciplinary information to reduce disciplinary differences. Our final dataset contained 49,350 fulltext articles in Biology with their publishing history and citation data with date.

Independent variables
The independent variable, Linguistic Complexity comprises Syntactic Complexity, the sentence-level complexity of language performance, and Lexical Complexity, the vocabulary-level language performance. Variables for syntactic complexity can be divided into two sub-groups: Sentence Length and Sentence Complexity (Vajjala & Meurers, 2012). And Lexical Complexity includes three sub-groups: Lexical Diversity, Lexical Sophistication, and Lexical Density (Ellis & Yuan, 2004; Kormos, 2011) (Table 1). Pearson’s Correlation Analysis showed no correlation between these variables.

</tr>
</tbody>
</table>

Dependent Variable
Since we had only obtained the total citation number for each article, we used the number of citations per month (CPM) as an alternative to eliminate the
possible effect caused by different periods of citation history. The variable was calculated as follows:

\[
CPM = \frac{\text{total number of citations}}{\text{Month(harvest date – published date)}}
\]

**Regression Analysis**

To investigate the relationship between Linguistic Complexity in scientific writing with scientific impact, we conducted regression analysis, using CPM as dependent variable and the 12 explanatory variables shown in Table 1. Considering that the variables had shown a strong trend of decrease after increase (two samples in Figure 1). Multinomial model \(Y = aX^2 + bX + c\) was to fit the data. articles with top 1% CPM ranking were selected as the most highly cited articles to compare the regression models.

![Figure 1. Scatter plots between CPM and JR (A) and MNL (B).](image)

**Results**

Table 2 shows descriptions of the two models: one for all the full text articles and another for the top 1% articles based on CPM ranking.

</tbody>
</table>

**Notes:** (1) Standard errors in parentheses; (2) \(p < .05, \quad **p < .01, \quad ***p < .001\).

In the first model, most features show quadratic relationships with CPM (p≤0.01), except for adverb length and noun ratio (positive linear relationship). The parameters suggest that moderate level of complexity in paper can promote the CPM and that the abundance of vocabulary provides a positive support for CPM of an article. In other words, moderate linguistic complexity is helpful to improving average citation of an article; however, too much complexity in syntactic level or word length may affect gain of citation since the difficulty in reading might dramatically increase according to studies (e.g., Juhasz, 2008).

However, the low level of R’s in the preliminary models might suggest that major efforts should be made in other areas to improve the content of an article, e.g., the novelty or contribution of the study articulated, which is supported by top CPM articles.

**Conclusion**

This preliminary study is to find out the relationship between linguistic complexity in scientific writing and scientific impact using regression analysis. The results might suggest that complex scientific writing helps improve scientific impact of an article to some extent but the major effort should be made in the content of it, e.g., the novelty and contribution to academic community. Given that the mutual effects of these variables to the impact has not been considered, more types of models should be used to clarify the relationships between them in the future.

A new method to quantify the spatiotemporal dynamic of the academic papers using centroid method

Wang Xuemei\(^1\)   Ma Mingguo\(^2\)

\(^1\)w20141103@swu.edu.cn
Southwest University Library, 2 Tiansheng Road, Chongqing (China)

\(^2\)mmg@swu.edu.cn
Southwest University, School of Geographical Sciences, 2 Tiansheng Road, Chongqing (China)

Introduction
The bibliometrics is an interdisciplinary field that combines mathematics, statistics and information science to study literature mining (Pritchard, 1969). The application of the geographic information system (GIS) technologies in the bibliometrics is an interdisciplinary field in the recent ten years (Allen, 2001). The spatial analysis capability is one of the most important functions in GIS. The application of GIS spatial analysis to bibliometrics is still in its initial stages (Wang et al., 2014). In this study, we try to expand the spatial analysis of the GIS in bibliometrics and develop a new method to quantify the spatiotemporal dynamic of the academic papers using centroid method.

Method
The global international papers of the geosciences from 1981 to 2016 were indexed and downloaded from the SCI-E and SSCI databases of the Core WOS Collection. Here the subject of the geosciences is based on the subject classification of Essential Science Indicators (ESI). The paper categories of ‘Article’ and ‘Review’ were included in our study. The published paper numbers and cited numbers of all authors for each country were counted.

For the polygon features, the geometric center is defined to balance the shape. The geometric center for each country was calculated based on this definition. The values of geographic parameter can be linked with the geometric centers of these polygon features. Then the centroid can be calculated based on the geometric centers and geographic parameters, which can reflect the change process of the spatial aggregation, dispersion and migration over time (Bansal et al., 2013). In this study, the published paper numbers and cited numbers of all the countries in the world were linked with these geometric centers. Then the centroid can be calculated using the following formulas.

\[
X_t = \frac{\sum_{i=1}^{n} (C_i \times X_i)}{\sum_{i=1}^{n} C_i} \quad (1)
\]

\[
Y_t = \frac{\sum_{i=1}^{n} (C_i \times Y_i)}{\sum_{i=1}^{n} C_i} \quad (2)
\]

Here, \(X_t\) and \(Y_t\) are the centroid coordinates of the longitude and latitude in the \(t^{th}\) year respectively. \(C_i\) is the published paper number or cited number of the \(i^{th}\) country in \(t^{th}\) year. \(X_i\) and \(Y_i\) are the longitude and latitude coordinates of the geometric center of the \(i^{th}\) country respectively.

Results
There are more than 190 countries or regions with the international papers of the geosciences during 1981 to 2016. But most of the countries or regions have the paper number less than 1000. Figure 1 shows that the percentage of the paper number for each country. The countries or regions with high percentages mainly distribute in the North America, Europe, Asia and Oceania. The top ten are United States of America (USA), United Kingdom (UK), China Mainland, Germany, France, Canada, Russia, Japan, Australia, and Italy in turn. The global international papers of the geosciences have the exponential increasing tendency and the exponential increasing coefficient is 0.0595 (\(R=0.9963\)) from 1981 to 2016. Similarly, most of the countries or regions have the exponential increasing tendency. The exponential increasing coefficients for the top 30 countries or regions with more paper numbers are shown in the Figure 1. It can be indicated that some countries or regions have higher coefficients than that of the global average level (green patches in Figure 1), such as South Korea, China Mainland, Chinese Taiwan, Turkey, Spain, Argentina, Austria, which means that they have more and more contributions on the global international papers of the geosciences from 1981 to 2016. Moreover, Russia, USA, Canada, New Zealand, UK, France, South Africa, Australia, India have the lower coefficients than that of the global average level (red patches in Figure 1).

The spatiotemporal dynamics of the centroids of the paper numbers and cited times are shown in Figure 2. It can be indicated that the centroids mainly move from west to east as a whole. The transfer speed of the centroids of the cited times is 1.43 degree/yr. Correspondingly, the transfer speed of the paper numbers is 0.93 degree/yr. It means that the cited times in the East have higher increasing speed than the paper numbers. On the
contrary, the centroids of the cited times are always located in the west of the centroids of the paper numbers. It indicates that the cited times in the West always occupy higher percentages than the paper numbers. But there is the decreasing trend from 1981 to 2016. The centroids of the paper numbers stuck at 17.7 degrees west of Greenwich from 1981 to 1995. On the contrary, the centroids of the cited times are approximately continuously migrating eastward.

![Figure 1. Exponential increasing coefficient and percentage of the paper number for each country](image1.png)

![Figure 2. The spatiotemporal dynamics of the centroids of the paper numbers and cited times.](image2.png)

**Conclusion**

The centroid method was successfully used to monitor the spatiotemporal dynamics of the paper numbers and cited times. Both of the centroids of paper numbers and cited times mainly move from west to east as a whole.

Faculties Activity Research based on Local and Global Databases. Case Study.

Veslava Osinska¹ Piotr Malak²

¹ wieo@umk.pl
Nicolaus Copernicus University, Torun (Poland)
² poitr.malak@uwr.edu.pl
Wroclaw University, Wroclaw (Poland)

This research is sponsored by Polish National Science Center (NCN) under grant 2013/11/B/HS2/03048/Information Visualisation methods in digital knowledge structure and dynamics study.

Introduction

The state of under-representation of the humanities and social sciences in the global databases such as Web of Science and Scopus has become permanent and detrimental. But for scientometric research on mezzo (institutional) level local databases can successfully complement world indexes. The authors present case study of using unstructured data, deriving from University Website and then visually analysing. Cleaning and processing allows to identify metadata which describe academic activities in organizing different events at University. Another data source is University bibliographic database Expertus, the most complementary information resource concerning the publications of employees. This way, two different activities: publishing and organisational one can be compared for each faculty or equivalent division and thus evaluate collective impact in academic environment.

Data and metadata

Data collecting

Application form accessible at University Website https://www.umk.pl/badania/konferencje/ allows to collect such metadata about conferences as: Date, Title, Faculty, Organiser(s), Place, Leader, Secretary, Description. Downloaded data due to HTML format required semiautomatic cleaning. The relatively small records quantity $N = 1344$ allowed for quick estimation of similarities and relationships. Due to field about organizers units asymmetric matrix has been created for the quantitative representation of the intensity of cooperation in conference organizing. Asymmetry is connected with unequal roles of the organizer and co-organizer.

Data aggregation

All identified University units (over 300) were grouped into the main categories corresponding to 17 Faculties and one additional, General. Thus, for publishing and organisational activity, cumulative data according 18 categories was obtained. In order to compare the received visualisations with the generated image according to the Web of Science data, the next level of grouping: faculties into scientific areas was performed. Ultimately, into study we involved domains, such as:

- humanities,
- natural science,
- life sciences,
- medicine/clinical sciences,
- engineering and technical science,
- social sciences.

Analysis

Graphs, maps and diagrams were used in the visualisations. To illustrate the dynamics of publishing activity for each Faculty area chart is used as the most effective in the trend study (Fig. 1).

Figure 1. Dynamics of faculties publishing per year.

The band width exposes publication quantity a year for each faculty. It allows to observe all changes and parallel to capture information which is the most effective unit for analyzed period.

For comparison local and global databases, ring charts were used. Figure 2 presents domain structure for three data sources. As mentioned before, standardized categorization was applied. All domains colored by scheme, which is available at InCites reports: https://incites.thomsonreuters.com/. Outer ring at Fig. 2 shows the best representation of publications for humanity and social sciences according local database –Expertus.
Figure 2. Domain structure of publications of University employees according three databases.

The visualisation of social activities working on joint ventures (conferences, symposia, seminars) can be accomplished by using graphs (Garfield, 1994). We used the legible kind of graph – circular network layout (Fig. 3). Band width indicates the intensity of cooperation in organizing conferences. This way we discovered the close relations in such kind of activity between faculties (for example history and politology).

In order to prove this observation NLP techniques were used. Texts of conferences description were processed by Ward’s clusters analysis (1963) and visualised - the result we can see on Figure 4. Dendrogram presents faculties similarity based on texts clustering. Visualisation results confirmed previous assumptions according relationships between organizational units.

The set of metadata predisposes for extending mapping and broadening the perspective of study.

Figure 3. Co-organizing local events by different faculties.

We can also carry out geomapping and provide analysis of foreign cooperation of University. We can compare publishing versus mobility for each year, but all maps exceed the scope of current work.

Figure 4. Co-organizing local events by different faculties.

Summary

The authors present analytical possibilities of local database in confrontation with global scientometric indexes. Humanity and social sciences became visible on science map based on local data. Visualisations techniques were chosen according datatypes and analysis purposes (Osinska & Malak, 2016). Thus, circular graph shows cooperation between units, area chart – dynamics, ring diagram – comparison and structure and dendrogram – close and far similarity. Authors proposed publishing activity of scientists to complement by alternative one - organisational and this way to broaden evaluation framework.

Always Gold Glitters:
When Accepted Papers Meet Processing Delay

Yingyi Zhang1 Chao Lu1,2 Chengzhi Zhang1,3,*
1. Department of Information Management, Nanjing University of Science and Technology, Nanjing, China, 210094
2. School of Informatics and Computing, Indiana University, Bloomington, US, 47405

zyyzjs@163.com; luchaonjust@gmail.com; zhangcz@njust.edu.cn

Introduction
Processing delay is a time span between acceptance and publication (Shi et al., 2016). If an article is accepted, it is recognized by editor and reviewer (Shen et al., 2015), and processing delay is decided by the articles’ publish time. A long processing delay means articles are deposited in the editorial offices, when the value of articles can fade. Therefore, processing delay may pose a potential effect on the citation count of the article (Yu & Li, 2006). Given that citation count has become so dominant a metric to evaluate scholars’ research impact (Abbott 2009; King 2004), it is necessary to discover the potential relationship between processing delay and citation count. In order to clarify this question, this poster employs a correlation analysis between the two variables based on a large set of scientific articles published in PLoS, an influential open-access journal family. The results show that processing delay does not necessarily mean high citation count, and all gold will glitter regardless of processing delay.

Methodology

Data
We collected 170,000 full-text journal articles with publishing history (the dates when the paper is received, revised, accepted, and published) detailed in dates from 2006-2015 published in PLoS®. To reduce the influence of disciplines, we select articles whose disciplines is biology. The initial dataset contained 61,534 full-text articles in biology with their publishing history and citation data.

To strengthen the reliability of results, data was divided into subsets by the publish year (Letchford, 2015). Figure 1 shows the numbers of articles in different publication years.

\[ \text{Figure 1. Numbers of articles in different years} \]

Independent variables
Processing delay is calculated as follows by days:

\[ \text{ProcessingDelay} = \text{PublishDate} - \text{AcceptDate} \]  \hspace{1cm} (1)

Where, \( \text{PublishDate} \) represents when one paper is publish by a journal and \( \text{AcceptDate} \) represents when the journal accept it. For example, if \( \text{PublishDate} \) and \( \text{AcceptDate} \) of a paper is ’2008/11/14’ and ’2008/8/4’ respectively, then its processing delay will be 102 days.

Dependent Variable
Citation count measures how many times a paper is cited by others publications. To normalize citation count, this poster adopted the normalized citation count (NCC) formula developed by Uddin et al. (2012), which is a common practice. The formula is shown as follows stated:

\[ \text{NCC} = \frac{\text{CC}}{\text{Duration}} \times 365 \]  \hspace{1cm} (2)

Where \( \text{CC} \) stands for citation count. \( \text{Duration} \) indicates the number of days between the harvest date and the published date of the article. These citation data are harvested between 2016 February 3-6. Since the duration of data collection is short, so that we can mitigate the potential error in citation data caused by different harvest timelines.

* Corresponding author: Chengzhi Zhang.
1 http://www.plos.org/
Correlation analysis

To investigate the relationship between processing delay and normalized citation count, we conducted correlation analysis. The Kolmogorov-Smirnov (KS) test (p<0.001) shows that all variables are not normally distributed, so we cautiously adopted the Spearman test to discover whether there is some correlation between processing delay and normalized citation count.

Results Analysis

Correlation analysis results

Table 1 presents the correlation analysis results between processing delay and citation count from 2006 to 2014. From 2006 to 2012, the correlation between these two variables is not significant. In 2013 and 2014, the correlation is significant. However, these are all less than 0.1, which are very small correlations. Furthermore, the correlation of all is not significant. Since most of correlation tests are not significant and are very small correlations, processing delay and citation count do not have correlation. And fast processing delay does not necessarily mean high citation count.

Note: All represents all the articles from 2006 to 2014.

![Figure 2](image)

Figure 2. Correlations of processing delay and citation count: (A) 2013 and (B) 2014.

Figure 2 represents the correlation of processing delay and citation count. Figure 2 (A) and (B) are samples of 2013 and 2014 respectively. Although there are strong trends of decrease in these figures, 2013 has negative correlation while 2014 has positive correlation in correlation tests. Trends of decrease are caused by some reasons including the long tail effect (Anderson, 2006) that most articles’ processing delay is short, and highly cited articles have high-probability of having a short processing delay.

Conclusion

This preliminary study is to analyse the correlation between processing delay and citation count. Results show that although processing delay can cause information loss, it is not the main factor of citation count. In order to strengthen the reliability of results, we also test the relationship in Medical Science; and we get similar results. Thus, scholars should not focus on how to shorten processing delays but the quality of their research (i.e., the novelty and contribution).

This poster did not control other variables (e.g. articles’ title and authors), and these variables should be taken in to consider in our following work. Furthermore, more articles of various discipline should be analysed.

Introduction
Massive Open Online Courses developed rapidly in 2012 and soon swept the world. MOOC has been accepted and promoted by the learners on the Internet because of its ease of use, low cost, rich learning resources, simplified video without time and space restrictions. How to design a popular content is a critical factor in determining the impact of the MOOC course. In this paper, taking “Webometrics & Scientific Evaluation” MOOC (as shown in Figure 1) as an example, we talk about our experience and understanding in designing the content of “Webometrics & Scientific Evaluation” MOOC, and hope it can be helpful when someone will design a MOOC in the future.

Methods
This paper uses the top-down design method to design the MOOC content. The whole MOOC content is divided into five parts: course objective, teaching goal, design principle, concrete plan and implementing scheme. Taking the course objective as the guidance, through the teaching goal and design principle of the norm, it will achieve concrete plan and implementing scheme, then complete the entire MOOC content design, as shown in Figure 2.

Course Objective
Course objective refers to the effect or impact that the MOOC is intended to achieve, such as curriculum style, social effect, teaching objects, etc.. The course objective of “Webometrics & Scientific Evaluation” MOOC is to create an interesting MOOC for the learners who are interested in Internet information resources, and hoping that people can improve their information literacy.

Teaching Goal
Teaching goal of the MOOC refers to the knowledge points that students should master, including the overall teaching goal of the MOOC course and the design of each section’s knowledge points and it’s difficulties. The teaching goal of “Webometrics & Scientific Evaluation” MOOC is to master the principle, method and application of webometrics. First, the knowledge points will be split into the introduction of webometrics, data sources of webometrics, analysis softwares of webometrics, analysis methods of webometrics, application of webometrics to scientific evaluation, and then refine these knowledge points step by step.

Design Principle
Design principle is the guideline of MOOC design, mainly including five principle: humanism-oriented education, practical content, streamline, fragmented but continuous, novel and diverse forms, as shown in Figure 3.

Concrete Plan
Concrete plan refers to the specific arrangements for the course content. It mainly solves following several questions. How many chapters will the MOOC course be divided into? How many sections will each chapter be divided into? How many knowledge points are there in each section? What specific material will be used for these knowledge points? Taking the Chapter 3, Section 3 of “Webometrics & Scientific Evaluation” MOOC as
Table 1 The concrete plan of “Webometrics & Scientific Evaluation” MOOC (Chapter 3, Section 3).

Implementing Scheme
Implementing scheme refers to the specific design scheme about how to record MOOC videos according to the concrete plan. Formulate a clear scheme to display each knowledge point concretely, such as by animation, location shooting, interview, interaction with students, as shown in Figure 4 and Figure 5.

Results
By using a top-down approach, we first make a clear goal and plan well-ahead of time, and then refine and fill the MOOC content constantly. It can design a wonderful MOOC systematically and reach the initial course objectives effectively. This MOOC developed by Beijing Normal University (China) releases on 8 April 2017. At this time, we had more than 9000 students enrolled, as shown in Figure 6.

Acknowledgments

Introduction

This paper describes the forecasting methods used to analyze the future demand for domain names under the ccTLD (country code Top-Level Domain) " .it". The aim of this analysis was to examine the trend over time of the demand for .it domain names. This is firstly to assess whether we are in a phase of growth and expansion or at a point of saturation. Secondly, this analysis enables us to compare the .it domain name market with those of other ccTLDs (.de, .uk, etc.) or of other gTLDs - general Top-Level Domains (.com, .edu, etc.).

Methods

In order to forecast the trend of demand for .it domain names, the main forecasting methods available in the literature were used. Before applying these forecasting methods, there was an analysis of the trend and seasonality of the series “variation in growth of .it” domain names. This is none other than the difference between registrations and cancellations recorded in the quarter x of year t. In general, a historical series can be broken down into a seasonal component, a trend and an erratic component. These components are usually estimated using the moving average. However, this method, albeit commonly used in the literature because of its ease of calculation, has some disadvantages. These are associated both with the limited accuracy of the estimates obtained and the loss of data relative to some terms due to the smoothing of the moving average. On the basis of these considerations, the trend, the seasonality and the erratic component of “ .it” domains were estimated using the loess method which, differently from the abovementioned method, gives more accurate estimates (Ricci, 2005). Subsequently, in order to estimate the forecasts of the .it domain names registration, some forecasting methods were applied. These included exponential smoothing methods, such as the Holt-Winters (additive and multiplicative) (Holt, 1957; Winters, 1960), which consider the presence of the trend and seasonality, and the stochastic processes like ARIMA - Auto Regressive Integrated Moving Average models (Box and Jenkins approach) (Box and Jenkins, 1976), in particular the SARIMA (seasonal ARIMA) version. The parameters of the various models were calculated using the maximum likelihood estimation. To assess the accuracy of the forecasts, resulting from the various forecasting methods, a range of indicators were used and analyzed which were able to give a measurement of the forecast error. These included the ME (Mean Error), MAE (Mean Absolute Error), RMSE (Root Mean Squared Error), MPE (Mean Percentage Error), MAPE (Mean Absolute Percentage Error) and MASE (Mean Absolute Scaled Error). The latter indicator, was proposed by Hydman and Koehler (2006) as an alternative to using percentage errors when comparing forecast accuracy across series on different scales. Furthermore, due to the predictive accuracy of the methods considered, also other indicators were analyzed such as the Akaike Information Criterion (AIC), Corrected Akaike Information Criterion (AICc) and Schwarz Bayesian Information Criterion (BIC). Finally, in order to identify the best forecasting method, also the correlogram of the residuals of the various models were analyzed (ACF-Function of autocorrelation and PACF-Function of partial autocorrelation). The application of these forecasting methods and statistical indicators was carried out using the “R” statistical environment. The registrations and cancellations of .it domains were extracted in the .it domain names database managed by the Institute for Informatics and Telematics (IIT) of the CNR (National Research Council) in Pisa. The analysis was done taking into account the time period of nine years, from 2008 to 2016. Each year was subdivided into four quarters.

Results

From the analysis of the calculation of the trend and seasonal components, our time series shows a trend (slow growth during 2008, steadying between 2008 and 2009, reaching its maximum in the first half year of 2011, decreasing after 2011 until 2014, renewed growth to subsequently steady again). Furthermore, there is a seasonal component, given that the registrations and cancellations of .it domains were extracted in the .it domain names database managed by the Institute for Informatics and Telematics (IIT) of the CNR (National Research Council) in Pisa. The analysis was done taking into account the time period of nine years, from 2008 to 2016. Each year was subdivided into four quarters.
seasonal component, so as to make the series stationary, due to the seasonality in the demand for domain names. The choice of this model, compared to other ARIMA models, was made based on an analysis of the residuals and their correlograms (ACF and PACF).

Besides the ARIMA model, the other models applied to our series were both the Holt–Winters model with damped trend (Gardner and McKenzie, 1985) and additive seasonal component, and the Holt-Winters model with multiplicative trend and seasonal component. Also in this case the choice of these models instead of others was determined by considering the residuals and their correlograms. Figure 1 shows application of the abovementioned models to the .it domain name time series (registrations - cancellations).

As shown in figure 1, the ARIMA model fits our data better than the Holt-Winters models, above all in the first years (in particular in 2008 the values calculated by the ARIMA model are equal to the observed values).

While table 1 shows the forecasts that are produced by the three models, in the individual quarters of 2017 and 2018.

</table>

Discussions and Conclusions

The estimates of the parameters of the Holt-Winters damped additive model indicate that the estimate of the level at the current time point is based on the less recent observations (the less recent observations have a greater weight than the more recent ones). On the other hand, for the Holt-Winters multiplicative model the estimate of the level at the current time point is based not only on the less recent observations but also on the most recent ones.

From analysis of the forecasts, the ARIMA model is the one which better fits the historical data compared with the models of exponential smoothing. This conclusion is valid, both when observing the graphs relative to the diagnostics of the residuals and the statistical indicators relative to the accuracy of the estimates. In fact, all the statistical indicators that give a measurement of the error of the estimates (ME, MAE, RMSE, MPE, MAPE and MASE) are lower when applying the ARIMA model, compared to the other two models.

As regards the diagnostics of the residuals, the p values for the Ljung-Box statistic in the various lags are higher for the ARIMA model, indicating that the hypothesis of absence of autocorrelation of the residuals, for all the lags, cannot be rejected. On the contrary, for the Ljung-Box statistic of the Holt-Winters models, the p values are very low compared to the ARIMA model and in some cases the test rejects the hypothesis of uncorrelated residuals. The same applies to other indicators which give a measure of the degree of fit of the models used. AIC, AICc and BIC are much lower for the ARIMA model than for the models of exponential smoothing.

In conclusion, according to the results in Table 1, the .it domain name registrations will be greater than the cancellations in both 2017 and 2018. For example, in 2018 it is foreseen that there will be an annual positive growth in domain names by about 135,000 domains as forecast by applying the ARIMA model, and by approximately 141,000 and 138,000 by applying the Holt-Winters multiplicative model and the Holt-Winters damped additive model respectively.

In summary, notwithstanding the forecast of a growth in domain names in the 2017-2018 two-year period, the increase is however limited, tending to reach a phase of saturation of the “.it” market.

Are the social sciences from the European post-socialist countries integrated in the "Western social sciences"?

Maja Jokić¹ Stjepan Mateljan¹ Nikola Petrović¹

maja@idi.hr; smateljan@idi.hr; nikola@idi.hr

Institute for Social Research in Zagreb, Amruševa 8, 10 000 Zagreb (Croatia)

Introduction

There are significantly fewer bibliometric studies focusing on social sciences than those in the field of natural sciences. Reasons for this vary from a conventional opinion that the paradigm of science communication in social sciences is significantly different from that in STEMM areas and the perception of social sciences as particularly susceptible to limitations of bibliographic and citation databases (Arunachalam et al., 2006; Nederhof, 2006; Butler & McAllister, 2009; Ossenblok & Engels, 2015) to a wide array of complex features within social sciences such as cultural and linguistic differences, national traditions, state-centred institutionalisation and locally-oriented research themes (Mosbah-Natanson & Gingras, 2014). According to Garneau (1985), until the end of the 1980s social sciences were divided into Western social sciences, or ‘first world social science’, and social sciences from communist countries, or ‘second world social science’. However, today’s European Research Area (ERA) includes all central and eastern European post-socialist countries (CEE), either as EU member states or EU candidate countries, and one of its principal aims is a complete integration mentioned countries into the European Union Research and Development Programs (Bruhns, 2012). In this research we tried to establish the extent to which social sciences in European post-socialist countries (N=15; 11 EU member countries and 4 EU candidate countries) have so far been integrated into ERA, using publishing and citation data for international/CEE journals.

Sample and Methodology

The sample was obtained from the Scopus database and it consists of papers in the field of social sciences authored by at least one researcher from one of 15 European post-socialist countries – 11 EU members states, i.e. Estonia, Latvia, Lithuania, Poland, Czech Republic, Slovakia, Hungary, Romania, Bulgaria, Slovenia, Croatia, and 4 EU candidate countries, i.e. Bosnia and Herzegovina, Macedonia, Montenegro and Serbia. The analysed papers (N=33,837), published in the period 1996 - 2013 in 2,587 international and 157 CEE journals, were reclassified according to the Croatian science classification, which is based on OECD classification fields (which include economics, education, information and communication science, law, political science, psychology, sociology and three interdisciplinary fields). We analysed paper distribution in international/CEE journals, paper frequency by subject fields and CEE countries' research output, while in case of international journals we analysed publishing orientation by country.

Results

Apart from the expected rise in CEE countries' research output, which is visible due to a relatively high number of CEE journals included in the Scopus database, the results indicate significant increase in the publication of papers in international journals after 2004 (Fig. 1), with their total share being 56%.

Figure 1. Paper distribution in international/CEE journals between 1996 and 2013 (Source: Scopus).

European post-socialist countries predominantly published their research results in social sciences in Western countries journals (Fig. 2). UK’s, Netherlands’ and Germany’s journals represent 90% of journals from EU-15 countries.
In both CEE and international journals, the majority of papers are in the field of economics, with their total share being 32.5%. However, scientific fields showing the strongest international orientation are political science, information science and all interdisciplinary social science fields (Fig 3).

The normalisation of each of the sampled countries’ research output by their respective population numbers shows that Estonia, Slovenia, Hungary and Lithuania are the most internationally oriented countries (Fig. 4).

One of the aspects of measuring integration is citedness which in international journals is 7.4 citations per paper, and in CEE journals 2. For a more comprehensive insight there is a need for more detailed citation analyses.

Conclusion

The results show evidences of a gradual integration of social sciences in European post-socialist countries into “Western social sciences”. A significant increase in this trend occurred after 2004, when most of CEE countries joined the EU. Political science, information science and interdisciplinary social science are fields that are frontrunners in this integration. CEE countries that are most oriented towards international journals are small CEE countries and Hungary. The project is planning more detailed bibliometric analysis, co-citation analysis as well as analyses of social contexts which all have a significant influence on integration.

An Artificial Neural Network Model Based on Altmetrics Indicators and Citation Counts

Li Xiaotao\textsuperscript{1}  Chen Changhua\textsuperscript{2}  Qin Ping\textsuperscript{3}

\textsuperscript{1}lixiaotao@nuaa.edu.cn
\textsuperscript{2}cchlib@nuaa.edu.cn

Introduction

The main advantages of altmetrics over traditional bibliometrics and webometrics is that they offer fast, real-time indications of impact, they are openly accessible and transparent, include a broader non-academic audience, and cover more diverse research outputs and sources (Costas et al. 2015). In the last few years, the interest in altmetrics has grown, giving rise to many questions regarding their potential applications.

The relationship between citation counts and altmetrics indicators of academic papers was a research hotspot in the field of informetrics and scientometrics. A meta-analysis across more than 40 cross-metric validation studies shows overall a weak correlation (ranging from 0.08 to 0.5) between altmetrics and citation counts, confirming that altmetrics do indeed measure a different kind of research impact, thus acting as a complement rather than a substitute to traditional metrics (Erdt et al. 2016). The quantitative relationship and influence mechanism between citation counts and altmetrics indicators required further research to reveal. Shall we predict papers citation counts with its altmetrics indicators?

Artificial neural networks were widely used for building the nonlinear model and pattern recognition among a number of variables(Basheer and Hajmeer, 2000). This paper aims to reveal the quantitative relationship and influence mechanism of citation counts and altmetrics indicators (such as bloggers, tweeters, F1000 reviews, Facebook walls, and so on) by constructing an artificial neural network model. The model’s veracity will be verified.

Material & Methods

PlumX, ImpactStory, and Altmetric.com were usually used for collecting data of altmetrics indicators(Peters et al. 2016). In this study, we select Web of Science and Altmetrics.com as data sources to collect citation counts an altmetrics indicators of academic papers. On March 15th of 2017, We respectively searched papers published on Nature in 2015 from the two data sources. Papers from the two sources were matched by their Digital Object Identifier (DOI). 968 papers were matched, then we got citation counts and altmetrics indicators of these papers.

The training set included 726 papers and their indicators, while the test set included the rest of the papers. We chose 11 indicators to construct the artificial neural network, including 10 altmetrics indicators (Bloggers, Tweeters, Google+ authors, F1000 reviews, News outlets, Facebook walls, Weibo users, Peer review sites, Wikipedia pages, Mendeley readers, CiteULike readers) as input node, and papers’ citation counts as output node.

The artificial neural network was constructed by R-project. All data had been normalized before imported into R. The correlation between predicted citation counts by the model and the actual value of test sets was analysed to evaluate the model precision.

Result & Discussion

Data collection

We collected citation counts and altmetrics indicators of 968 papers published on Nature from web of science and Altmetrics.com respectively. There were 11 indicators selected for constructing artificial neural networks, including bloggers, tweeters, google+ authors, F1000 reviews, news outlets, facebook walls, weibo users, wikipedia pages, mendeley readers, CiteULike readers and citation counts. Some of the data were listed in Table 1.

Data normalization

Due to the numerical distribution range of indicators was not good for the construct of artificial neural network, all data had been scaled by min-max normalization before imported into R-project.
\[ y_i = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} \]

**Model construction**

The neuralnet package of R was used to construct the artificial neural network model. The training set included 726 papers. Altmetrics indicators were trait as input node, while citation counts were considered as output node and two hidden node were inserted. The model constructed on training set was shown as figure 1.

**Table 1. Altmetrics indicators and citation counts of papers.**

![Model construction](image)

**Figure 1. The artificial neural network model**

**Model precision**

We imported data of test set including 242 papers into the model and calculated citation counts by data of input nodes (altmetrics indicators). The correlation coefficient of predicted result and actual citation counts was 0.62. The Scatter diagram of predicted result and actual citation counts was shown in figure 2.

![Figure 2. Scatter diagram of predicted result and actual citation counts.](image)

**Conclusion**

The artificial neural network is highly nonlinear, capable of complex logical operation and non-linear relationship realization. The artificial neural network provides a new way to explore the quantitative relationship between altmetrics indicators and citation counts. The artificial neural network model of this paper is only a preliminary attempt, and the complexity and accuracy of this model is still to be optimized. In the future, we may be able to construct more accurate mathematical models with deep neural networks, and predict the cited frequencies of papers by altmetrics indicators.

Using Full-text to Evaluate Impact of Different Software Groups

Shutian Ma\textsuperscript{1}  Chengzhi Zhang\textsuperscript{1,2,*}

\textsuperscript{1}Department of Information Management, Nanjing University of Science and Technology, Nanjing, China, 210094
\textsuperscript{2}Fujian Provincial Key Laboratory of Information Processing and Intelligent Control (Minjiang University), Fuzhou, China, 350108

mashutian0608@hotmail.com; zhangcz@njust.edu.cn

Introduction
To analyse the impact of software on science, researchers have tried to extract software entities from scientific literature (Pan et. al., 2015) and examined how software is mentioned and cited across disciplines (Pan et. al., 2016). However, previous study doesn’t consider functional relations among different software. In this paper, we evaluate impact of software groups with the same usage. Firstly, deep learning models are used to learn distributed representations of software entities based on full-text. Clustering technique is then applied to find software groups. Finally, we analyse the impact of each software group.

Methodology

Framework
Figure 1 shows framework of impact evaluation of different software groups.

\begin{figure}[h]
  \centering
  \includegraphics[width=\textwidth]{framework.png}
  \caption{Frameworks of Impact Evaluation of Different Software Groups}
  \label{fig:framework}
\end{figure}

Firstly, we represent each software as vectors via distributed representation. Then, we divide them into different groups by clustering method. Finally, we count the mentioned times of each software and evaluate software groups based on total number of mentions and average number of mentions in full-text.

Distributed representation
Currently, Word2Vec (Mikolov et. al., 2013) can provide state-of-the-art word embedding. It can learn high-quality word vectors from huge corpora automatically. Based on this, Doc2Vec (Para2Vec) is proposed to obtain representations for larger blocks of texts, such as sentences, paragraphs even entire documents (Le & Mikolov, 2014). Specially, we add procedure which matches software entities and groups literature into documents set containing the same software when training Doc2Vec model. Here, word dimension is 200, document dimension is 100. The maximum distance between predicted one and context used for prediction is 5.

Clustering algorithm
Affinity propagation (Frey & Dueck, 2007) is used for clustering. It works based on similarity between pairs of all the data points by considering all points as potential cluster centres. In this experiment, preference is needed to be set which indicates preference that data point is chosen as a center. Here, similarity between documents are calculated with squared Euclidean distance and preference is set up to be: -5, -10, -15, -95, -100, with 5 as interval.

Experiment and Results Analysis

Dataset and Tools
The scientific literature are all collected from PLOS ONE\textsuperscript{1}. We downloaded 114, 510 papers in XML format. Software list is obtained from work (Pan et. al., 2015). We clustered 1, 617 software entities. Word2Vec and Doc2Vec are applied in Genism\textsuperscript{2}. Affinity propagation is done via Scikit-learn\textsuperscript{3}.

Evaluation Metrics
Silhouette Coefficient (Rousseeuw, 1987) is used to measure clustering performance. Suppose a is the mean distance between a sample and all other points

\footnotesize{\textsuperscript{1}http://journals.plos.org/plosone/}
\footnotesize{\textsuperscript{2}http://radimrehurek.com/gensim/index.html}
\footnotesize{\textsuperscript{3}http://scikit-learn.org/stable/index.html}
in the same class, $b$ is the mean distance between a sample and all other points in the next nearest cluster. It’s calculated via formula below:

$$Sil = \frac{b-a}{\max(a, b)}$$

(1)

Experimental Results Analysis

Clustering results which cluster number is over than 4 and silhouette coefficient is above 0 are shown in table 1 and 2. Evaluations are made based on the two best results shown in bold italics. A higher silhouette coefficient means better clustering results.

Figure 2(a) displays Word2Vec results where we can find two clusters directly, figure 2(b) displays results of Doc2Vec. As we can see, software are projected into different places using Word2Vec and Doc2Vec.

Software entities of each clusters are also shown in table 3 and 4. We give top-5 entities ordered by number of mentions. All Men is the all the software mentioned times within each cluster, Ave is the average mentioned times. Firstly, we find software within cluster have the same usage, like analysis of sequence data, graphics, visualization and so on. For example, in table 3, top-5 members of 6th cluster are software to analyse biological sequences, which is the same with 3rd cluster in table 4. Based on number of all mentions in table 3 and average mentions in table 4, statistical software for gene data tend to have more impact than others. Besides, it shows our method can help us to find similar software by clustering.

Figure 2. Visualization of Clustering Results

Conclusion

In this paper, we evaluate the impact of different software groups based on full-text. Experimental results show that statistical software shows more impact than other kind of software in PLOS ONE literature. Current conclusion is simply from the preliminary investigation, problems are needed to be solved, like cluster analysis, matching strategies.

Introduction
Monitoring research activity and impact is essential for the competitiveness of countries and regions since it can indicate strengths in science and identify fields that need to improve performance in the global context.

This paper presents an assessment proposal of regional and global science in Latin America & Caribbean (LAC) based on bibliometric indicators and contributions of Sociology of Science. The project aims to analyze the scientific profiles of countries in the region, their strength, excellence and scientific specialization, and the reflexes of these configurations on the positions occupied by the countries in global science.

The research focus is on five dimensions: (1) countries’ publication profile and impact; (2) countries’ scientific performance (scientific strength); (3) scientific specialization of the region and its countries (activity and impact normalized); (4) identification of centers of excellence in regional and global science (highly cited publications); and (5) reflexes of these configurations on the positions occupied by these countries in the international scientific field.

Data sources and methodology
The present study is based on bibliographic data extracted from Web of Science - WoS (Science Citation Index, Social Science Citation Index and Arts & Humanities Citation Index) and SciELO Citation Index. Only original and review articles published between 2003 and 2014 were taken into consideration. Publications were assigned to countries on the basis of their corporate addresses which appear in the field country (CU) of WoS. All countries of LAC listed in the Standard Country or Area Codes for Statistics Use of United Nations and indicated in the address field were considered. A three-year citation window was applied and included citations and self-citations. The full counting method was used and the thematic classification is based on research areas (SC), common in the two databases. In macro analyzes the SC were transposed into the six major fields of the Frascati Manual.

Data collection was carried out in March 2017 and the search strategy combined the fields country (CU), document type (DT), and publication year (PY). The data were collected in four steps:

Step 1. Bibliographic records of LAC articles and absolute citations.
Step 2. Global absolute numbers of articles by SC.
Step 3. Citation data of region, by year and SC.
Step 4. Citation data by country, year and SC.

The collected data was pooled into two unique databases (WoS and SciELO) and the duplicate records were excluded. The statistical language R (RStudio interface), Microsoft Excel and BibExcel were used for data processing and analysis.

Publication profiles will be assessed by means of Activity Index (AI) and Country Profile Index (CPI), while the citation profiles will be based on the Relative Citation Impact Score (RCIS) and Attractivity Index (AAI) (Schubert & Braun, 1986; Tuzi, 2005; Schulz & Manganote, 2012).

AI = \frac{\text{Percentage of country publications in the field}}{\text{Percentage of world publications in the field}}

CPI = \frac{\text{Number of country publications in the field}}{\text{Number of country publications in all fields}}

RCIS = \frac{\text{Average of country citations in the field}}{\text{Average of regional citations in the field}}

AAI = \frac{\text{Percentage of country citations in the field}}{\text{Percentage of country citations in all fields}}

The countries specialization profiles will also be evaluated with the indicators Scientific Strength (SS) (Abramo, D’Angelo, & Di Costa, 2015) and Scientific Specialization Index (SSI) (Abramo, D’Angelo, & Di Costa, 2014), which consider both publications and citations received. SS results from the sum of the normalized impact, obtained by Article Impact Index (AII), and is relativized for the total field values in the LAC.

AII = \frac{\text{Number of citations of article in field}}{\text{Average citations of articles cited in field}}
The SSI is based on the IIA and SS values, and integrates the data normalized by field, country and year of publication. The SSI of the country k in the SC j \((SSI_{kj})\) is defined as:

\[
SSI_{kj} = 100\cdot \tanh \left( \frac{SS_{kj}}{\sum_{k}SS_{kj}} \left( \frac{\sum_{k}SS_{kj}}{\sum_{k}SS_{kj}} \right) \right)
\]

Identification of centers of excellence will be based on highly cited articles by authors from the region, starting from a threshold of 5% of the most cited articles in the WoS and 1% in the SciELO. This avoids a limit of citations for each research area which could exclude most of the fields and compromise the analysis of the geographical distribution of centers of excellence (Tijssen, Visser, & van Leeuwen, 2002). Positions held by LAC countries in the international scientific field (Bourdieu, 1988) will be evaluated by aspects such as: positions of countries in world rankings (outputs and impact); participation and leadership of international organizations; awards; among others.

**Preliminary results**

The LAC output in WoS in the period is 643,221 articles, with a mean of 12.8 citations per article and a total of 8,231,334 citations. In the SciELO database the region presents 274,335 articles and 513,903 citations – mean of 1.9 citations per article. The study includes comparative analyzes between global or mainstream science (WoS) and regional or peripheral science (SciELO Citation Index). This paper, however, presents only preliminary results based on WoS data, without results of SS and SSI. Figure 1 shows the evolution of LAC output by major fields of the Frascati Manual.

**Figure 1. Evolution of LAC output by major field in WoS, 2003-2014**

The pattern of linear growth in the number of articles reaches a certain degree of stability in recent years. Natural Sciences and Medical & Health Sciences are the most productive fields of LAC, with \(R^2\) 0.9944 and 0.9618, respectively. Table 1 presents the relative indicators of activity and impact of the most productive LAC countries in the three SC with the highest number of articles.

**Table 1. Activity and impact of the most productive LAC countries in WoS, 2003-2014**

The most productive areas are not necessarily those with greater activity and relative impact. This suggests that the absolute productivity, by itself, does not reveal whether the country is more or less active or specialized in the field, nor its contribution to global knowledge.

On normalization by division and comparing citation counts

Lawrence Smolinsky¹

¹smolinsk@math.lsu.edu

Department of Mathematics, Louisiana State University, Baton Rouge, LA (USA)

Introduction

Bibliometric measures based on citation counts are often used as an objective measure of research productivity. Finding a method of comparison is extremely challenging given the diversity of scholarly publications particularly by field and age. These are some aspects that effect the way publications accumulate citations. Developing measures using citations depends on understanding the distributions of citations of publications. Methods for normalizing the count across fields for comparison is in constant development.

Division

One heuristically attractive idea is to divide by a version of the expected number of citations to the paper. It may be done for individual papers, institutions, states, etc. Some of the reasons division is attractive is that it is simple to do and transparent in that percentage above or below average may be used in daily life. Some indicators that rely on division are the mean normalized citation score (MNCS) or InCites’s mean category normalized citation impact or normalized citation impact.

Whether division by a mean, median, or other parameter can make citation counts between different areas comparable is dependent upon the distributions being normalized. Each field may be thought to have its own distribution of the number of papers having a given number of citations. These distributions can be interpreted as probability distributions by dividing by the number of papers. For the purpose of cross field comparisons, they should ideally be adjusted so they have the identical distributions for each field. Normalizing by dividing by the mean may give the various distributions the same mean, but otherwise they may be quite different. However, there are families of distributions which become identical with a division adjustment by the mean. In other words, there are well-known families of distributions for which two random variables X and Y in the family with respective distinct means mx and my have \( \frac{x}{mx} \) and \( \frac{y}{my} \) identically distributed. The mean is then a scale parameter. These distributions include the exponential, Exp(\( \lambda \)), the gamma distribution with fixed \( n \), \( \Gamma(n, \lambda) \), and, a standard candidate in bibliometrics, the lognormal with a fixed \( \sigma \), Lognormal(\( \mu, \sigma^2 \)). Discrete distributions are problematic for scaling since the domain may change.

The lognormal scaling was essentially examined in Radicchi, Fortunato, and Castellano (2008) for data in sample areas for the year 1999. They examined the distribution of articles published in a single year in a specific area and approximated it by a lognormal and then compared the various distributions by scaling. The model has its flaws. For example, the lognormal is zero at zero while the number of articles with zero citations is significant. Furthermore, while Radicchi, Fortunato, and Castellano only give an exponential scale graph including multiple areas (2008 Fig. 2 p. 17269), one can visually see some fields below the normalized graph in the tail, e.g., anesthesiology and mathematics. However, suppose one accepts the lognormal with a fixed parameter \( \sigma \) for as the model for the distribution of citations in all fields, i.e., only the parameter \( \mu \) changes from field to field. Then division by the mean for each field normalizes the citation distribution to the common distribution Lognormal[-\( \sigma^2/2 \), \( \sigma \)] for each field. An indicator like the MNCS, which is a sum of \( n \) normalized random variables (for a fixed \( n \)), will have a common distribution across fields. Even though the distribution may be complicated, it will the same across fields. Furthermore, although the lognormal is sometimes called a thick-tailed distribution, all of the moments of the lognormal exist and the central limit theorem applies to it. Again, assuming that only the parameter \( \mu \) changes from field to field, one can normalize by the median rather than the mean. One has then normalized the citation distribution to the common distribution Lognormal[0, \( \sigma \)] for each field. We also note that Leydesdorff and Opthof (2011) commented that “... the ‘mean’ is not a proper statistic for measuring differences among skewed distributions” and suggested using the median. In the lognormal model with a fixed \( \sigma \), both the median and mean are scale parameters.

The discrete lognormal may be a candidate for citations to articles to a single subject and year (Evans, Hopkins, & Kaube 2012; Radicchi, Fortunato, & Castellano, 2008; Thelwall & Wilson, 2014), but it is not clear that \( \sigma \) is fixed across fields. The hooked power is another candidate (Thelwall & Wilson, 2014). But power laws are also candidates (Katz 2016; Yao et al. 2014) and it may depend on the time period. With such variation of opinion and variation of citation distributions, following
principle six of the Leiden Manifesto (Hicks et al. 2015), “Account for variation by field in publication and citation practices” seems a challenge for normalization by division or other formulas.

**Percentiles**

Knowing the full information of percentiles for two continuous distributions, allows one to transform them into a common distribution. Discrete distributions may pose problems. Eugene Garfield concluded his book (1979 p. 249) commenting on the power of percentile comparisons:

*Evaluation studies using citation data must be very sensitive to all divisions, both subtle and gross, between areas of research; and when they are found, the study must properly compensate for disparities in citation potential. This can be done very simply. Instead of directly comparing the citation count of, say, a mathematician against that of a biochemist, both should be ranked with their peers, and the comparison should be made between rankings. Using this method, a mathematician who ranked in the 70 percentile group of mathematicians would have an edge over a biochemist who ranked in the 40 percentile group of biochemists, even if the biochemist’s citation count was higher.*

In other words, the proper way to make comparisons would be by percentiles. But this method has its challenges too. It still requires an understanding and integrity of the field distributions. As Garfield (1979 p. 249) continued, “We still know very little about how sociological factors affect citation rates. There is still much uncertainty about all the possible reasons for low citation rates. And there is still much to learn about the variations in citation patterns from field to field.” It is still true today and poses a serious issues if citation analysis is to respect the first principle of the Leiden Manifesto (Hicks et al. 2015), “Quantitative evaluation should support qualitative, expert assessment.” We take the example of one field in which to perform citation analysis and normalization.

**Mathematics**

Details by subfield classification in mathematics was examined by Smolinsky and Lercher (2012). Even in a single Journal Citation Report field, the distribution of citations in subfields may be very different and at odds with expert assessment. They examined young researches who were the highest respected by expert assessment, i.e. Sloan fellows. They classified Sloan fellows using a classification by the joint committee of the mathematics, applied mathematics, and statistics societies. The researchers fall into 9 fields (the field of statistics was not included).

In terms of the expert assessment, Algebra seemed to be the highest assessed. It had by far the most Sloan fellows (32 of 99). Hiring of new PhD’s at the top 48 “Group I” mathematics departments was also greatest in algebra. However, this was in contrast to the bibliometric data. The algebra Sloan fellows were 7th out of 9 in the number of publications per fellow and 6th out of 9 for citations per paper.

Putting aside the contradiction between the two assessments, the variation in a single field among subfields is well known. Glänzel and Schubert (2003 p. 357) sum it up: “The classification of scientific literature into appropriate subject fields is…one of the basic preconditions of valid scientometric analyses. Publication activity and citation habits considerably differ among subfields.”

**Acknowledgments**

The author is grateful to George Cochran for a discussion on scale parameters in probability distributions.

Predicting the Future Impact of Scholars through Time-aware Academic Networks

Jun Zhang, Wenjie Kang, Jiaying Liu, Teng Guo, Ivan Lee, Feng Xia

f.xia@ieee.org
School of Software, Dalian University of Technology, 116620, Dalian (China)

Introduction
The scientific impact of scholars has been studied by researchers with diverse backgrounds for a long time. Predicting the scientific impact of scholars through utilizing the scholarly big data (Xia et al., 2017) can shed light on many problems, such as discovering potential collaborators, tracking research trends, and providing basis for awards or foundation applications etc. Therefore, predicting scholars’ scientific impact is of great significance and has drawn increasing interests.

Generally, predicting the impact of scholars can be divided into two main categories: citation-based metrics and network-based methods. Citation-based methods mainly consider the dynamics and distinctions of citations to predict the future influence of scholars (Sinatra et al., 2016). In network-based metrics, the different academic network topologies and various importance ranking algorithms are utilized to predict the impact of scholars. However, one important fact is neglected, i.e., the dynamics of the academic networks. Previous studies have employed different academic network structures to depict the real academic networks. As a matter of fact, academic networks evolve with time, for instance, articles will get new citations and scholars will cooperate with different authors. It is challenging to capture the dynamics of academic networks for better predicting scholars’ future influence. Motivated by the above mentioned phenomena, we propose the TARank method to predict scholars’ impact. Our method not only considers the mutual influence among different scholarly entities, but also captures the dynamics of heterogeneous academic networks to predict the future impact of scholars. Furthermore, the performance of our methods is explored on Microsoft Academic Graph (MAG) dataset.

TARank Method
As shown in Figure 1, our TARank method mainly consists of four main parts. We first construct four academic networks, i.e., time-aware paper citation network, time-aware coauthor network, time-aware paper-venue network, and time-aware paper-author network. The detail calculation procedures through utilizing these time-aware networks are as follows.

**Time-aware paper citation network**
There exists an edge between papers if one paper cites another in the time-aware paper citation network. Through analyzing the MAG dataset, we found that most recently published papers get more citations in the future comparing to papers that have been published for a long time. According to this phenomenon, we calculate the impact of articles through the time-aware weighted citation relationship between papers, and the calculation formula can be represented as:

\[
PR(p_i) = \frac{(1-d)N_p + d \sum_{j=1}^{m} \frac{PR(p_j)}{L(p_j)} \times e^{-\alpha(T_{co} - T_{ci})}}{1}
\]

where \(PR(p_i)\) represents the impact score of paper \(p_i\), \(m\) is the total number of papers that cite \(p_i\), \(L(p_j)\) is the sum of outgoing links of \(p_j\), and \(N_p\) is the total number of papers. \(T_{ci}\) is the current time, \(T_{ci}\) is the time when \(p_j\) cites \(p_i\), and \(d\) is the damping factor (set as 0.85).

**Time-aware coauthor network**
There exists an edge between authors if they have cooperated in the same paper in the time-aware paper citation network. The abilities of coauthors can significantly influence the qualities of the corresponding papers, and furthermore influence the impact of scholars themselves. Therefore, we assume that if a scholar cooperates with influential scholars recently, then he or she will more likely collaborate with them in the future. We calculate the impact of authors through the time-aware weighted cooperation relationship between authors, and the calculation formula can be represented as:

\[
PR(a_w) = \frac{(1-d)N_a + d \sum_{k=1}^{n} \frac{PR(a_k)}{L(a_k)} \times e^{-\alpha(T_{co} - T_{cw})}}{1}
\]

Figure 1. Architecture of TARank.
where $PR(a_w)$ represents the impact score of author $a_w$, $a_k$ is the cooperator of $a_w$, $m$ is the total number of $a_k$, $L(a_k)$ is the sum of outgoing links of $a_k$, and $N_a$ is the total number of authors. $T_{cp}$ is the current time, and $T_{cp}$ is the time when $a_k$ cooperates with $a_w$.

**Time-aware paper-venue network**

The time-aware paper-venue network contains two kinds of nodes, which are papers and their corresponding venues. One type of relationship is included, which is the publication relationship between papers and venues. The qualities of papers and venues influence each other, and papers that publish in recent years are more indicative of the future impact of venues. The time-weighted publishing relationship between papers and venues can be denoted as:

$$TW_{pq} = \beta \times e^{r-\gamma(T_{pq}-T_{pb})} - \theta$$  \hspace{1cm} (3)

where $TW_{pq}$ represents the weight of the edge, and $T_{pb}$ is the publication time of paper $p$. In order to capture the mutual influence among papers and venues, we set up specific updating procedures. We first apply the HITS algorithm to calculate the impact values of venues according to papers’ impact scores (Eq. (1)). Then according to the impact values of venues we get, the scores of papers can be updated.

**Time-aware paper-author network**

The time-aware paper-author network contains two kinds of nodes, which are papers and their corresponding authors. One type of relationship is included, which is the writing relationship between papers and authors. It is universally acknowledged that the impact of scholars can be conveyed through their papers, and on the contrary, the qualities of papers can reflect the authors’ capacities. Therefore, we assume that the recently published papers can more indicative of scholars’ future influence. The time-weighted writing relationship between papers and scholars can be denoted as Eq. (3). The values of authors (Eq. (2)) and papers according to the last step are used as initial values. We first update the impact score of scholars according to their papers’ values, and then update the impact value of scholars through their papers through the random walk process. Repeat the above two steps until convergence, i.e., the sum of the differences of scholars’ values computed at two successive iterations falls below 0.000000001.

**Experiments & Results**

The sub-dataset used for our experiments is acquired from the MAG dataset. It contains the detailed paper information of each scholar, which includes article's title, keywords, coauthors, the date of publication, venues, authors' affiliations and its citation relationships. To conduct our experiments, we choose scholars from computer science area and they have no missing information. We use the data before 2010 to get the results of each method, and take the citation counts of each scholar in the recent 5 years as the ground truth to verify the prediction performance.

We compare our TARank with the following methods to evaluate its effectiveness on predicting scholars’ impact. **TARank_notime** applies our algorithm on the traditional academic networks without time-aware functions. **MRCoRank** is introduced in (Wang et al., 2016). As shown in Figure 2, the average citation counts of the top ranking scholars of our TARank is the highest compared to other methods. The results demonstrate that our method can efficiently predict the impact of top ranking scholars.

**Conclusion**

In this paper, we propose the TARank method to predict the scientific impact of scholars, and the experiments on real dataset indicate that our method can efficiently predict the future impact of top ranking scholars. In future work, we will investigate the performance of our method from more aspects on more dataset.

Using Readership to Measure Interdisciplinarity

Chengzhi Zhang¹,² and Shurui Xu¹

¹. Department of Information Management, Nanjing University of Science and Technology, Nanjing, China, 210094
². Fujian Provincial Key Laboratory of Information Processing and Intelligent Control (Minjiang University), Fuzhou, China, 350108

zhangcz@njust.edu.cn, 115107000840@njust.edu.cn

Introduction

Interdisciplinary research is an important topic in the library and information science. There are a lot of interdisciplinary measurement indexes, such as Rao-Stirling diversity (Stirling, 2007), Integration Score (Porter & Cohen et al., 2007), etc. These indexes are mostly based on co-occurrence of authors, institutions or references. These objects belong to internal information of papers, e.g. references data. However, few scholars measure the degree of interdisciplinarity according to papers’ external information, e.g. readership data. A reader, as a recipient of paper knowledge, belongs to a certain discipline. We can detect interdisciplinary knowledge output of papers according to their readership data. This paper proposes a new approach for interdisciplinary measurement which is based on the proportion of disciplines covered by readerships.

Methodology

Framework

Since reference and readership data is different in discipline classification system, disciplines in these two classification system must be unified. After unifying of disciplines classification system, we compute interdisciplinarity according to reference and readership data respectively. Correlation analysis between these two interdisciplinary measurements is presented. Finally, readership data is used to analysis trend of interdisciplinary development. Flowchart of interdisciplinary measurement analysis is shown in Figure 1.

Data

We collected readership data of papers from Mendeley¹ on June 14, 2016. As shown in Figure 2, ‘Readership Statistics’ is presented in every paper page. For instance, readership of paper “How far does scientific community look back?” included “34% Social Sciences”, “32% Computer Sciences” and “9% Arts and Humanities”.

The papers we chose were published on PLOS ONE² from 2012 to 2015. The reference data of corresponding papers was obtained from PLOS ONE xml files directly. The quantity distribution of papers is shown in Table 1. A total of 48,930 papers with 2,363,861 references were obtained. All these papers have readership data. There are about 63% papers whose corresponding discipline can be found in the unified disciplines classification system.

Unifying of Disciplines Classification System

We unify disciplines of classification system for reference and readership data based on Science-Metrix system. Science-Metrix system can be regarded as three-level classification tree (Archambault & Beauschesne et al., 2011). In this paper, we only use the first and second level of Science-Metrix system to reduce difference between Science-Metrix system and discipline classification system.

¹ http://www.mendeley.com
² http://journals.plos.org/plosone/
Computing Interdisciplinarity

We adapted a metric known as interdisciplinary distance (IDD) (Bromham and Dinnage et al., 2016) to measure the degree of interdisciplinarity of a paper. Interdisciplinarity degree of each paper based on references and readership data is denoted as Ref_IDD and Read_IDD respectively. The IDD index was derived from Phylogenetic Species Evenness (Helmus & Bland et al., 2007). The IDD index takes into account the evolutionary relatedness of disciplines to each other, as well as their relative abundances. The metric is standardized so it falls between 0 and 1. The formal definition of IDD is:

\[
IDD = \frac{m_{\text{diag}[C]} M - M' C}{M' M - m_m^2}
\]

where \( M \) is a \( n \times 1 \) column vector containing the values of \( m_1, m_2, \ldots, m_n \), \( M' \) is the sum of \( m_i \) (\( \sum_{i=1}^{n} m_i \)), \( \text{diag}[C] \) is a \( n \times 1 \) column vector giving the main diagonal of \( C \), and prime (') denotes the transpose.

Experimental result analysis

Correlation Analysis

Table 2. Spearman correlations between Read_IDD and Ref_IDD (N=48930)

<table>
<thead>
<tr>
<th>Metrics</th>
<th>Read_IDD</th>
<th>Ref_IDD</th>
</tr>
</thead>
<tbody>
<tr>
<td>Read_IDD</td>
<td>1</td>
<td>-0.018*</td>
</tr>
<tr>
<td>Ref_IDD</td>
<td>1</td>
<td></td>
</tr>
</tbody>
</table>

Correlation between the interdisciplinarity based on references (Ref_IDD) and the interdisciplinarity based on readership (Read_IDD) is analysed according to 48,930 papers. As table 2 shown, the Spearman correlation coefficient of Read_IDD and Ref_IDD is -0.018 (p=0), indicating that there is a negative correlation between them.

Trend of Read_IDD

We monitor development of the readership disciplinary data from 2012 to 2015. The results are shown in figure 3. According to figure 3, we can see that trend of interdisciplinarity based on readership is increasing over time (about 7% growth). This result is almost the same as the change in Integration Scores over time (Porter & Cohen et al., 2007).

Conclusions

This paper uses readership data of papers to measure their interdisciplinarity degree. There is a negative correlation between references-based and readership-based interdisciplinarity. The trend of interdisciplinarity based on readership is increasing. Readership also shows that science is indeed becoming more interdisciplinary.

Hokkaido University, Kita 21, Nishi 10, Kita-ku Sapporo 001-0021, Japan

Introduction

Nowadays, it becomes increasingly important to gain efficiency and usability of equipment and assets in universities to maximize outcomes of research and education within the limited resource and budget. This is also ranked as a high-priority government policy dealing with the development of reform and functional enhancement of universities in Japan.

The Global Facility Center (GFC) provides a variety of services related with the use of more than 150 leading-edge machines (named “open facilities”) and high technologies accumulated in the 140 years’ history of Hokkaido University to support research and educational activities for not only on-campus but also off-campus researchers, students, and engineers (Figure 1). Total number of users is now about 35,000 per year.

As the result of equipment sharing activity in Hokkaido University, we have already stored the dataset of users, hours of equipment on active and so forth for over 10 years.

In this research, we try to show one proposal on the future strategy of the equipment sharing from short term to long term using the dataset we stored.

Logic Model for sustainable project management

Logic Model is one of the management tools to visualize concrete activities and evaluate indicators for final goals of the organization. In Euro-American countries, some manuals to utilize the Logic Model are prepared. In Japan, Logic Model has been used to develop a basic program for policy assessment activities. Logic Model is utilized in hierarchical PDCA cycle like Figure 2. In previous studies, the post-project evaluation or performance evaluation using benchmark analysis for the case of the road asset management are proposed. Using these concepts, the management of research infrastructure in universities is more advanced and more efficient in every hierarchical level; field, tactical, and strategic levels.

Methodology

In this research, we focus on the strategic level, “Number of users using the sharing equipment.” Since the number of users is changing as time proceeds, time-series analysis is adopted as a trend analysis or future forecast methodology.
forecasting and calculating evaluation indicators using these datasets on a trial basis.

Results and discussions

Figure 3 shows one of the time-series datasets for number of users (solid line) and forecasting results. Just by visualizing the stored data, some trends are qualitatively grasped. Dotted line, grey area, and light grey area show forecasting data, 75%, 95% confidential interval, respectively. Furthermore, upper, middle, and bottom figures show 1, 3, and 5-year forecasts, respectively.

The prediction period in the time-series analysis is generally defined as 10%-20% of the sample size. However, three confidential intervals of forecasting results in figure 3 is almost the same range. In this research, 3-year forecasting data is adopted as an equipment sharing strategy.

As a trial consideration focused on the future trend of the utilization situation, the correlative relationship among research organizations is calculated. Figure 4 shows relationships of research institution (RI) A, B, and C. In this case, there is no relation between RI trend A and B (a-1, a-2). On the other hand, there is a relation between RI trend A and C (b). It is hoped that these results are basic information for investment strategy to purchase new leading-edge equipment, repair sharing equipment and so forth.

Figure 3. Time-series data of users on one of the sharing equipment. Solid line, dotted line, Grey area, and light grey area show historic data, forecasting data, 75% confidential interval, and 95% confidential interval, respectively. Furthermore, upper, middle, and bottom figures show 1, 3, and 5-year forecasts, respectively.

Figure 4. Correlative relationship among research organizations.

Introduction
The keywords, especially ones with high frequency, are often applied to mining research focus and disciplinary core knowledge. But the keywords are mainly computing by counting frequency and cooccurrence relation. This paper, based on WOS (1985-2016) data of Artificial Intelligence (AI), computing the h index of each keyword by using the formula proposed by Hirsch (2005). From the perspective of statistical modeling, Malesios (2015) explores the variations on the standard theoretical models for the h-index. Bar-Ilan and Levene (2015) give a novel method of computing the h-index for web pages (the hw-rank) based on a variant of the h-index. Murray et al. (2016) find that the H-index is a useful quantitative measure for comparing different diseases.

Introduction to data source and computing method and Analysis of the distribution
All keywords of AI were directly extracted based on the paper from WOS. The data source gained from WOS is introduced as the following table 1.

<table>
<thead>
<tr>
<th>Set</th>
<th>Results</th>
<th>Search criteria</th>
</tr>
</thead>
<tbody>

According to the detailed value, the power-law between citation times and amount of keyword is shown. In order to observe the distribution phenomenon obviously, all keywords are processed based on the logarithmic computation. A scatter diagram which consists of citation times and amount of keyword is drawn. Figure 2 gives the whole distribution.

Fig. 2 The Power-law distribution of keyword

X-axis shows the citation times of keywords and Y-axis is the logarithmic computation result of amount of keyword. Figure 2 presents a linear trend which is consistent with power-law distribution. This paper, on the basis of the relation between h index in information output processing, Zipf’s Law, and Lotka’s Law proposed by Egghe (2006), proves the existence of such relation between keyword’s h index, the frequency and citation of keyword of WOS (1985-2016) data of Artificial Intelligence (AI). The following formulas explains the relationship.

\[ f(j) = \frac{C}{j^\alpha} \]

\( C > 0, \ \alpha > 1 \). \( f(j) \) means the total frequency of keywords of WOS (1985-2016) data of Artificial Intelligence (AI) whose citation times is \( j \). Therefore, the total frequency is:

\[ T = \int f(j) dj = \int \frac{C}{j^\alpha} dj = \frac{C}{\alpha - 1} \]
Then, the total frequency of keywords of WOS(1985-2016) data of Artificial Intelligence (AI) whose citation times is more than \( n \) is:

\[
\int f(j) \, dj = \frac{C}{\alpha - 1} j^{\alpha - 1} = T^{\alpha - 1}
\]

Let \( T^{\alpha - 1} = n \), then \( h \) is the solution to the equation.

\[
h = T^{1/\alpha}
\]

Formula presents the relation between \( h \) index and the total frequency of keywords (T) in WOS(1985-2016) data of Artificial Intelligence (AI). By verifying such relation, a mathematical relation between them can be concluded: when \( \alpha > 2 \), the total times cited of all keywords of WOS(1985-2016) data of Artificial Intelligence (AI) are:

\[
A = \int f(j) \, dj = \int \frac{C}{j^{\alpha - 1}} = \frac{C}{\alpha - 2} \quad A = T^{\alpha - 1} \quad \frac{1}{\alpha - 2}
\]

Therefore, Formula could be turned into

\[
h = \left( \frac{\alpha - 2}{\alpha - 1} A \right)^{1/\alpha}
\]

So, the relation between \( h \) index and A times cited of keywords of WOS(1985-2016) data of Artificial Intelligence (AI) is:

\[
h = \left( \frac{\alpha - 2}{\alpha - 1} A \right)^{1/\alpha}
\]

Meanwhile, the average times cited of each keyword of WOS(1985-2016) data of Artificial Intelligence (AI) could also be reached:

\[
\mu = \frac{A}{T} = \frac{\alpha - 1}{\alpha - 2}
\]

**Keyword’s \( h \) index computing**

The keyword’s \( h \) index is computed based on the computing method of Fig.1. All of the keyword’s \( h \) index are derived from the papers of WOS(1985-2016) data of Artificial Intelligence (AI). Table 3 presents the top 10 keywords with high \( h \) index and arranges them in descending order.

### Table 3 Top 10 keywords of WOS(1985-2016) data of Artificial Intelligence in order of \( h \) index

</tbody>
</table>

In order to show the differences among the three values of \( h \)-index, frequency and citation times, the figure 3 gives the visualization results of top ten keywords.

The keywords computed by the \( h \)-index in Tab.3 and Fig.3 balance the frequency and citation times of keywords in all papers from WOS. So the keywords are more rational and scientific in distribution.

**Conclusion**

The computing method of keyword’s \( h \) index is put forward according to the definition of \( h \) index. The relationship between \( h \) index and frequency of keywords is explored, and the verification formulas is deduced based on the keyword of WOS(1985-2016) data of Artificial Intelligence (AI). The keywords \( h \) index of WOS(1985-2016) data of Artificial Intelligence (AI) are computed and shown in table and figure.

**Acknowledgments**

2 José Luis Aleixandre Benavent

Introduction
The burning of fossil fuels is a major cause of global climate change. The development of renewable energies (RE) is thus a significant strategy to mitigate global climate change (Cong, 2014; Cong, 2013). Meeting energy demands by increasing renewable energies is one of the crucial approaches of the power industry towards a sustainable development and climate change prevention. For example, China’s electricity sector is aiming to reduce with the use of RE nearly 50% of its greenhouse gas emissions by 2020 (Steenhof & Fulton, 2007). The first steps for the promotion of RE appeared in the 1990s from international environmental treaties such as the UN Framework on Climate Change in Rio, Brazil (1992) and the Kyoto protocol (Japan, 1997) (Chien & Hu, 2008). On the other hand, RE are becoming a very important asset for the development of the society, since during 2015 a 5% employment increase in the renewable energy sector was observed, to a total of 8 million jobs (direct and indirect) (REN21, 2017).

This work thus aims to investigate a possible correlation between scientific production and impact, power production and funding on global renewable energies (2007-2016).

Methods
Records on publications, citations and funded papers were obtained from Web of Science Core Collection (WOS) platform from Clarivate Analytics. A bibliometric analysis was performed to determine indicators of scientific productivity, impact, power production and funding. Key words for the search strategy included: biomass, geothermal, hydroelectric, solar, ocean and wind, all of them combined with “energy*”. The generic term “renewable energ*” was also taken into account. The key words were truncated if necessary to obtain variants of the same term. The search was limited to original articles within the 2007-2016 decade.

Our hypothesis includes: a) a possible correlation between power production on RE -expressed in Gigawatt hour (GWh)- and scientific production -as observed in a number of scientific published and funded papers; b) a possible correlation between power production and impact of the research.

Data on power production of renewable energies were extracted from the International Energy Agency (www.iea.com).

Results
A number of 12,167 papers that received 185,410 citations were recovered. The evolution of papers and citations is shown in Figure 1 with one third of the papers published in the 2015 and 2016 years.

![Figure 1. Number of published papers and citations per year](image-url)
Table 1 shows the 15 countries with more than 300 published papers. United States is the leading country in papers and citations, with China as the country with the highest percentage of funded papers (80%), followed by South Corea (77%) and Spain (61%).

In order to answer the question of whether there is a relationship between energy production and the number of funded articles, Figure 2 was investigated. As can be observed, there are countries in which there is very little correlation, such as United States, which shows a large number of both funded and not funded articles with a low RE production. By contrast, China doubles US in energy production despite having fewer published and funded articles. Other countries with a good correlation between the energy production and the scientific production, including both funded and not funded, are Canada, Italy, Japan and India. Some countries in which the correlation was also positive include Germany, France and Turkey. It should be noted that the country with the least relationship is United Kingdom; country that funds more than 50% of the articles, but has a low energy production. The same can be said for Spain and South Corea as they share a high percentage of funded articles but a low energy production.

Conclusions

Articles and energetic production on renewable energies has increased in recent times. The correlation between energy production, scientific production and funding is uneven, with countries showing good correlation (China, India, Canada, Italy, France and Japan) while others not (United States, United Kingdom, Spain and Australia). It will be desirable to investigate the behaviour of the RE individually and by countries with the aim of identifying the reasons that explain these discrepancies.

Introduction

Prepublication ensures a better chance in the diffusion of the papers, but is not easy to know how far this practice can really improve some bibliometric parameters of the authors, as the number of citations to their papers or the publication of their articles in journals with higher citation indexes. The repository of scientific manuscripts arXiv is nowadays an important tool for diffusion of research, mainly in Physics and Mathematics but, recently, also in other branches of science and technology (Moed, 2007; Davis & Fromerth, 2007). The aim of this work is to study whether or not pre-publication in arXiv benefits the authors or rather produces a dispersion of citations that takes away relevance to their publications.

Methods

We searched the references to papers published in arXiv in the Web of Science database (WoS) in December 2015 in the field Cited Work of Cited Reference Search. After fixing the right reference, Google Scholar was used to determine if the paper was already published in a regular journal. This gave us a set of 557 preprints as a working sample. Once the set of preprints was identified, several analysis were done: a) how many preprints in arXiv appeared in references of papers published in journals that are listed in WoS; b) Difference among the year of standard publication and the year in which the preprint was deposited in arXiv; c) Cites computation for papers that were published in a standard journal and cites in arXiv of the preprints. In case the journal does not provide the number of citations to its papers, Google Scholar was used instead registered in Google Scholar, and the difference among these quantities.

Results

A1. Publication ratio and publication delay

Table 1 shows the total number of deposited and published papers, respectively, for some scientific fields that have been chosen by the bigger number of papers appearing.

<table>
<thead>
<tr>
<th>Scientific Areas</th>
<th>Deposited</th>
<th>Published</th>
<th>Ratio (%)</th>

<td>377</td>
<td>67.2</td>
</tr>
</tbody>
</table>

The result depends a lot on the subjects. In the grouped area of Mathematics, Statistics and Nonlinear Sciences, the ratio obtained is 64.3. It may indicate that mathematicians consider relevant to publish in a standard journals those manuscript that the community consider relevant enough to be cited in their papers. The opposite behavior can be observed regarding “Physics”. It should mean that, up to a point, some authors considers to deposit in arXiv enough for providing visibility to their research.

Other interesting bibliometric information that can be obtained concerns the mean of the time that is needed for publishing a paper after it is deposited in arXiv. It is supposed that the authors introduce the paper in arXiv when they finish the research work, so after this moment the delay can be directly interpreted as exclusively due to the publication process. The results are shown in Table 2 for the
grouped specialties. It must be remarked that the dispersion of the result is very big (high variance).

A2. Elapsed time for publication versus impact of the papers

For all the manuscripts, we computed the citations in arXiv (provided by INSPIRE). Then we applied two different rules depending on if the paper was finally published or not:

a) If the preprint was finally published, we found the number of citations in the journal where it was published, or in Google Scholar instead in case the journal did not provide this information (figure 1).

b) If the paper was never published, then we used as external measure of citations the number given by Google Scholar (figure 2).

A weak positive correlation may be observed in both cases. There are a lot of papers without citations inside arXiv that have a big citation rate when they are published in a standard journal, or in Google Scholar.

Figure 2. Citations in arXiv (by documents in arxiv) versus Citations in Google Scholar

Conclusions

1. There are not fixed rules that allow us to understand the general behavior of researchers regarding pre-publication of their scientific results. It seems to depend strongly on the particular specialty that is considered, and no general tendency is observed.
2. It seems that there is a lack of general reasons regarding motivation of researchers to deposit their manuscripts in arXiv. Short publication delay sometimes appears together with big ratio of publication. Disciplines with a high publication delay may have small publication ratios, what would imply that researchers lose interest in publication once their results are communicated. Thus, we must claim again about the need of measuring impact of deposit of manuscripts via number of citations to really consider this way of scientific exchange.
3. It seems natural to think that in the near future also consideration of non peer reviewed articles will enter in the evaluation systems, since their impact can also be measured in terms for example of citations or downloads, but the current state of the art does not allow to consider them as publications.

References

Introduction
The scientometric and social network analysis of key words has great potential to expand valuable understanding of the advancement of the research in a specific journal as well as in cases of emerging fields such as new technologies and processes (Jarvelin & Vakkari, 1993; Leydesdorf & Welbers, 2011; Wang et al., 2012). The purpose of this work is to analyse the evolution and relations of bibliometrics with other Information Science topics, as reflected in the scientific literature published in the Information Science Journal of broad scope entitled Online Information Review.

Methods
Key words included in a set of 758 papers included in the Web of Science database from 2000 to 2014 were analysed. We conducted a subject analysis considering the key words assigned to papers containing almost one bibliometric term. A social network analysis was also conducted to identify the number of co-occurrences between key words (co-words). The Pajek software was used to create and graphically visualize the networks. A threshold of more than 2 co-occurrences was established.

Results
Table 1 includes the distribution of papers according to the assigned key words in three five-year periods. Impact is the most frequently assigned key word (n=31), followed by Social networks (n=24), Citation analysis (n=15), h-index (n=13), Indicators (n=13) and Rankings (n=13). Other key words that highlight with more than 10 published papers are Impact factor (n=80) and Cluster analysis (n=11). Most key words increased during the three analysed periods, highlighting h-index, Indicators and Webometrics. Key words with an annual decreasing tendency of frequency include Cluster analysis.

Figures 1 to 4 show the network of co-occurrence of key words (co-words) over the three considered periods and over the entire period. During the first period, 2000-2004 (figure 1), the network comprised 9 key words. Three key words occupied
a more central position and a prominent intermediary position: Search engines, World Wide Web and Science.

Figure 1. Network of co-words in the 2000-2004 period

During the second period (2005-2009) (figure 2), the network comprises 13 key words and World Wide Web and databases were the key words with the most centrality.

Figure 2. Network of co-words in the 2005-2009 period

During the third period (2010-2014) (figure 3), the network of co-words included 16 key words, and Science and Search engines were the key words with the most centrality and connections.

Figure 3. Network of co-words in the 2010-2014 period

Figure 4 shows the network of co-words during the entire period.

Figure 4. Network of co-words along the complete analyzed period (2000-2014)

Conclusions

Our results reveal that Bibliometrics, as represented by Online Information Review, is an evolving discipline that draws on literature from a relatively wide range of subjects to embrace new lines of research (Chen & Xiao, 2016).

As expected, “classical” key words related to information systems and words related to the Internet environment and bibliometrics predominate. In the last years, new domains that have emerged and play a major role in stimulating research are investigations related to scientific publications based on bibliometric approaches to research evaluation, such as Citation analysis, Impact factor, h-index, Social network analyses and Rankings.

Increasingly, impressive growth has occurred in topics related to new technologies, new databases and products, such as electronic commerce, social networks, Google Scholar, Scopus and open systems.

Abstract
With the rise of green technology, green patent value evaluation is critical to the enterprise. In order to explore the influencing factors of green patent value, we take the LED industry as an example. Then we use the number of patents cited as the proxy patent value, and divide the patent into high-cited patents and low-cited patents based on the H index of LED patents. We also introduce the social network analysis, trying to explore the influencing factors of patent value with network centrality and network position from a dynamic view. The results show that the social network indicators out-degree centrality and effect size have a significant positive impact on the patent value.

Conference Topic
Patent analysis

Introduction
As the increasing environmental pollution and resources shortage problems, many measures have been taken. One of these measures is developing green technologies. Green technologies are also known as environmental sound technology, which refer to technologies and products using more clean and energy-efficient raw materials. Green technologies reflect humanity's introspection about the consequences of damaging the ecological environment resulted by modern sciences and technologies. The concept of green technologies was first proposed by Braun e. and Wield d. in 1994 (E. Braun & Wield, 1994), then got the wide acceptance. According to patent statistical manual published by the organization of economic co-operation and development (OECD) in 2009, about 80 technologies are regarded as green technologies, and they can be divided into 7 aspects, including environmental management technologies, water-related adaption technologies, biodiversity protection and ecosystem health technologies, climate change mitigation technologies related to energy generation, transmission or distribution technologies, capture storage sequestration or disposal of greenhouse gases and climate change mitigation technologies related to transportation and buildings.

Based on the high value of green technologies, green patents also got rapid development. Except patents’ traditional characters, such as novelty, creativity and practicability, green patents have the unique character--environmental friendly, which means that green patents are the results of highlight for environmental benefits with the requirements of environmental protection in modern society. Now, many countries have provided the quick patent censor system for green patents. For example, in 2009, the UK launched the first green channel for patent applications, aiming to promote green technology innovation and gain a leading position in global competition through the rapid review of green patent technologies.

The research and development of green technologies and green patents have brought both opportunities and challenges to enterprises. On the one hand, the development of emerging green industries has brought huge potential market for enterprises, which can enlarge the sales of products and lead to more profits. On the other hand, it takes additional costs for enterprises to meet the national environmental standards proposed by the policy. Besides, more and more consumers will consider the environmental impacts of products as a significant selection
standard due to the environmental value of green patents, which will lead to increasing preferences for green patented products. So, enterprises must upgrade their existing equipment and invest more in R&D to product more environmentally friendly products in response to these changes.

In response to the environmental trends, patents applied in environmentally-related areas are increasing in recent years. In China, there were more than 200 million patents in 2015 according to the data from Intellectual Property Office. But it is well known that applying for a patent requires a great cost, so the importance of patent should not rely on the patents’ number, but also the patents’ quality. According to the statistical data from OECD, which said that 37.7% of the world's environmentally-related innovations were patented in China, but only 3.9% of the world's environmentally-related innovations were developed in China, which means that the utilization of patents is far from expectation compared with developed countries, and the value of these patents need to be improved. So, it is urgent for enterprises to realize the important of evaluating patents and use their limited resources to build their patent pools, which can maximum the cost-effectiveness when faced with more and more patents application.

Although the green patents are receiving more and more attention, there are only a few formers research study about the value of green patent, and they are mainly focus on the institutional level. Some researchers have made some progresses by setting up the establishment of evaluation indicators, building the model and doing empirical analysis in the area of patents’ value. Except using patents’ own attributes such as the number of patents cited forward and backward, the number of patent claims to measure a patent’s value, some researcher also discovered some professional and comprehensive indicators, like patent’s innovation and mature of technology as evaluation indexes. But, they only considered the patents’ own attributes separately and ignored the role of the patents played in the process of technology evolution. Usually, the importance of a patent’s value is showed by how important the role it plays in the technical knowledge flow process, meaning that if a patent pushes forward the whole technical knowledge evolution, it values higher compared with other patents without doubt.

As an important part of green patents, LED has the concept of green energy and is at the forefront of the global electronics industry. LED has characters such as low power consumption, long life, fast response and non-polluting. These characters make it highly important in semiconductor lighting field. Optoelectronic Technology represented by LED is the most promising industry technology in 21 century. So, studying the values of LED patent will contribute to the same researches in green technological fields and provide reference to the green patent examination system. In order to study the evaluation system, we divide LED patents into two kinds which are highly cited patents and low cited patent based on H index. We introduce Social Network Analysis method and we use the patent as the nodes of the network, and make the citation relationship between patents as the connection between nodes. We conclude that the social network indexes, out-degree centrality and effect size have positive effects of patent value.

We hope this study could help enterprises to do better in evaluating patents and construct better patent pools and establish competition strategies matches themselves. Besides this paper also provides new ideas to other green technology fields, which can be reference to the patent examination system for review patents more efficient.

**Literature review and research hypothesis**

**Social network analysis**

Social network analysis (SNA) is the method of studying the social relationships and structures, which mainly study the internal network between different social actors (Wasserman & Faust, 1687)
Social network analysis was used to analyse the relationships between people, and it originated in the 1930s. After the rapid development, combined with mathematics, statistics and computer science and other disciplines, social network analysis became an interdisciplinary analytical method.

Social network is comprised by nodes and ties in sociology. Nodes imply actors, which may be the individual, team, enterprise or other social organizations. Ties imply the relationships between nodes, and scholars always describe ties by matrix and graph. Matrix and graph are the manifestations and the research foundation of social network. The distribution and characteristics of the relations in the social network can be analysed by using the matrix, and the structure between the nodes and the overall properties of the network can be observed by the network graph which connect the actors.

Since Yoon and Park (2004) applied social network analysis to patent research, more and more scholars have begun to build patent networks for analysis. For example, Gress (2010) pointed out that the internal and external reference in patent citation network can reflect the technical dependency and related contributions between the patent groups. Lee, Su, and Wu (2010) studied the conductive polymer nanocomposite industry. They constructed a patented network diagram for this industry, and discussed the evolution of the technology by calculating and analyzing the relative distance and network location of the patent in the network. Kim and Song (2013) introduced the social network to analyse the litigation relationship between the 26 major companies in the smartphone industry. In this study, we focus on the LED industry, using the social network to analyse the impact factors of patent value.

**H-index**

The h-index was originally used to analyse the individual academic achievements of the scientist and was a new indicator proposed by Jorge E. Hirsch in 2005 (Hirsch, 2005). Hirsh, in his study of the contribution of physicists, defined the "h-index" as: In the N papers published by the scientists, the maximum number of papers is quoted at least h times.

Compared with the traditional evaluation index, h-index takes both the number and the quality of scientists into account at the same time. Therefore, the H index become one of the most commonly used evaluation indicators. T. Braun, Glänzel, and Schubert (2006) first applied the h-index to the field of journal evaluation. Mingers, Macri, and Petrovici (2012) used the h-index as a measure of the quality and contribution of journals. They studied 455 journal samples in the field of business and management and analysed the h-index with the impact factor and the cites per paper. The conclusion shows that the h-index is superior compared with the traditional bibliometric index. Molinari and Molinari (2008) found that the h-index can be used to assess the scientific results and contributions of research institutions.

As for patents, Guan and Gao (2009) explored the relationship between the patent h-index and patent counts, citation counts, the mean family size, the result showing that the patent h-index is an effective index to evaluate the technical importance and influence of the assignee. Since then, h-index is widely used to evaluate the patent value. This study will follow the h-index in the field of patent research, calculating the LED industry patent h value. According the h-index, the patent citation is divided into two regions: the patented cited number of times higher than the h value and the number of patent cited less than h value.

**Patent citations and patent value**

Patent citations are the mutual references between patents and patents or non-patents. According to the different citation orientation, patent citations can be divided to backward citations and forward citations. Backward citations mean the patent cite the existing patents, and it is a continuation of the previous art, while the forward citations mean the patent is cited by other patents, reflecting the implication to follow-up arts.
In the past research, although the forward citations and backward citations can reflect the information about the related patents, but the usage of these two indicators are different. Generally, backward citations information is used to study the trajectory of research and development, technological diffusion, knowledge flow, etc. Forward citations information is usually consider as the indicator of patent economic value, technological innovation and implication. Trajtenberg (1990) first used the number of patents cited for patent value analysis, then many theoretical and empirical studies have proved that the use of the indicators to assess the effectiveness of patent value subsequently. For example, Harhoff, Schererc, and Vopeld (2003) found that there is a significant positive correlation between the number of citations and the value of patents. So, we continued the existing literatures, using the number of patent citation to evaluate the patent value, and divided the patents to high-cited patents and low-cited patents according the H index which evaluated through patent cited number.

**Network centrality and patent value**

Network centrality is the focus of social network research, and it is an important structural location indicator. In sociological research, centrality is often used to measure the importance of the individual, the status of superiority and social prestige. (Freeman, 1979), for example, argues that the central place in the social network reveals the rights and status of an individual in a group, which means that the more the actors are at the center of the network, the greater their influences. By applying network centrality to the patent citation network, the patent can be used to measure the position of the patent in the whole network and to identify the higher patent value in the whole patent network.

**Degree centrality**

Degree centrality evaluates the positions or superiorities of nodes in the social network, reflecting the direct influence of actors in the network. In social network, if an actor has many direct ties with lots of actors, then the actor is at the local position, and it has widespread influence. In directed graph, the degree centrality can be divided into the In-degree centrality and Out-degree centrality according to the direction between the actors and other actors. In-degree centrality refers to the number of other actors in the network to receive a relationship issued by the other, while the out-degree centrality refers to the network of an actor to the number of other actors to issue a relationship.

As the patent citation network is ordered network, according the different citation orientation between patents, forward citation can be reflected as the out-degree centrality, while backward citation can be reflected as the in-degree centrality. According to the previous section, the number of patent be cited as the evaluated indicator is overlap with the in-degree centrality of patents, so we only consider the out-degree centrality, and ignore the in-degree centrality of patents.

As for patents, the out-degree centrality reflects the references and inheritances from other patents, and this indicator also shows the degree of dependence of this patent on other science and technology. In this rapid develop modern society, most of the patents are based on previous skills, and they are products developed and improved based on previous skills. From this perspective, if a patent cited more prior arts, it shows that the technological area of this patent is relatively mature, and the technology this patent contains is mainly improvement of the previous mature skills. Therefore, if a patent cited more previous patents, it can be said that it is based on a large number of comparatively mature previous technologies, which means that the patent can integrate the existing knowledge and technology better, and its covering technical field is more broader compared to other patents. Allison, Lemley, Moore, and Trunkey (2004) pointed out that the more valuable patents are usually cited more advanced technology, and
they are more easily cited by other patents at the same time. Thus, the higher value a patent has, the more patents it will cite, which means the higher out-degree centrality the patent has. Therefore, we present the first hypothesis:

\[ H1: \text{Compared to low-cited patents, high-cited patents have higher out-degree centrality.} \]

**Closeness centrality**

Closeness centrality is the sum of the shortest distance from a node to all other nodes in the network. Closeness centrality evaluates the distance between a node to other nodes, the distance more short, the more easily of the nodes reach to the other nodes. In social network, if an actor is connected to many other actors through a relatively short path, the actor has a high degree of nearness to the center, meaning the actor is in the center position of the network. Freeman (1979) said that if all the paths an actor connected to other nodes are short, meaning that the actor is close to many other actors. This actor is less dependence on other actors in the process of information transfer, while a non-core positions must transfer information through a lots of actors. In other words, the actors occupying the near-center position are more efficient in communicating information throughout the network than other actors because of their shortest path to other actors. Such actors also tend to act as key roles, which can reflect quickly in the process of resolving the problems. Thus, closeness centrality is the primary measure of the ability of the actor not to be controlled by other actors or the efficiency of the transmission of information between actors.

Similar to the degree centrality, the closeness centrality of directed graphs can be divided into in-closeness centrality and out-closeness centrality. The closeness centrality refers to the sum of the shortest distances required by other actors to contact or cite actors, and it is a passive approach to the actor. In contrast, out-closeness centrality refers to the sum of the shortest distance the actor wants to associate with or quote from other actors, reflecting the active approach of the actor. Likewise, this article deals only with the outward-near centrality of patents, the sum of the shortest distances required for a patent to be directly or indirectly cited to all other patents. When the outward orientation of the patent is close to the central degree, it means that the patent can efficiently absorb the information and knowledge contained in the previous patent in the citation network and acquire the technical knowledge or information in other fields. In contrast, the inventor of the patent may more effectively cite prior patents to develop and improve upon extensive reference to other patents and may therefore be of higher technical content than other patents, and its value is also higher than other patents. Thus, we propose hypothesis 2:

\[ H2: \text{Compared to low-cited patents, high-cited patents have higher out-closeness centrality.} \]

**Eigenvector centrality**

Eigenvector centrality is another standardized measurement method of actors’ centrality. Combining the centrality of the actors contacted with the specific actor in the whole network, eigenvector centrality measures the most core actors of the network, which means that the centrality of an actor not only decided by the number of the actors contacted with it, but also the quality of these actors.

As for patent network, eigenvector centrality weighs the most core patent for that this measurement index measure the patent and its contact patents’ centrality at the same time. In the citation network, if one patent has many relationships with many other high centrality patents, then the patent is important in the network. On the contrast, a patent may be at the
center of a local patent citation network but not the entire network if this patent is connected to a number of a number of non-central patents.

So, we can conduct actors that connect to an actor having high eigenvector centrality are always connected by many other actors. Thus, if a patent has high eigenvector centrality, those patents which cite or cited by this patent also have high centrality. So we can say that a patent has higher eigenvector, the patent is closer to the core position of the patent citation network. So, in the entire patent citation network, the patent can influence many patents by direct or indirect contact, that is to say that the greater the influence of such a patent, the higher the value. So, the hypothesis 3 as follows:

**H3: Compared to low-cited patents, high-cited patents have higher eigenvector centrality.**

**Network structure and patent value**

In addition to the centralities of specific nodes in the network, the network structure also plays an important role in social network analysis. Research has often divided the social network structure into open networks and closed networks. Open structure can be linked with different groups, and can control the flow of information through the intermediary position, so as to obtain more advantages. This view takes Burt's Structural Hole Theory as the main representative (Burt, 1992). In Burt’s theory, structural holes are some of the gaps in network relationships, that is, there is an indirect link rather than direct link between some actors in network relationships and other actors. Structural Hole theory holds that the structure which have gaps between the actions can contain less redundant information, so structural holes the efficiency of the entire network of information exchange can be improved. Besides, the advantages of this network structure also derive from the intermediary opportunities created by information exchange, that is, in an open network structure, the actors can establish contact with groups that are not associated with each other and obtain more resource advantage by controlling the information channel.

In contrast to open networks, closed network structure can facilitate the flow of information within the network and help foster the trust between internal actors, which is the positive effect of network closure. Specifically, the actor in this closed network structure has a high joint density, so the cohesion of the network will be very strong, and if there is abnormal information or abnormal behavior in the whole network, each actor can quickly reflect soon, and the abnormal information or behavior can be spread quickly and be the excluded of the network, so that all actors will benefit.

There are two metrics for measuring the degree of network closure: Network Constraints and Network Effect Size. The network constraint coefficient measures the degree of dependence of an actor on the other actors in the network and the amount of redundant information contained in the relationship. The effect size is used to measure the overall influence of the structure-hole actor, which is defined as the sum of the non-redundant links in the network structure. In this study, we use the effect size to measure the network structure of a specific node. The effective size larger, the more non-redundant links in the network. Therefore, we presents the following hypothesis 4:

**H4: Compared to low-cited patents, high-cited patents have lower network effects.**
Research method

Sample selection and data collection
This study uses the US patented LED patent data in the Thomson Innovation database as of May 2011, including three technical areas: LED epitaxial growth, chip fabrication and chip packaging technology. Searching the technical information of the above technical fields, 40,330 pieces of LED patents was picked up. After screening and removing the patents which was isolated, a total of 4650 patents was remained. The 4650 patents were then numbered and sorted in descending order according to their cited number of times until the number of a patent was greater than the number of citations of the patent. Finally, we subtract 1 from the serial number, and the answer was the patented h-index.

After the initial calculation of the LED patent, h-index is 105, that is, in the 4650 patents, there are 105 patents cited more than its serial number, such a patent is defined high-cited patent. Then we selected the related patents based on the principle of high-cited patent and low-cited patent ratio of 1: 2 for data screening. However, due to the number of patent applications and patent claim counts, there are 17 high-cited patents cannot accurately match the relevant low-cited patents. Such a non-matching high cited patent are removed, finally a total of 264 patents were included in this study, including 88 high-cited patents and 176 low-cited patents.

We divided patents into high-cited patent and low-cited patent by using the H-index of the patent, and the H-index is used as the proxy variable of patent value. In order to construct the patent citation network, we use the patent as the node and the patent citation as the link between the nodes, then we convert the filtered patent data into the matrix required by social network analysis, which there is the relationship between the two patents in the matrix Marked as 1, and there is no citation relationship between the two patents are marked as 0. Then we import the matrix into the social network research software Ucinet and calculate the patent network center and network patent location indicators, and Logistic regression analysis was performed.

Variable operational definition
This study selects the patent cited as a proxy variable of patent value. According to the above calculation of the patent H index, the LED domain patent citations are divided to the high cited patent and the low cited patents. According to existing research, compared to the low cited patent, the high cited patent is more valuable.

Degree Centrality. Degree centrality is the number of other nodes that are directly associated with a particular node i, and is often seen as the degree of the node directly gets the flow information in the network. Degree centrality includes the out-degree centrality and the in-degree centrality. We only uses the out-degree centrality to analyze the nodes. For a network diagram with n nodes, the out-degree centrality of node i is calculated as follows: (1):

\[ C_{DO}(n_i) = d_o(n_i) = \sum_{j=1}^{n} x_{ij} \]

\( x_{ij} \) is the direct relationship between node i and node j, whose value is 0 or 1.

Closeness Centrality. Closeness centrality is the sum of the shortest path distances from node i to other reachable nodes. In general, nodes with shorter paths tend to have a higher closeness centrality than the other nodes. Similar to the degree centrality, closeness centrality can be divided into out-closeness centrality and in-closeness centrality, and we only consider the out-closeness centrality. It is calculated as follows (2):

\[ C_e(n_i) = \left[ \sum_{j=1}^{n} d(n_i, n_j) \right]^{-1} \]

\( x_{ij} \) is the distance from the node i to node j.
Eigenvector Centrality. Eigenvector centrality is the central index of the node \( i \) after considering the centrality of other nodes connected to \( i \), and it measures the degree of influence of the other nodes on the node \( i \). The centrality is calculated as (3):

\[
Ce(i) = \lambda^{-1} \sum_{j=1}^{n} a_{ij} e_j
\]

\( d(n_i, n_j) \) is the connected relation between node \( i \) and its adjacent matrix \((i, j)\). If connected, it is equal to 1, otherwise equal to 0, \( \lambda \) is the eigenvalue of the adjacent matrix, and \( e_j \) is the eigenvector corresponding to each eigenvalue.

Effect Size. Effect size is often used to measure the node’s impact on the entire network, reflecting the degree of non-redundant information network. The effect size of node \( i \) is calculated as follows:

\[
ES = \sum_i \left( 1 - \sum_q p_{iq} m_{jq} \right), q \neq i, j
\]

where \( j \) represents all nodes connected to \( i \) and \( q \) represents the nodes except for \( i \) and \( j \); \( p_{iq} m_{jq} \) represents the redundancy between patent \( i \) and \( j \), and \( p_{iq} \) represents the proportion of the relationship input from patent \( i \) to \( q \).

We mainly use the patent characteristic index as the control variables, including Claim Counts and Inventor Counts. Claims counts refer to the extent to which the patentee requests protection when submitting a patent application. The greater the number of patent claims, the more technical areas covered by patents. The inventor counts of patents refers to the sum of the number of patented inventors. The number of inventors of patents not only reflect the complexity of the patent, but also reflect the degree of R & D expenditure. The more inventors of the patent, the higher complexity of the patent may be, so the value of the patent may be higher.

**Empirical analysis**

*Descriptive statistics*

Table 1 is the descriptive statistical analysis of the independent variables and control variables in the model. From descriptive statistics, the mean and standard deviation of Out-degree Centrality, Effect Size and Inventor Counts are large, and the mean and standard deviation of other variables is relatively small.

**T-test**

Table 2 shows whether there is a significant difference between the average of the variables between high and low cited patents by using the T test. The results show that there are significant differences between Out-Degree Centrality, Out-Closeness Centrality, Eigenvector Centrality and Effect Size. Compared with the low-cited patent, the social network index of high-cited patent are significantly higher, and the disparities of the degree of out-degree
centrality and the effective size are most obvious. There is no significant difference in claims counts and inventor counts between two different types of patent.

Results of Logistic regression analysis

According to the number of patent citations, the patent H index is used to divide the patent into the highly-cited patent and the low cited patent. These two kinds of patents are used as binary virtual dependent variables, the out-degree centrality, the out-closeness centrality, the eigenvector centrality and effect size as independent variables, the claim counts and inventor counts as control variables, then we perform the logistic regression analysis.

Table 4 is the regression analysis results. The results show that the out-degree centrality and the effect size of the patent network is significant, but the influences of these two index on the patent value are opposite. Among them, the out-degree centrality has a positive effect, while the effect size has a negative effect on the patent value. It is proved that hypothesis 1 and hypothesis 4 are established. On the other hand, the out-closeness centrality and eigenvector centrality does not have a significant effect on the patent value, proving hypothesis 2 and hypothesis 3 are not found.

Conclusions and discussion
Based on the number of patents cited in the field of LED technology, we divide the patents into high-cited patent and low-cited patent according H index, calculating the network centrality indexes by constructing the patent citation network to analysis the patent value. The results show that there are significant differences between the high-cited patent and the low-cited patent. Combined with the analysis of social network, it is found that there is a significant positive correlation between the out-degree centrality of patents and the patent value. The higher the degree of patent expulsion is, the higher the patent value is. On the contrary, effect size has significant negative impact on patent value. The larger the effective size of the patent network, the lower the patent value. Out-closeness centrality and eigenvector centrality does not constitute a significant impact on patent value.
Therefore, when assessing the value of green patents, the enterprise can construct the patent citation network and calculate the relevant social network index of the specific patent to determine the value of the patent and choose a relatively high value of the patent to build a favorable patent portfolio, which can achieve cost-maximizing of technological innovation and obtain sustained competition advantages. At the same time, enterprises can also build a citation network to analyze the history and development trends of technological fields, and identify the core technology to adjust their own innovation strategies continuously.
In the process of green patent applications, in addition to the characteristics of the patent itself, the enterprise should also place patents in the all patent network to consider its value. Due to the negative correlation between the effect size of the patent network and the patent value, the enterprise can apply green patent on the basis of extensive reference to the existing technology, and strengthen the technical cooperation with the same field for reducing redundant information of the entire network.

A scientometric method for assessing an institution’s scientific collaboration policy

Hamid Bouabid,
Faculty of Science, Mohammed V University in Rabat, 4, Avenue Ibn Battouta, BP 1014 RP, Rabat, Morocco, h.bouabid@hotmail.com

Abstract
The paper suggests a comprehensive method for an institution's scientific collaboration policy assessment. This method is based mainly on indicators: signed agreements, co-publications, their citations and scientific fields as front science. The method also uses a mapping of collaborative institutions and fields to assess the proximity of the institution in its collaborative cluster as well as multidisciplinarity in this cluster. Three major classes of collaborative institutions are derived from the method: (1) a class where there is coherence between co-publications and agreements; the university has to faithfully intensify its collaboration with this class; (2) a class where there is a substantial amount of co-publications but no collaboration agreement; the university should consider setting up a formal frame for collaborative research; and (3) a class grouping institutions which cited the university knowledge and considered as potential partners for the university.

Conference topic
Methods and techniques - Science policy and research assessment.

Introduction and background
Science and technology (S&T) are increasingly open, multidisciplinary and highly integrative. Therefore, collaboration offers several opportunities and contributes to increased productivity and excellence in S&T. Several authors have demonstrated that there is a strong correlation between scientific collaboration and research productivity and impact (Katz and Martin, 1997, Lee and Bozeman, 2005, He et al., 2009, Abramo et al., 2011a and Finlay et al., 2012). Defazio et al. (2009) modeled the effect of collaboration and funding on productivity for three periods: pre-funding, during funding and post-funding. They found that receiving funding increases researcher productivity by approximately 14%, while collaborating with a partner in the network in the post-funding period increases productivity by approximately 70%. The positive
effect of collaborations on the impact of papers has also been proven using citations or impact (Katz and Hicks, 1997, Guerrero-Bote et al., 2013, He et al., 2009, Levitt and Thelwell, 2010). While there exists a rich literature offering findings and conclusions on collaboration assessments at the scientist-micro-level (Traore and Landry, 1997; Melin, 2000; Hara et al., 2003; Jha and Welch, 2010; Lee and Bozeman, 2005), or at the regional, national or international-macro-level (Tijis and Glanzel, 2010; Hoekman et al, 2010; Choi, 2012, Bordons et al., 2013), there are far fewer assessments of scientific collaboration at the institutional level, as done by Adams (2005), Ponds et al. (2007), Ortega and Aguillo (2013), Barth et al. (2014), Han et al. (2014) and Yan and Guns (2015). Furthermore, the methods applied in these papers are different and less methodologically organized to link collaborative inputs (agreements) to outputs (co-publications) for policy issues. Indeed, for example, Ponds et al. (2007) make use of the gravity model to examine the proximity effect of collaboration between different kinds or similar institutions. The work by Barth et al. (2014) was based on network and cluster analysis (carried out using VOSviewer software) to identify similar institutions for collaboration and potential partner’s ones. Finally, Yan and Guns (2015) applied eight algorithms to collaboration at the author, institution and country levels for predicting and shaping the dynamics of collaboration starting from existing topology.

Data and Method

In this assessment, all frameworks, agreements, conventions and Memorandum of Understanding (MoU), were considered acts of collaboration. Other types of contracts, tenders, and sponsoring agreements or similar were excluded. During the whole period, UM5S signed 248 agreements.

The University Mohammed V - Souissi (UM5S) comprises the following 10 institutions:

- Medicine and pharmacy faculty;
- Dental medicine faculty;
- National high school of technology teaching;
- National high school of computer science and systems analysis;
- Law and Economics faculty in Souissi;
- Law and Economics faculty in Sale;
- Education sciences faculty;
- Institute for African studies;
- Institute for Arabic studies and research;
- University Institute for scientific research.

The Web of Science database was used to retrieve publications and co-publications (co-authored ones), where all kinds of publications were considered (article, review, proceeding, letter, editorial, etc). In order to compare agreements and co-publications, the analysis covers
the second period from 2010 to 2013 (end of June 2013). UM5S published almost 600 publications during this period, of which 63% were co-publications. In this analysis, a co-publication is defined as a paper authored by the UM5S and at least one other institution (national or international).

To map and analyze co-publications, Salton's Cosine (Salton, 1983) is used as the index for calculating the proximity between the entities (institution, field, key-words, etc) of the network. Figure 1 reports the proposed method to assess the policy of university scientific collaboration.

![Figure 1: Scheme and stream of the proposed method for collaboration policy assessment](image)

Figure 1 plots the method process. The first stage consists of compiling data and information as a policy inputs. The second stage refers to the process of the analysis itself comprising three levels: (i) the stock of active collaboration agreements, which represents, for a given year, the difference between the number of cumulative valid agreements and the number of expired agreements up to that year, (ii) the coherence between agreements and co-publications and (iii) the impact of co-publications as measured by their citations. To achieve this analysis five indicators are produced in order to build up the three classes of collaborative institutions. In another institution's assessment, this number will depend on its collaboration policy.

**Results and discussion**

For the whole period, the stock of active collaboration agreements has been calculated, as described in the Data and Method section. Its analysis is not part of this paper.
**Coherence between agreements and co-publications**

Through the indicator of co-publication, the method quantifies the share of each institution in the collaboration activities of the university. For UM5S, the method has shown a national co-publication dominance amongst overall university co-publications (Table 1). Major national collaborative institutions are the Specialized Hospitals in Rabat, Hassan II University in Casablanca, and Ibn Tofail University in Kenitra. The different institutions belonging to the CHU Ibn Sina are from now on not considered separately but included in it. Furthermore, Academy Hassan II of Science and Technology is excluded since it is more of a funding body and not a research institution. Similarly, and for coherence purposes, the Ministry of Health will not be considered at all as a collaborative institution.

On the international level it is also noted that there is a diversity of collaborative institutions (Table 1). It is worth mentioning that two-thirds of the 39 UM5S collaborative institutions (above the threshold of 10 co-publications) according to co-publications with UM5S are not under any collaboration agreement with UM5S, demonstrating a clear distortion between agreement as input proxy and co-publication as its output proxy. Cross-checking the results in Table 1 from either signed agreements and co-publications according to the method in Figure 1 allows us to build up two classes:

- **Class 1**: institutions with which the university has collaboration agreements as well as co-publications with their researchers, such as National Institute of Health, University Mohammed V Agdal, Ibn Sina University Hospital (CHU), University Ibn Tofail, CNRS-France, University Zaragoza, University Bordeaux, Université de Montréal, Université Laval, Cheikh Zaid Hospital, University Cadi Ayyad;

- **Class 2**: institutions with which there is no collaboration agreement, but there is substantial co-publication activity, such as: Military University Hospital Mohammed V, University Hassan II (Casablanca and Mohammedia), University Autonoma of Madrid, King Saud University, University Mohammed I, University of Technology Czestochowa, University Lodz, University of Kyoto, European Hospital Georges Pompidou, University Nancy 1, Hospital Virgen Camino, Medical Center Erasmus, University Valencia, University Rouen, CHU Limoges, University Liege, CHU of Tours, University Sidi Mohammed Ben Abdellah, University Paris 7.

While Autonoma University in Spain appeared to be a collaborative institution to the UM5 without any agreement, we found that the university had signed several agreements with other Spanish institutions but with no scientific output, such as: University Laguna, Universi
Holding, university Murcia, university Las Islas Baléares and University Cadiz. It is one of the illustrative cases of discrepancy between agreements and co-publications.

</tbody>
</table>

* Ibn Sina Hosp institutions
** including ENSEIRB, Univ Michel de Montaigne and univ Montesquieu
The same case holds for some French institutions. Indeed, while no agreement was signed with University Paris 7 despite many co-publications, we found that several agreements were set with institutions in Paris such as: University Paris 13, University Paris Dauphine, University Paris René Descartes, Institute for Languages and Civilizations.

**Impact of co-publications**

This part of the method is mainly based on science mapping which has been proven to be a useful tool in assessment.

1. **Impact of co-publications**

Collaboration with high-productivity partners tends to increase impact as proved by Katz and Hicks (1997) who found that while collaborating with an author from the home or domestic institution increases the average impact by approximately 0.75 citations, collaborating with an author from a foreign institution increases the impact by about 1.6 citations. Likewise, Abramo et al. (2011b) confirmed that more productive scientists and those with high impact collaborate more abroad than their colleagues (They warned, however, that the reverse was not always true). In this regard, we provide in Table 2 the impact indicator for institutions of the two classes in order to ascertain those with higher impact than that of UM5S. Table 2 shows that almost all of the collaborative institutions were more knowledge productive (not normalized to university size). Despite its slightly lower impact rate, but closer to that of UM5S, Ibn Tofail University is one of the small-size but performed universities in Morocco (Bouabid, 2014).

Three institutions were excluded for having a number of publications below the threshold of 100 publications during the same period: National Institute of Health (Class 1), Hospital Cheikh Zaid (Class 1) and Hospital Virgen Camino (Class 2). Two other institutions were excluded for having lower impact than that of UM5S (shown in grey in Table 2).

At the end of this stage of the method's stream, the two classes comprise the following:

- **Class 1**: University University Mohammed V-Agdal, University Ibn Tofail, CNRS-France, University Zaragoza, University Bordeaux, Université de Montréal, Université Laval, University Cadi Ayyad. The scientific collaboration with this class should be strengthened since there is correlation between co-publication practices and collaboration agreements;

- **Class 2**: University Hassan II (Casablanca and Mohammedia), University Autonoma of Madrid, King Saud University, University Mohammed I, University of Technology Czestochowa, University Lodz, University of Kyoto, European Hospital Georges Pompidou, University Nancy 1, Medical Center Erasmus, University Valencia, University
Rouen, University Liege, CHU of Tours, University Sidi Mohammed Ben Abdellah, University Paris 7. The scientific collaboration for this class is distorted and unbalanced and the university should consider setting up a formal framework for collaboration for its researchers to enhance their research activities.

</table>

*p*: is the number of publications during the period from January 1st 2010 to June 30th 2013.

**c**: is the number of citations gained by the publications *p* in the time window: January 1st 2010 to December 31st 2014.

-- : means that the number of publications is below the threshold
As a policy implication, for the Class 2 institutions a 'bottom-up' approach is required to identify university researchers involved who would contribute to setting up formal scientific collaboration with these institutions. In fact, the scientific collaborations were found to be mostly based on individual initiative as was reported by Bordons et al. (2013) rather than a result of policy action. Melin (2000) suggested that scientists themselves should choose with whom they would like to cooperate, and under which forms.

2. Multidisciplinarity in co-publications

To assess proximity to collaborative institutions and the multidisciplinarity in collaboration of UM5S, as a key component of the method clusters are drawn in a heterogeneous map crossing both collaborating institutions and scientific fields for the university in terms of co-publications (Figure 2). Despite its relative complexity, this kind of map provides a complete visualization and is of greater value by combining both institutions and fields. For the first point, higher proximity - e.g. closeness - is shown to be more prevalent with specialized institutions in Rabat such as Children’s Hospital (Hôpital des enfants), Ibn Sina University Hospital, Mohammed V Military Hospital and National Institute of Health, as well as with Ibn Tofail University (35 kilometers north of Rabat). For the second point, Figure 2 pictures a multidisciplinary collaboration with very limited institutions: Ibn Tofail University (Class 1) and Georges Pompidou European Hospital (Class 2) as identified by the overlap of more than two different circles - sub-clusters (marked with arrows in Fig. 2). Policy collaboration focus should be on these institutions as multidisciplinary collaborative ones.

3. Research Fronts/advanced knowledge in co-publications

In addition to the classification presented above, a qualitative indicator is employed to check the relevance of considering these classes in the university collaboration policy. The objective is to ensure that the topics addressed in the research collaboration with these institutions are in 'Research Fronts' as defined by Thomson Reuters in its Science Watch©. This part of analysis is not presented in this paper. However, it was found that the topics addressed in the scientific collaboration were generally in the Research Fronts such as: genetics, genomes and gene expression, tissue engineering, immunology, aging, thin films, remote sensing, neurosciences, polymer, etc.
Finally, considering the overall knowledge production stream, the results showed that some institutions from emerging countries such as China, India, Brazil and Turkey are likely to be potential collaborative partners for the university since they have been citing its papers (Table 3) and with respect to their fast-growing knowledge production. These institutions are grouped into a third class as potential partners. Surprisingly, no co-publication or agreement were found with any of these institutions. Only institutions having more than five citations each (as a threshold) to UM5S' publications are considered as citing institution from these countries.

Setting this threshold, all Turkish and Indian institutions were excluded. After this filter, the UM5S's potential partners are listed in Table 4. Neither publications nor citations of the Chinese Academy of Science is reported, because it is more a funding and policy-making body than a research institution, even if its output is almost 120,940 publications during the period of study. Similar to the institutions of classes 1 and 2, all the institutions of class 3 were found to have a higher impact on the scientific community worldwide (between almost 4 and 6 citations per publication) compared to that of the UM5S (1.82).

4. Conclusion

A method is suggested for assessing a university scientific collaboration policy. Starting from data on agreements, co-publications, *Research Fronts* and citations, scientometric indicators were built along with science mapping in a comprehensive and organized method to inform about the coherence between co-publications as research collaboration outputs and collaboration agreements as a 'legal' frame input. The method stands to provide valuable inputs for policy assessment and design by identifying three distinctive institution classes for collaboration. The first class comprises institutions for which there were both co-publications and collaboration agreements; the university has to intensify its collaboration with this class. The second class comprises institutions with significant co-publications and higher impact but no collaboration agreement; the university should consider setting up a formal 'bottom-up' frame of collaboration to better enhance existing individual collaborating activities. The third class comprises institutions highly citing university knowledge and having higher impact, thus providing potential collaborative partners.

Abstract
This paper takes the TOP100 literatures with the highest Altmetrics Scores in the Altmetric.com in 2016 as samples. Taking the advantage of SPSS19.0, the correlation analysis between Altmetrics score and citation counting was presented, and the Pearson correlation coefficient is 0.036, which means that the Altmetrics score does not correlate with the citation counting and the Altmetrics indicator maybe independent variable to assess the literature impact. Meanwhile, the multiple linear regression analysis was conducted, which the Altmetric scores was viewed as dependent variable and some component indicators as independent ones. The fitness between the independent variable and the dependent variable is very good, and the significance test of the variable coefficient is also verified.

Conference Topic
Altmetrics

Introduction
With the development of open access movement and social media, the impaction of scientific achievements is not only reflected in academic fields, but in social ones. Academic impacts reflect the academic status of researchers and the academic values in their discipline, and in some extents, social impacts are the cognitions perceived and understood by the ordinary people outside the academic peers and communities (Zhao Rongying et al, 2016). At present, more and more experts, scholars and non-academic communities began to exchange academic achievements through social media, and Altmetrics, reflecting the social impact in some extents, is born in such context. Altmetrics is an evaluation method based on social network, measuring the mentioned degrees by social media, to reflect the impaction of scientific achievements in a comprehensive and immediate way(Piwowar, 2013). Priem(2012) further noted that Altmetrics will be an important tool in next generation to measure the impaction of academic achievement.

In recent years, relying on its direct and rapid responding feedback mechanism, Altmetrics has been playing a more and more important role in the scientific evaluation of academic achievements. Many publishers and databases, such as Nature, Science, Elsevier, Wiley-Blackwell, NPG, and Springer, have begun to vigorously promote Altmetrics indicators to measure the concerning or concerned degrees for their published papers and works, meanwhile a large number of measuring tools have been developed to solve data collection and their computation, such as the typical
Altmetrics score for their recorded papers in Altmetrics.com.

For a long time, the citation counting was an important indicator for academic evaluation in science of science, which has been widely concerned by the author, the scientific management bureau and the relevant stakeholders. So what is the relationship between the Altmetrics indicators and citation counting? Many scholars have carried out a lot of related works. Thewall et al(2013) have found that there are strong relationship between citation counting and six Altmetrics indicators, including Twitter, and cited data from WoS (excluding the self-cited), but the relationship between the citation counting and the Google+ is very weak, and the other four Altmetrics indicators are very low. Wang et al(2016) pointed out that the correlation between PDF downloading index and citation counting is very strong, but the correlation between Altmetric score and citation counting is very weak, which is obviously lower than the Mendeley. Cabezas-Clavijo et al(2010) have been utilized 8945 articles in PLOS to verify the relationship between Scopus citation counting and scientific blog linkage numbers and tweets, which results are positive one between Scopus citation counting and scientific blog links and tweets. Eysenbanch(2011) selected 55 highly cited papers in JMIR and then found that 75% of selected papers were recommended by Altmetrics tools. LiXuemei et al.(2012) used 1613 articles published in Nature and Science in 2007 to validate the relationship between cited indicators (WoS and Google references) and the readers numbers in document management tools (Mendeley and CiteULike), and the conclusion showed that academic references have a strong correlation with readers numbers in Mendeley and CiteULike, where the correlation coefficient between WoS references and Mendeley readers is 0.55, and the one between Google Scholar references and readers numbers in Mendeley is 0.6. Torres et al.(2013) also found that there was a strong correlation between citation counting and reader number in document management tool.

As the above have showed, there are more and more studies to explore the correlation between the Altmetrics indicators and citation indicators, but these studies are focused on the relation between the citation number and single Altmetric indicator, and few studies focused on the correlation between citation counting and aggregate variable, such as Altmetric score. This paper attempts to identify the relationship between them, and to analyze the contribution of every indicator to the Altmetrics score at the same time.

Data and Methods

Data collection

In order to identify the relationship between Altmetric score and citation counting, the 100 Top academic papers (following called TOP100) in Altmetrics.com, ranked by the Altmetric score, were selected, and some related data, such as the data about Twitter, Blog, Facebook, Google+, were downloaded on January in 2017. Meanwhile, the corresponding citation data are retrieved from Web of Science.
Research methods

The linear trend was showed in the scattering plot between Altmetric score and citation counting, so the Pearson correlation analysis was utilised to address the relationship. As we know, the Pearson correlation is used to describe the degree of linear correlation between the variables, and its correlation coefficient is in the range between -1 and +1. The greater the correlation coefficient is, the stronger the correlation between variables. In fact, if the value is more than 0.8, the two variables can be viewed as equivalent or alternative ones.

In order to analyze the contribution of every indicator to the Altmetrics score, Altmetrics score of the TOP100 samples were regarded as the dependent variable, and the other indicators, such as Twitter, Blog, Facebook, Google+ score, were viewed as independent variables. Multiple linear regressions is a excellent method to explore the relationship between the multiple explanatory variables (independent variables) and the explained variable (dependent variable). So the Multiple linear regression was used to measure the contribution of every elements to the Altmetrics score.

Results

Correlation between Altmetrics Indicators and Citation Counting

The related data of TOP10 articles in the TOP100 sample were listed in table 1. From the table, we can see that Altmetrics score ranking has a certain difference to the WOS citation frequency. In the TOP10 articles, the highest-cited literature has been cited 128 times, but Altmetrics score was ranked in 6th; the first ranking literature in Altmetrics score is 8152, but its citation number only is 15. So we can see that non-highly cited literature may also have a relatively high Altmetrics scores and high Altmetrics scoring documents may not be highly cited. Focusing on the publication time, most of the high Altmetrics score literatures were published in 2016, so the less citation can be interpreted easily. In contrast to the papers published earlier, later papers in publishing time, if they focused on academic fronts, may get more attention immediately and have higher Altmetrics score in a minute. But citation indicators is the opposite, generally the citation is taken place after publishing one year or more. So the Altmetrics indicators have very fast responses and feedbacks on the latest hot results, which is just another way to solve the time-delayed problem in traditional citation indicator and impact factor (IF), and readers can grasp the latest front and hot researched in time (Li et al, 2016).

Table 2 is the result of the correlation between Altmetric scores and citation numbers. The Pearson correlation coefficient is 0.036, and the two-tailed significant value Sig. (2-tailed) is 0.732. According to the theory of correlation analysis, the coefficient between the two variables is very weak, in some extents it can be considered there is no correlation between them, namely the two variables are dependent one. Thus, it can be considered to some extent that the Altmetrics score and the citation counting are not substitutive, but complementary and mutually relationship. The scores from Altmetric.com only reflect the quality and quantity of online attention to the papers, rather than reflect the quality of scientific research (Curry, 2014). Traditional indicators just offset the deficiency of Altmetrics ones, and Altmetrics indicators also compensates the shortcomings of traditional ones, which can’t highlight the social attentions.

**Contribution of the components Indicators in Altmetrics Scores**

Altmetric.com has collected all of the online awareness data of papers from social networks (such as Twitter, Blog, Facebook, and Google+), document management systems (such as Medenley, CiteULike, and F1000), mainstream media (News Outlets) as well as multimedia (YouTube), and created a new comprehensive indicator, Altmetric score, which took the values to represent the social impact of the literature (Wang et al., 2014). Table 3 has showed their data for some components of the Altmetrics score (only the first 10 articles are listed). First, the data distributions are not balance, namely that the values of some components are relatively larger, and others are smaller. To the Altmetrics score, the greater the value of components, the more important it is, so they have played an important role in the comprehensive index. The News Outlets, the mentioned times of Twitter and Facebook, and the number of Mendeley readers have played important roles to reflect the social impact.

In order to reflect the distribution of each component or variable, the average value of each variable are calculated and ranked. Table 4 has showed the calculated average value of Altmetrics score and the component indicators. From the point of view of magnitude, Tweeters, Mendeley readers, and News Outlets are the first group, Facebook users, Blogs, and Google+ users are the second one, and the remained are the third one.

### Table 4 the distribution of the average score of the indicators

<table>
<thead>

<th>average</th>
<th>No.</th>
<th>indicator</th>
<th>average</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>score</td>
<td>2305.40</td>
<td>7</td>
<td>Google+ users</td>
<td>19.15</td>
<td>13</td>
<td>Q&amp;A thread</td>
<td>0.24</td>
</tr>
</tbody>
</table>
From the statistics can be found, Altmetric.com's TOP100 papers were mostly published in 2016. Altmetrics scores are ranging from 1619 to 8152, and average total score is 2305.40. From the average value of each indicator, social networking Twitter has made the greatest contribution, with an average of 942.49 tweeters mentioned or forwarded. The second is document management system Mendeley, which is saved and shared by 261.67 Mendeley users. The third is news outlets, which average number of individual papers reported by the media was 183.91 times. Facebook and blogs are also the main data source for Altmetric.com, and the average of each paper was 48.42 and 21.02 users discussed and mentioned. The data sources, such as book reviewers, policy source, peer review, Q&A thread, and research highlight platform are less.

To further illustrate the impact of each indicator on the Altmetrics score, multiple linear regression analysis was conducted, which the Altmetric scores was viewed as dependent variable and some component indicators as independent ones. Table 5 and Table 6 show the main results.

<table>
<thead>
<tr>
<th>Model</th>
<th>R</th>
<th>R Square</th>
<th>Adjusted R Square</th>
<th>Std. Error of the Estimate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>.994</td>
<td>.987</td>
<td>.986</td>
<td>104.533</td>
</tr>
</tbody>
</table>

As can be seen in the results of goodness-of-fit test in Table 5, the Adjusted R Square is 0.986 and very close to 1, which means that the fitness between the independent variable and the dependent variable is very good. More than 98% of the dependent varieties can be explained by the independent variable, and the error caused by random factors is less than 2%. Based on these data, a conclusion can be drawn that the selected independent variable is more complete and the established regression
equation model is valid in a whole.

What does each independent variable devote to the dependent variable? The regression coefficient of each independent variable in Table 6 can give us the answers, which shows the change ratio of dependent variable caused by the unit variety of independent variables. Before examining the specific effects, we must first confirm the validity of variable coefficients. Except the two variables of Twitter and Facebook, which significant levels are slightly greater than 0.05, the significant level of other variables is far less than 0.05. So the coefficient validity of all the variables can be convinced. Two other test indexes, collinearity tolerance and statistical VIF, make us believe the mutual independence of all the interpreting variables.

<td>.437</td>
<td>.054</td>
</tr>
</tbody>
</table>

a. Dependent Variable: score

The coefficients of all the independent variables are positive, and the variable coefficient of News is the largest one, indicating that it has the most obvious impact on the Altmetric score, which implies that once an article is mentioned by the mainstream news media, the Altmetric score correspondingly increased 8.025. The following variable is Blogs, which coefficient is 6.775, and the third one is Google+, which coefficient is 1.586. The impaction of other independent variables is relatively less.

Contrasting with the data of Table 4, we can found some interesting phenomena. Although the data provided by Twitter, Facebook, Mendeley etc. network tools is larger, the contribution rate to Altmetric scores is not significant in terms of single data impact, especially Mendeley, whose unit contribution is only 0.056. Thus, when the comprehensive metrics indicator, Altmetric scores, was created by Altmetric.com, the mainstream media and social networks have been given more higher weighty, and the document management systems relatively lower.

According to Table 6, we can get the multiple linear regression equation to Altmetrics total score:
\[ Y = -65.495 + 0.723 X_1 + 0.056 X_2 + 8.025 X_3 + 0.545 X_4 + 6.775 X_5 + 1.586 X_6 \]

Among them, \( Y \) stands for Altmetrics score, -65.495 for constant, \( X_1 \) for twitter, \( X_2 \) for Mendeley, \( X_3 \) for news, \( X_4 \) for facebook, \( X_5 \) for blogs, and \( X_6 \) for Google+. If the values of all independent variables are given, the Altmetrics score can be computed and the error can be predicted.

**Conclusions and Discussion**

Altmetrics indicators mainly focus on the readers’ number of academic literatures, as well as their interaction behavior, such as recommendation and comments, through online social media and their depth of social communication in traditional media to measure their social influences and social concerns, but less on involving academic influences related to the quality of articles. While the traditional citation indicators directly measure the academic influences through citation counting, which directly reflect the academic value and influences of scientific researches, but it cannot reflect the social influences. In our studies, the correlation between Altmetrics scores and citation counting give us good example. In terms of the literature evaluation, Altmetrics is only a complementary indicator rather than alternative in essence, so it is inevitable for us to combine the traditional indicators and Altmetrics indicators to measure the complete impact of articles from different perspectives in the web2.0 era. How to combine traditional indicators and Altmetrics indicators is a great problem to further study.

In the sample literatures, a large number of comprehensive Altmetrics indicators were constructed to reflect the social influence. However, these indicators are not as efficient as traditional indicators. The main reason is that these indicators are strongly dependent on using frequency of social software tools. Because some social tools are not popular for common users, the responding indicator value is very low and it is difficult to make a substantial contribution to the evaluation. In our researches, some tools, such as book reviewers, policy sources, peer review, Q&A thread and research highlight platform, provides only a small amount of data. How to choose reasonable Altmetrics indicator will be an important issue in the future studies.

It is important for us to note that Altmetrics has some limitations to evaluate social impaction. Firstly, it can only count Altmetrics data produced online, and cannot collect the data offline, such as the data in some printed media. Secondly, many Altmetrics tools are created around 2010, and the accumulative data is limited relatively to the traditional citation data. Finally, due to its geographical limitations, Altmetrics tools selected are used mainly in Europe and the United States, and less in non-English-speaking countries, so the collecting data are mainly concentrated in the Anglo-American countries. How to introduce the social tools of non-English-speaking countries to enrich the Altmetrics index is another problem to be solved.

On the one hand, new indicators and tools are needed to create to meet the diversification and the digitalization of scientific making and publishing. On the other
hand, it is possible for us to get online scientific communication and their evaluation data quickly and gives us more opportunities to create new evaluation indicators to improve the evaluation system of science and technology. Altmetrics is a very good example and its application has become an international trend to evaluate the social impact for academic literatures. It is also very likely that it will become an important criterion to assess the quality of scientific journals, papers and institutions. How to perfect the classification of Altmetrics indicators and how to construct a reasonable, effective and comprehensive evaluation system of literature impact still need more detailed and in-depth studies in large sample context in the future.

Analyzing the efficiency of research grants: a case study of grants issued by the National Natural Science Foundation of China

Hui Fang

fanghui@nju.edu.cn

State Key Laboratory of Analytical Chemistry for Life Science, School of Electronic Science and Engineering, Nanjing University, Nanjing 210023, (China)

Introduction

One bibliometric topic in relation to grants is whether grant decisions are correct and fair. Nepotism has been found in the grant peer review system (Wennergås & Wold, 1997). Bornmann et al. (2008) found overestimation of approvals and underestimation of rejections in grant decisions. It is disputed to use applicant performance after receipt of grants to assess the correctness of grant decisions, because access to more abundant resources can explain why successful grant applicants on average produce more output than unsuccessful applicants (Melin & Danell, 2006). It is reasonable to compare researcher performance under identical funding conditions. Comparisons of PI performance should consider differences in grant size in financial terms. Measuring grant performance relative to grant size can help to identify researchers who use funds efficiently. It allows us to further investigate the distribution of fund utilization efficiency, and help to efficiently promote research development.

The grant efficiency of institutions and areas has been analysed by dividing their academic output by total financial input for a given year (e.g., Basu, 2014). However, this method ignores the delay in the transformation of inputs into outputs. In contrast, analysing funding efficiency based on inputs and outputs of individual grants can avoid errors arising from associating research outputs with inputs that did not support them.

Evaluating individual grants’ efficiency based on the articles they supported should also consider that many articles are supported by multiple grants. Each grant acknowledged in such an article only contributed partial financial support to it. In fact, the priorities of different funding bodies may overlap. Further, some authors took more money than they need, a practice known as double-dipping (Rigby & Julian, 2014).

This study evaluates grant efficiency arising from National Natural Science Foundation of China (NSFC) and exams grants’ efficiency changing with grant size. The NSFC supports basic research. We take the fact that articles may be supported by multiple grants into account, and avoid the delay in the transformation of inputs into outputs.

Data

On its website, the NSFC publishes detailed information on its grants. We chose to use medical sciences grants from the NSFC in this case study, as medical sciences are currently active research areas. Articles supported by the grants investigated can be retrieved from the WoS, which provides funding information on indexed articles published after August 2008.

This investigation was limited to grants starting in 2009, because articles supported by these grants were published after August 2008, and thus can be retrieved in the WoS. Many of these articles were published in the period 2009–2012. Grants that supported articles published after 2012 were removed, because we use a citation time window of at least 2 years in this preliminary study.

Methods

For articles supported by multiple grants, we assigned credit for an article equally to all grants supporting it. For an article supported by $g_{grant}$ grants and obtained $n_c$ citations, each grant is estimated as contributing $n_{ac}$ articles: $n_{ac} = 1/n_{grant}$, and obtaining $n_{cc}$ citations: $n_{cc} = n_c/n_{grant}$. $n_{ac}$ and $n_{cc}$ are defined as article credit and citation credit, respectively, that a given grant obtains from a specific article.

Each grant may support multiple articles. The total article credit of a given grant that support $n_a$ articles can be estimated as:

$$n_{ac} = \frac{1}{\sum_{i=1}^{g_{grant}} n_{grant}(i)}.$$  (1)

Its total citation credit can be evaluated as:

$$n_{cc} = \frac{n_c(i)}{n_{grant}(i)}.$$  (2)

PIs who have received larger grants have a higher probability of realizing larger achievements. So we define the article efficiency of a grant as its total article credit divided by its size $s_c$: $e_{ac} = n_{ac}/s_c$. Its impact efficiency is defined as its total citation credit divided by its size: $e_{cc} = n_{cc}/s_c$.

When evaluating the efficiency of a group of grants, we can integrate each grant’s outputs and size. The article efficiency of a group of $g$ grants can be estimated as:
\[ e_{\text{gps}} = \frac{\sum_{i=1}^{n_p} n_{\text{ts}}(i)}{\sum_{i=1}^{n_p} s(i)} \]  
\[ e'_{\text{gps}} = \sum_{i=1}^{n_p} n_{\text{ts}}(i) / \sum_{i=1}^{n_p} s(i) \]  

Its impact efficiency can be evaluated as:

\[ e'_{\text{gps}} = \sum_{i=1}^{n_p} n_{\text{ts}}(i) / \sum_{i=1}^{n_p} s(i) \]  

Results

We investigated 1,461 NSFC medical sciences grants issued starting in 2009, all of which supported articles published before 2013. This study included 8,988 articles. Individual grant sizes of the grants we investigated ranged from 80,000 to 10,000,000 RMB.

Figure 1 shows that a grant’s average total article credit and total citation credit increases with grant size. Certain grant sizes were uncommon, and associated with only a small number of grants. Grants of these sizes were combined with the closet grant sizes in one category using average size of the grants that were included to ensure that every point in Figure 1 represents at least 40 grants, except for the rightmost point, which represents only 34 grants.

![Figure 1. Change in total article credit ($n_{\text{tw}}$) and total citation credit ($n_{\text{tc}}$) with size of NSFC grant in medical sciences starting in 2009.](image)

Figure 2 shows the change in grant efficiency with grant size. In medical sciences, grants of 100,000 RMB or less have the highest efficiency in terms of both quantity and impact, and grant efficiency decreases with grant size before bottoming out, then rising, and finally stabilizing. The bottoming out occurs at 330,000 RMB. Each point in Figure 2 represents the same grants as the corresponding point in Figure 1.

![Figure 2. Change in grant article efficiency ($e_{\text{gps}}$) and grant impact efficiency ($e'_{\text{gps}}$) with size of NSFC grant in medical sciences starting in 2009.](image)

Discussion

Nowadays, there is an increasing concentration of resources among a smaller number of researchers (Bloch & Sørensen, 2014). It is thought that larger-sized grants, which foster the concentration of research resources partly at the expense of smaller grants, can improve overall scientific performance by funding top researchers. However, analysis shows that the National Science Foundation’s Small Grants for Exploratory Research program was highly successful in supporting research projects that produced transformative results (Wagner & Alexander, 2013). Our investigation shows that on average, small grants have the highest efficiency. It is consistent with the findings by Fortin and Currie (2013).

Figure 2 shows that large grants have higher efficiency than the medium-sized ones. One potential reason is that most PIs received large grants have high academic positions and reputations, which may help their articles be published more readily and obtain more citations.

Abstract
The aim of this study is to map and analyse the dynamic structure and the evolution of topics in business model research during the period of 1993-2016. Co-word analysis and maximum spanning tree analysis were employed to identify the main topics, while clustering analysis and strategic diagrams were applied to identify the research trends. The data set included 4134 articles that were grouped into three different periods: 1993-2005, 2006-2013, and 2014-2016, in order to reveal both how the results changed over time and what were the most recent research trends. The results showed business model literature had a stable diversity over time, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to topics of electronic commerce in the early times, and it was closely related to technology development played as an important driving force especially in recent literature.

Conference Topic
Co-occurrence analysis   Mapping and visualization   Co-word analysis

Introduction
The business model has attracted increasing attention from both academics and practitioners since the 1990s. As a new integrated interpretation of business value creation accompanying the thriving of electronic commerce, business model construct has occupied the core logic of the firms (Linder & Cantrell, 2000). And it continually expands it framework to account for corporate growth and success, as well as influence the whole business picture. The academic field has examined the business model through different lenses and varying aspects. These areas include business economics, computer science, telecommunications, and operation management and so on. Part of this diversity can be attributed to the cognitive difference in the very concept, on which consensus is hard to reach in terms of its definition, nature, structure, and evolution (Morris, Schindehutte, & Allen, 2005). Therefore, a co-word analysis can provide an important unifying effort to identify the main characteristics and focal points of business model research as well as the relationship and structure among business model research topics. It will also help to grasp the directions and trends of this research area in its continual development.

Related Studies

Business model concept.
The business model had long been integral to economic behaviour, but its concept didn’t become prevalent until the increasing popularity of the Internet in the mid-1990s, and it has
been gaining pace since then (Zott, Amit, & Massa, 2011). The earlier definition of business model was “an architecture for the product, service and information flows, including a description of the various business actors and their roles, of the potential benefits for the various business actors, and of the sources of revenues” (Timmers, 1998). Later Amit & Zott(2001) placed more emphasis on the value aspect and referred to the business model as “the design of transaction content, structure, and governance so as to create value through the exploitation of business opportunities”. Morris et al.(2005) went on to identify six fundamental components of business models: value proposition, customer, internal processes/competencies, external positioning, economic model, and personal/investor factors. A more recent definition depicted the business model as “a reflection of the firms realized strategy (Johnson, Christensen, & Kagermann, 2008)”.

These definitions have some common key points, such as the stress of value, including value creation and value capture, and the stress of systematic nature of business model components as a whole. However, there isn’t one generally accepted definition of ‘business model’ (Morris et al., 2005), and this lack of unanimous definitions is somewhat a potential source of confusion, dispersing rather than converging the researches on business models (Zott et al., 2011).

**Business model related research area**

On the whole, the current business model research spreads around two areas: business model ontology and business model design. Business model ontology studies seek to uncover the intrinsic quality of business models and reach a unified logic for them, mostly through case study or literature review. Some simply described the essence of a business model in the logic of value creation, capture, delivery and conversion (Teece, 2010), while some identified several orders of themes and structure the concept into levels of decomposition with increasing complexity and depth (Osterwalder, 2004). Business model design researches seek to achieve growth and generate revenues for a specific type of company or market. These researches cover a wide range of industries including electronic commerce, airline carriers, hospitals, and pharms, Internet of things, banks, scholarly publishing and energy systems and so on, and they deal with nearly all segments inside a company or market, varying from production to logistics, from pricing strategy to financial sustainability, and from technology innovation to corporate social responsibility. Timmers(1998) identified eleven business models of electronic commerce and examined their degree of innovation, among which e-shop was the most innovative while value-chain integrators was the least innovative. In order to replace the prevailing profit-based journal publishing model, Fyffe and Shulenburger(2002) introduced a BioOne business model to meet the interlocking goals of both providing broad and enduring access and supporting the publishing enterprise of scholarly societies. And Tan and Yavuz(2015) presented a new business model design to offer energy saving technologies as a service, it captured energy efficiencies improvements, energy consumption variation, energy prices uncertainty and carbon offsets revenues, thus leading to a win-win situation for business and the environment.

Despite the twenty years’ development and many excellent research papers in business model literature, we found that most studies dealt with a very specific and rather limited research area, and few focused on the whole structure and topic correlations of business model research, nor did they systematically examine the evolution of this literature. This study aims to use co-word analysis to uncover the hidden information of various business model research areas since its existence, including relationships of keywords, research structure and research advances.

**Co-word analysis and maximum spanning tree analysis**

Co-word analysis is an important bibliometric way to reveal the relationships of concepts and ideas within a specific scientific domain. Co-word analysis rests on the assumption that
extracted high-frequency keywords could represent a specific research subject and direction of a field (Callon, Courtial, & Laville, 1991). It also calculates the co-occurrence frequency of each word pair (Yan, Lee, & Lee, 2015b). Higher co-word frequency means stronger correlation in keyword pairs, and a cluster of keywords based on similarity of these keyword pairs can be understood as a short description of a research theme (Hu, Hu, Deng, & Liu, 2013; Huang et al., 2015).

Maximum spanning tree (MST) is an algorithm that can be applied to co-word analysis to generate a network representation of the similarity matrix, which helps to develop intuition about the structure of the specific scientific domain as well as the dynamics of keywords. It was used by Hidalgo, Klinger, Barabási, and Hausmann (2007) to identify industry dynamics in product space and reveal the transformation path of products. This method gives us a quick visual way to show the most relevant links and to determine where the keywords are located and where they could be headed in the network. It also gives us an idea of core-periphery structure of the given network. The basic principal of MST approach is to generate a “skeleton” of the whole network, which contains a sum of weights that is maximal.

While co-word analysis was rarely used in business model domain, we then applied this method together with maximum spanning tree analysis to map the evolution of structure and hot topics and to examine the development tendencies in this research area.

**Research methods**

**Data Collection**

In this study, we chose Science Citation Index Expanded (SCI-Expanded), Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI) of the institute for Scientific Information (ISI) Web of Science as the data source. The data were collected in January 3rd 2017. Data retrieval strategy: the theme is “business model” or “business models”; the publication period is from 1993 to 2016. To make data more accurate, we confined the reference type to “articles” and language “English”. Finally, a total of 4134 records were obtained.

Figure 1 shows the yearly output of business model research. The output distribution has periodical characteristics: there were only 53 records before 1998, and the year of 1999 saw a start of obvious growth, which reaches its peak in 2005. This growth period resulted in 736 records. After a small decrease in 2006, there was an accelerated growth from 2006 to 2013, with a total records of 1991. The records of 2014 were almost the same compared to 2013, and the recent three years have a total records of 1354.

![Figure 1. The output of business model research during 1993-2016](image)
In order to study the evolution of the topics and the recent research trends in the literature, we divided the records into three sub-periods based on the output periodical growth characteristics and the number of target documents published per period. The three sub-periods are 1993-2005, 2006-2013, and 2014-2016. Following Dehdarirad, Villarroya and Barrios(2014), we fixed a longest first sub-period in order to get a representative number of published papers and keywords, and a relatively short last period to reveal recent research fronts. The first period (1993-2005) spans 13 years (and includes 789 records, accounting for about 19% of the total records), the second (2006-2013) and third periods (2014-2016) spans respectively 8 years (1991 records: 48%) and 3 years (1454 records: 33%). Figure 2 shows the output of business model research in each period.

![Figure 2. The output of business model research in three periods](image)

**Data process**

The co-word analysis conducted in this study involved six sequential steps, as shown in Figure 3. They are data extraction, keywords selection, matrices construction, MST analysis, clustering and visualization. Firstly, for each period, keywords were extracted from papers in the specific time span using bibexcel software, and we got 1685 keywords from 789 papers in period 1, with an average 2.13 keywords for each paper; we got 3286 keywords from 1991 papers in period 2, with an average 1.65 keyword for each paper; we got 2754 keywords from 1354 papers in period 3, with an average 2.03 keywords for each paper.

Secondly, for each period, we eliminated invalid keywords and standardized some keywords by combining synonyms to achieve more precise results, E.g. “e-business” and “e-commerce” were replaced by “electronic commerce”; “low cost carrier” and “low cost airlines” were replaced by “low-cost airlines”; “base of the pyramid”, “BOP” and “Bottom-of-the-pyramid” were replaced by “bottom of the pyramid”. Then, g-index method was used to select the high frequency keywords: If it ranks in decreasing order of the number of keywords frequency, the g-index is the (unique) largest number such that the top g keywords receive (together) at least g2 frequency(Yan, Lee, & Lee, 2015a). In our case, the g-index was respectively 14, 28 and 22 for period 1, 2 and 3.

Thirdly, for each period, we obtained a co-occurrence matrix of these high frequency keywords with Bibexcel software. On the basis of the three co-occurrence matrices, we calculated the
similarity index between two words according to the study of Hidalgo et al. (2007) with Excel. The formula is as below:

$$\Phi_{ij} = \min\{P(nR_{ij}|nR_i), P(nR_{ij}|nR_j)\}$$

$\Phi_{ij}$ is the similarities between keyword i and j; $nR_i$ is the frequency of keyword i; $nR_j$ is the frequency of keyword j; $nR_{ij}$ is the co-occurrence frequency of keyword i and j.

---

**Figure 3. Data process flow**

Fourthly, for each period, we performed MST analysis on each similarity matrix in order to get the “skeleton” of the network that shows where the keywords are located and where they could be headed in the network. Instead of using binary values of the matrices, MST analysis takes every similarity value into consideration, thus offering one new and useful angle to look at the pairwise relationships and whole network relationships of these keywords. For the first step, we considered the strongest non-diagonal value of the similarity matrix and then selected the strongest link connected to that dyad. We then picked up the strongest link connecting a new node to our triad and continued adding links until all the nodes on the network were included (Hidalgo et al., 2007). The above process was completed using Java, and Netdraw software was then applied to show the three MST networks.

Fifthly, for each period, we conducted clustering analysis to classify keywords into different groups. Clustering analysis is an exploratory tool to group relatively homogenous observations or cases. Each cluster thus describes the class to which its members belong with the application
of different techniques (Yan et al., 2015b). There are a variety of methods for clustering analysis, such as hierarchical clustering, Girvan-Newman clustering (Girvan & Newman, 2002), density-based clustering (Sander, Ester, Kriegel, & Xu, 1998) and so on. We used combinatorial optimization clustering in Ucinet software to classify the keywords in each of the three period. Combinatorial optimization is about finding an optimal object from a finite set of objects. It deals with problems where exhaustive search is not feasible and the set of feasible solutions is discrete (Du & Pardalos, 2013).

Finally, for each period, strategic diagrams were drawn in order to identify and visualize the status and evolution trends of clusters in business model research. A strategic diagram is a two-dimensional space with abscissa axis represents the centrality and the ordinate axis represents the density (Dehdarirad et al., 2014). Centrality is used to measure the correlation degree among different clusters, while density is to measure cohesiveness within one specific cluster (Hu et al., 2013). In strategic diagram, the origin is the median of these two axis, and there are four different quadrants accordingly. Research topics in quadrant I are considered to be well-developed with relatively high centrality and density, while in quadrant II, they only have well-developed internal ties but unimportant external ties, which indicates they are specialized and peripheral in nature. In quadrant III, research topics have both weak centrality and weak density, these topics are considered as either emerging or disappearing, and in quadrant IV, and research topics have high centrality but low density, indicating they are general or basic topics in literature (Dehdarirad et al., 2014). In our study, the density and centrality were first calculated using Ucinet software, and the strategic diagram was then displayed using Excel.

Results and discussion

Research direction distribution analysis

In Table 1, the top 10 research directions in business model area during each of the three period are presented. For all the three periods, Business & Economics, Engineering and Computer Science always occupies the first three places in the rankings, while in period 1 Computer Science instead of Business & Economics was the most popular research direction. This indicated business model research is the most productive in these three directions and greatly related with them as well. However, Health Care Sciences & Services and Communication in period 1 fell out of top 10 during period 2 and 3, while Environmental Sciences & Ecology and Energy & Fuels were emerging and gaining pace in the last two periods. The rest six research directions remained in the top 10 rankings throughout the three periods, which suggested that business model research spread across broad yet stable research directions in literature during these years.

Frequency analysis

The results of the frequency analysis in the three periods are shown in Table 2. In period 1, “Electronic commerce” and “Internet”, the thriving of which invited increasing attention to business model research, were among the highest frequency keywords. “Electronic markets”, “Pricing” and “Security”, which were related to E-commerce studies (Yan et al., 2015a), were also high-frequency keywords in business model research. “Low-cost airlines” was another business model that received attention besides electronic commerce in period 1.

In period 2, “Electronic commerce” and “Internet” were still very hot topics in the literature. However, there saw the emerging of three new keywords that were never seen in business model research in period 1: “Cloud computing” and “Web 2.0” reflected the development and application of technology, and “Open innovation” was a new way of thinking in business model innovations. Moreover, keywords such as “Sustainability”, “Strategy”, “Entrepreneurship”, “Intellectual property” and “Regulation” received much more attention in period 2 compared to period 1.

In period 3, the most recent trends showed “Electronic commerce”, with a rank of 19 in frequency, was not that popular anymore, and “Internet” even fell out of the high-frequency keywords. Their places were replaced by “Sustainability” and “Business model innovation”. New emerging keywords in period 3 were “Big data” and “Internet of things”, reflecting the further development of technology. Besides, two of the three emerging keywords in period 2 still maintained high frequency in period 3, namely “Cloud computing” and “Open innovation”. Keywords like “Servitization” “China”, “Electric vehicles” and “Renewable energy” received much more attention in period 3 compared to the other two periods.

</table>
Throughout the three periods, “Electronic commerce”, “Innovation”, “Case study” and “Value creation” were always high-frequency keywords. The other three keywords had a relative stable rank in frequency except “Electronic commerce”, which as noted before experienced dramatic frequency decline in period 3. It indicated that business model research had a broad and diverse topics and it has close relation with technology development.

Correlation matrix
Based on the co-occurrence matrix calculated through Bibexcell, we used conditional probability method according to Hidalgo et al. (2007) to measure similarity between two keywords. Two keywords are more related if the pairwise similarity index is higher. Similarity matrix is not presented here for limited space.

MST analysis
After obtaining the similarity matrices, we performed MST algorithm using Java on each matrix and visualized the results using Netdraw software, as shown in Figure 4, 5 and 6. The nodes represented keywords and the links represented similarity between these keywords. The width of links within each figure was determined by the relative value of similarity between the two nodes, and two keywords that are more related have a wider line. MST analysis, which contains a sum of similarities that is maximal, offered one new and useful angle to look at the pairwise relationships and whole network relationships of these keywords in three periods. Firstly, “Business model” varied in network positions within the literature throughout the three periods. In period 1, it was related closely with “Electronic commerce”, which was one important driving element to speed up business model research during 1993-2005; but in period 2, “Business model” was more closely related to “Innovation” in the MST network, and this relationship continued in period 3, while “Business model” was closely connected with “Sustainability”, “Value creation”, and “Entrepreneurship” as well. It indicated more direct aspects of business model had been studied and rooted in the literature since its emergence with ecommerce.

Secondly, for the newly emerging keywords in period 2 and 3, their paths to enter the literature could be revealed. In Figure 2, “Cloud computing” and “Web 2.0” were respectively closely connected with “Services” and “Collaboration”, while “Open innovation” was highly related to “Intellectual property”; In period 3, “Big data” and “Internet of things” appeared to connect closely with each other, while “Big data” was also deeply related to “Cloud computing”.

Thirdly, in the MST networks, keywords with more links with other keywords were more popular or more deeply rooted in the literature during each period (Hidalgo et al., 2007). In our analysis, one salient keyword in the literature needed to satisfy two conditions: 1. it had more than 2 links with other keywords; 2. it ranked above (or equaled) middle-place in frequency of keywords of each period. So in period 1 the salient keywords were “Electronic commerce”, “Electronic markets” and “Supply chain management”, and in period 2, the salient keywords were “Internet”, “Strategy” and “Innovation”. Salient keywords in the most recent period appeared to be more diverse, they were “Business model”, “value creation”, “open innovation”, “Entrepreneurship” and “China”.

Finally, a keyword located in the periphery of the MST network with the weakest link was loosely connected to the literature, which indicated its less importance in the existing literature compared to others. “Low-cost airline” in period 1, “Supply chain management” in period 2 and “Bottom of pyramid” in period 3 were such keywords. As “Supply chain management” was a salient keywords in period 1, it experienced a dramatic popularity decline in period 2.
Figure 4. MST of keywords in period 1(1993-2005)

Figure 5. MST of keywords in period 2(2006-2013)

Figure 6. MST of keywords in period 3(2014-2016)
Combinatorial optimization clustering was performed to group the keywords in each of the three periods into different groups with Ucinet software, and the results are shown in table 3-5. In order to achieve deeper understanding of each cluster, we calculated the total word frequency and average frequency as well (also in table 3-5). Keywords in each cluster can reflect the corresponding research directions, and keywords with more frequencies attracted more attentions (Hu et al., 2013).

In period 1, the keywords were divided into three clusters with a fit value of 0.399 and r-square value of 0.361. In table 3, Cluster 1-1 was highly related to electronic commerce, Cluster 1-2 was more about supply chain management, and Cluster 1-3, which included research topics as “Electronic markets”, had some overlaps with Cluster 1-1, but discussed more about management issues such as “Knowledge management”, “Pricing” and “Security” as well. Overall, Cluster 1-1 had a much higher average frequency than Cluster 1-2 and Cluster 1-3, so in period 1, business model research had devoted its greatest attention to electronic commerce (Zott et al., 2011).

In period 2, the keywords were divided into six clusters with a fit value of 0.373 and r-square value of 0.394. In table 4, Cluster 2-1, with an average frequency of 73.33, was the most popular cluster in period 2, and it included two salient topics discussed in MST analysis: “Innovation” and “Strategy”. Cluster 2-2 and Cluster 2-5, with relatively lower average frequencies compared to the other four, were respectively represented by “Web 2.0” and “Cloud computing”, which as discussed before were two new developments in the literature driven by technology advances in period 2. Cluster 2-3 was related to internet and business model innovation, and Cluster 2-4 was about electronic commerce. Cluster 2-6 focused on strategy as it includes topics as “Case study”, “Business strategy” and “Value chain”. So for business model research in period 2, while it still emphasized on electronic commerce, strategy and innovation related topics received increasing attention and web 2.0 and cloud computing related topics were newly emerging.

In period 3, the keywords were divided into five clusters with a fit value of 0.431 and r-square value of 0.324. In table 5, Cluster 3-1 attracted the most attention from recent literature with an average frequency of 36.33, and its representative keywords were “Sustainability” and “Innovation”. Cluster 3-2 had the lowest average frequency of 15.00, but it included the newly emerging topics in period 3: “Big data” and “Internet of things”; this cluster indicated the technology development trends in recent business model literature. Cluster 3-3 and Cluster 3-4 were respectively about entrepreneurship and business model innovation, and Cluster 3-5 included some other topics besides the above such as the emerging market of China and the declining topic of electronic commerce. So for the most trends in business model research of period 3, while innovation and technology development was still an important part, entrepreneurship related topics attracted more attention and topics tend to becoming more diverse.

In each of the three periods of business model research, there were some overlaps between clusters, which increased the difficulty to define its subfields in this already diverse literature. However it was also this interlink that made this literature integrated and drive the literature move forward.

**Visualization**

The centrality and density calculated for each cluster in three periods were shown in table 4, 5 and 6, and the strategic diagrams on this basis were shown respectively in figure 7, 8 and 9. In each diagram, the clusters were represented by spheres of different size, which were proportional to the number of keywords in each cluster. From the strategic diagrams, the position and evolution of clusters, as well as the trends of current research can be revealed.

In period 1, as shown in figure 7, quadrant I includes cluster 1-1, indicating that electronic commerce related topics were well-developed in period 1. And it could be considered the core trend of this period. Cluster 1-3 fell into quadrant with relative high density but low centrality, indicating that these topics were rather specialized and located peripherally in period 1. Cluster 1-2 in quadrant III had both low centrality and density, and it was regarded as either emerging or disappearing topics in period 1.

In period 2, as shown in figure 8, quadrant I includes cluster 2-1, cluster 2-2 and cluster 2-3. Cluster 2-1, which includes two salient keywords of “Innovation” and “Strategy” and have highest average frequency as discussed before, was very well-developed, and could be viewed as the core trend of this period as its centrality ranked top to indicate its wide connection to other clusters. Cluster 2-2, although had low average frequency, had a relative high density and centrality, indicating its deep root in the literature with its emphasis on technology and networks. Cluster 3-3 with the salient keyword “Internet” in period 2, also had close internal connections and wide external connections in the literature. In quadrant II, Cluster 2-5 as represented by “Cloud computing” seemed rather specialized and was still in the periphery of the literature in
this period. Cluster 2-4 and Cluster 2-6 were in quadrant III, as discussed before, electronic commerce related topics were slowly losing its popularity since period 2, while other topics were still emerging.

In period 3, as shown in figure 9, Cluster 3-1 with the highest centrality and Cluster 3-2 with the highest density were both in quadrant I, indicating they were well-developed. As Cluster 3-1, represented by “Sustainability” and “Innovation”, had the most external connections and Cluster 3-2, representative of recent technology developments, had the most internal connections, they could be core trends of this period together. Cluster 3-4 was in quadrant I as well, but close to quadrant IV, and Cluster 3-3 and Cluster3-5 were in quadrant III, indicating they were either emerging or disappearing in period 3.

Figure 7. Strategic diagram for period 1(1993-2005)

Figure 8. Strategic diagram for period 2(2006-2013)

Figure 9. Strategic diagram for period 3(2014-2016)
Conclusion

In this study, we conducted co-word analysis together with maximum spanning tree analysis (Hidalgo et al., 2007) to describe the evolution and current state of the business model research by dividing the literature into three sub-periods (i.e., 1993-2005, 2006-2013, 2014-2016). Through using the tools of bibexcel, Java and Ucinet, we obtain some clear analysis results of business model research.

1) In terms of evolution of the number of documents, the results revealed that about one third of the total body of literature was published in the recent three years, suggesting the current rich interest of researchers on business model research. Moreover, business model research spread across broad yet stable research directions throughout the three periods, indicating the stable diversity of this area.

2) Frequency analysis reveals the evolution of hot topics in the literature. Throughout the three periods, “Electronic commerce”, “Innovation”, “Case study” and “Value creation” always maintained hot-topic status, although “Electronic commerce” started to experienced dramatic frequency decline since period 2. In terms of research methods, case study was obviously important and frequently used in this literature. Period 2 had new emerging topics of “Open innovation”, “Cloud computing” and “Web 2.0”, while period 3 had “Big data” and “Internet of things”.

3) MST analysis reveals the evolution of pairwise relationships between high frequency keywords. As “business model” was connected most closely to keywords from “Electronic commerce” to “Innovation”, and finally to a keyword group of “Sustainability”, “Entrepreneurship” and so on, the literature has had more direct aspects of business model studied and rooted over time since its emergence accompanying electronic commerce. Period 1 had salient topics of “Electronic commerce”, “Electronic markets” and “Supply chain management”, and period 2 had “Internet”, “Strategy” and “Innovation”, while salient topics more recently appeared to be more diverse, they were “Business model”, “value creation”, “open innovation”, “Entrepreneurship” and “China”. By contrast, “Low-cost airline” in period 1, “Supply chain management” in period 2 and “Bottom of pyramid” in period 3 were loosely connected to the body and in the periphery of literature in each period.

4) Cluster analysis and visualization analysis using strategic diagram reveals the evolution of topic clusters in business model research over time. Keywords in period 1 could be divided into 3 clusters and the core trend was cluster 1-1 represented by “Electronic commerce”; keywords in period 2 could be divided into 6 clusters and the core trend was cluster 2-1 represented by “Innovation”, “Sustainability” and “Strategy”; keywords in period 3 could be divided into 5 clusters and the core trends were cluster 3-1 represented by “Innovation” and “Sustainability” and cluster 3-2 representing technology development in business model research. For the main body of business model literature, it showed that business model first attracted research attention mostly due to the rise of electronic commerce, but continued its development into innovation, sustainability and strategy related areas, with the driving force of technology development such as the emerging of cloud computing techniques and web 2.0 network techniques, and most recently, the research trends no longer emphasized electronic commerce related topics, but had embraced technology development related topics as a major research area besides the already well-developed areas as “innovation” and “sustainability”.

In summary, this study reveals the research advances of business model research in different time periods, and helps us grasp the current status and trends by reasonable interpretation of the results. The analysis across three periods is necessary and important for understanding the dynamic structure of the literature, for it can provide information about specific transient trends (Dehdarirad et al., 2014), and can be used to identify gaps to promote research in emerging areas in the future.

Abstract: This paper takes “technical term” of patent literature as basic analysis unit. Based on an in-depth study of patent texts, a quantitative description of leading enterprises’ patented technology and industry technology standards as well as the entire industrial technology development has been made. Taking the patents and essential patents of communication industry in recent 24 years as samples, this paper reveals the function mechanism of industry leaders in the process of industrial technology development via a similarity comparison between leading enterprises’ patented technologies and industry technology standards and industrial patented technologies. Results indicate that technologies of leading enterprises are ahead of leading industrial technology of the same period and compose an important part of the contemporaneous pioneering technology thus providing important technological base for the formation of new technological paradigms. Meanwhile, leading enterprises in communication industry take an active part in standardization work and possess a large number of standard patents during the process of industrial standardization, which promotes significantly the formation of both industrial technology standards and technological paradigms.

Keywords: Leading enterprises; Technology standard; Industrial technology development; Patented technology; Content analysis

1 Introduction

With the arrival of the era of knowledge and information based economy, enterprise and industry technology analysis based on patentometrics also rose gradually (Zou and Li 2002). Griliches (Griliches 1998) even point out that patent is the unique resource of information which can timely identify the process of technical change. Nothing else even comes close in the quantity of available data, accessibility, and the potential industrial, organizational, and technological detail. Patent, as an important carrier to convey technical knowledge, has been introduced to the field of technology development by its objectiveness, availability and timeliness. In recent years, patent data has been widely used to measuring innovation econometrically in both firm and industry level.

Some scholars started to explore the development route of industrial technology by analyzing the development of enterprises’ patented technology within the industry. For example, Holger Ernest made an analysis of the technical development of NC machine tool industry based on patent data (1984-1992) of 50 German machine tool companies (Ernst 2001). Besides, after studying the development of patented technology of Fortune Global 500 Companies, Xianwen Wang (Wang, Zeyuan et al. 2010) made a research of the relationship of technological development among different industries with reference to their core competence in patented technology and competitive situation. Furthermore, Dehai Guo (Guo 2008) analyzed the patented technology...
distribution of multinational pharmaceutical companies in China. He made it clear that how foreign medical companies developed their patent in China and proposed some advice for the development of traditional Chinese medicine in industrial patented technology. At the same time, the analysis of the impact exerted by technical standard on industrial revolution and development is also on the rise, including its impact on the choice of leading industry planning and the interrelationship between technical standard and technological revolution of the industry (Bekkers, Iversen et al. 2006; Bekkers and Martinelli 2010).

Most of the study regarding the relationship between enterprise patented technology and industry technology development is based on structured patent information such as number of patents, patent classification and patent citation. Meanwhile, researchers acknowledge that unstructured information with patent content, like patent abstract, patent claims and patent specification contains more valuable information, which could depict the development of technology more directly, accurately and intuitively. Few analyses deeply into patent texts of unstructured information such as abstracts, independent claims and specification have been made.

Meanwhile, technology standardization has always been regarded as a powerful weapon in international market competition. With the emergence of anticipatory standards, the improvement of the standardization bodies’ database and the real-time update of standardization information, technology standardization shows an obvious forward-looking of the industrial technology development. As technical standard tends to be patented, patented technology standard gradually break the scope of traditional technical specification and plays an important role in international market competition and normalizing industrial technology order as well as promoting industrial technology development.

Since patent tends to be standardized, traditional analysis methods and tools can hardly reflect the relationship between standard and patent accurately and intuitively (Feng and Zhang 2011). In researches about leading enterprises’ patented technology and the relationship between technical standard and industrial technology development, what role do leading enterprises play in the process of industrial technology development? How? With traditional analysis methods and measurement of structured patent information only, it is rather difficult to make a clear description of the technological development trace of leading enterprises and the industry, not to mention to figure out the function mechanism of leading enterprises’ development on industrial technology development.

With the constant improvement of patent database electronization and the development of text mining technology, makes the in-depth analysis into the patent content level feasible. This paper takes “technical term” of patent literature as basic analysis unit and analyses deeply into patent texts by making use of Natural Language Processing, text mining technology and patentometrics so as to achieve a quantitative description and a comparative analysis of industrial technology and leading companies’ patented technology content. Theoretically, this study could offer new theoretical perspectives and analyzing thoughts for figuring out that how leading enterprises’ technological development promote industrial technological development so as to get a quantitative, deep and accurate understanding of the general development process of industrial technology. Practically, by analyzing how leading enterprises function in the process of industrial development through technical standard, this paper explores factors that determine industrial technology development and the rules beneath, thus being significant for leading enterprises playing their role and achieving innovation-driven development in China.
2 Data Sources and Methodology

2.1 Data Sources and Retrieval of Communication Industrial Patent

In this paper, all the patent data of communication industry was taken from Derwent Innovation Index (DII). DII has recorded more than 10 million basic patents and about 30 million patents, which come from over 40 patent institutes all over the world since 1963, and updates at a speed of over 25000 patents per week. Besides, Thomson Scientific organizes about 350 experts every year to make a further processing of patents in DII. They index each patent text of different countries, remove those obscure terminologies of the original patent texts and rewrite or extend those titles and abstracts in English with commonly used technical words. The adoption of this database not only increases the extraction efficiency of technical terms but also makes the extraction results of patent subject terms more meaningful, which will directly affect the mining results of technical subjects and technical intelligence hidden in patents.

As for the retrieval of communication patents, this paper adopted a combined retrieval strategy based on subject terms and classification codes. Taking core patent set of international communication technology standard as the test set, it was found that almost all core communicational technology focused on Derwent patent classification code such as W01, W02, T01, W04 and W05 and International Patent Classification Code such as H04 and that there was a strong cooccurrence relation in those technology fields. Figure 1 shows how the test was conducted in details:

![Diagram showing the retrieval process](image_url)
In Figure 1, Q represents training set consisting of all testing patents QA. Firstly, after making a statistical analysis of the International Patent Code (IPC) and Derwent Manual Code (DC) in test set, a frequency of occurrence ranking of IPC and DC is got and store the Top 1 IPC and MC. Then search patents that contain Top 1 IPC number in all testing patents and get a patent dataset Qtop which is removed later from the training set Q thus getting a new patent dataset QN. If QN makes up more than 5% of QA, the new dataset QN will be taken as training data set (Q=QN) and a new cycle begins from re-ranking the frequency of occurrence of IPC and DC in training set. In contrast, a proportion less than 5% for QN in QA means that the patents corresponding to selected classification codes account for over 95% of the total amount.

Through a retrieval test on combined classification codes, a retrieval strategy was finally defined as follows: TS=communication and (IP=H04* and DC= (W01 or W02)) with a time span from 1990 to 2014 and index database including CDerwent, EDerwent and MDerwent. As a result, 474409 patents related to communication technology in recent 24 years were retrieved.

2.2 Data Sources and Pre-processing of Communication Industrial Technology Standard

Technology standard is the competition focus of the entire communication industry. There is a great difference among 2G, 3G and 4G in the process of technological development of communication industry. Standard development divided industrial development into obviously different stages. The 3rd Generation Partnership Project (3GPP) is devoted to establishing standard which is globally applicable during the technological evolution from GSM core network to mobile communication of the next generation. 3GPP progresses with a series of constantly modified versions of technology standard (Release) which almost cover most standardization work of 2G-4G in the communicational development process. In order to manage patents concerning technology standard better, European Telecommunication Standards Institute (ETSI) stipulated that it should be informed by the members of the essential patents that its standard concerned as soon as possible according to FRAND principle within a reasonable scope. Technically, in the case of no patent infringement, if a patent is unable to meet the standard requirement during the production, sale, lease, repair and operation of facilities and acquisition of methods, then the patent is identified as an essential patent(Zeng and Peng 2008). In order to increase the transparency of intellectual property rights it has recorded, ETSI has established a specialized database to make regular update and disclosure of essential patents. Enabled in March 2011, ETSI IPR Online Database contains all the standard patents of the 3GPP standardization work from Release 99 until today and provides valuable samples for us to deeply analyze the relationship of industry technology standard and industrial technology development.

Standard patents of communication industrial technology were obtained from ETSI IPR Online Database. By January 2014, we have downloaded all the 2553 3GPP standardization projects from Release 1997 to Release 13 and 50110 essential patents in that database. As for the 50110 essential patents, we made a data cleaning, which included unification of format, deduplication and deletion of informationally incomplete patents, and merged the patent families according to the first patent number marked in each patent data thus finally getting 2208 patent families. Then a second retrieval in DII database based on essential patent number was made to establish a standard patent database of communication technology for a further analysis.
2.3 Methodology

It was reported by the World Intellectual Property Organization that patent was the greatest information source of technology in the world and that it covered more than 90% of global R&D output in which about 70% of the inventions had never been published in non-patent literature (Liu and Yang 2008). For the sake of a clear analysis of industrial technology knowledge, we need to obtain those technology contents from the carrier of technological knowledge. In patent texts, technical terms are the main representation of technological knowledge. Since there is not a structured storage of those technical terms in patent texts, a detailed analysis of the patent texts is thus needed.

First of all, the extraction of technical terms was realized by natural language processing to construct a dictionary of industrial patent content. Compared with journal articles, patent literature lacks of keyword fields so that “technological terminology” needs to be selected from texts as technical terms. The technical terms of patent literature were extracted by two procedures, part-of-speech tagging and rule definition of word phrase extraction. This paper employed Stanford Log-linear Part-Of-Speech Tagger (Toutanova and Manning 2000) developed by NLP group of Stanford University to tag the part of speech of each single word of patent titles and abstracts followed by the extraction of technical terms by rule definition (Liu and Chen 2013). By the way, the accuracy can be above 95% when tagging English words with that system.

Next step was a manual denoising of the extracted technical terms, mainly including the unification of number, the merging of synonyms, the use of en dash “-”, full name and its abbreviation as well as proper phrases. Some commonly used words such as “communication”, “network” and “system” in communication field were deleted and some synonyms such as “D2D” and “device to device”, “OFDM” and “Orthogonal Frequency Division Multiplexing” were merged. After several rounds of manual screenings, 7173 “groups” of word phrases (such as merged synonyms, singular& plural words and abbreviations, etc.) were preliminarily kept as a dictionary of patented technologies in communication field.

Secondly, an analysis of high-frequency words, burst terms and newly emerging terms was undertaken with patentmetrical methods. The statistical analysis of word frequency enabled us to generally estimate technological hotspots and identify the newly emerging technologies (Hu, Zhang et al. 2013). Analyze word frequency of the annual patented technology and high-frequency technical terms were regarded as technological hotspots of that year. The calculation of high-frequency technical terms, burst terms and newly emerging terms is shown as follows:

High-frequency words of Year $i$ $T_i = \text{top 50} \{ F(i,j) \}$, this represents the top 50 most frequent words of one year;

Newly emerging words of Year $i$

$N_i = \{ W(j) \mid F(n,j) = 0, F(i,j) > 0, N > i > 1, i > n > 0 \}$

Burst terms of Year $i$

$B_i = \{ W(j) \mid | F(i,j) - F(i-1,j) | > 10, N > i > 1 \}$

$Y(i)$ represents Year $i$, $N >= i > 0$;

$W(j)$ represents the jth word phrase, $M > j > 0$;

$F(i,j)$ represents the frequency of occurrence of word phrase $W(j)$ in Year $(i)$.
Finally, with the use of vector space modal and cosine similarity algorithm contained in text mining technology, the similarity of patented technology among different years was measured. Vector space model (Wu and Xu 2003) simplifies text content processing to vector operation in vector space and it presents the semantic similarity intuitively via spatial similarity. If documents are represented as the vectors of documental space, the similarity between documents then can be measured by calculating the similarity between those vectors. The computational formula of similarity between vector A and vector B is shown as follows:

\[
\text{similarity} = \cos(\theta) = \frac{A \cdot B}{\|A\| \|B\|} = \frac{\sum_{i=1}^{n} A_i \times B_i}{\sqrt{\sum_{i=1}^{n} (A_i)^2} \times \sqrt{\sum_{i=1}^{n} (B_i)^2}}
\]

The smaller the distance between vectors is, the more technical terms overlap and more similar the technology content of different years are. If the technology content of different years are very dissimilar, the distance between vectors will be larger, which is accordingly taken as the division point of technological cycle.

3 The Relation Judgment of Leading Enterprises’ Technology Development and Industrial Technology Development

3.1 The Selection of Leading Enterprises in Communication Industry

This paper selected patent leaders of the industry mainly based on the technological strength reflected by patents. Aimed at exploring enterprises’ overall strengths of patented technology, this paper made a comprehensive consideration of the existing evaluation indicators of patent in view of scientific algorithms, available and operable data. Indicators such as Number of Patents, Patent Growth Index and Patent Impact Index were chosen to reflect enterprises’ technological capability in patent.

The technological capability of a company can be preliminarily revealed by the number of patents, but number of patents only is imprecise for it does not take the value of each patent into account. Hall (Hall, Jaffe et al. 2005) and his colleagues had found that market value has a closer relationship with weighted number of patent by citation than with number of patents itself. Therefore, this paper further studied the Top 100 companies with most number of patents per annum about the times cited of their patents so as to give more weight to companies whose patents are frequently cited. Meanwhile, in order to stand out the recent dynamic changes of domainial potential, this paper also added Recent Growth Index to reflect whether patents of institution tend to act actively or slowly. More details about indicators and computing methods can be seen as follows:

Number of Patents: \( P_{ij} \)

Number of patents is the most basic indicator based on which many other indicators are computed. The development tendency of a particular industry can be discovered through an analysis of authorized patents in a certain period. \( P_{ij} \) represents the number of patents company i possesses in Year j.

Patent Impact Index: \( \text{PII}_{ij} \)

Patent impact index reflects the influence of institutional patents on technological development of a field. A lot of researches have indicated that there is a strong positive correlation between patent citation and the importance of technology (Narin, Noma et al. 1987; Albert, Avery et al. 1991; Breitzman and Narin 2001). Patent impact index is the ratio of citations per paper of
all the patents the institution has authorized and obtained during the last 5 years to that of all patents in technology field of the same period, in which the former one has been standardized and get rid of the impact of industry and scale. A PII greater than 1 means that the patents of that institution are frequently cited to a level higher than the average level of the domain. It is thus speculated that the company has a better patent quality because its technologies exert a greater influence on industrial technology development. The computational formula of PII is shown as follows:

$$\text{PII}_{ij} = \frac{C_{ij}}{\sum_{l} C_{lj} / \sum_{l} K_{ij}}$$

(2)

$C_{ij}$ and $K_{ij}$ represent respectively the times cited and the total number of the patents that company $i$ has authorized in $j$ field during the last 5 years.

Patent Growth Index: $G_{ij}$

As a proportion of the number of patent an institution authorized in a particular year (say 2013) to the average amount of patents it has authorized in the last 5 years (2009-2013), patent growth index reflects the patent activity of an institution in recent years. A $G_{ij}$ greater than 1 means an increase of the institution’s patent activity compared with the last 5 years; a $G_{ij}$ less than 1, in contrast, reflects a decrease of its patent activity in recent years. Since $G_{ij}$ is a regulatory index, we set an upper limit of 2 for it in case that companies which do not act actively early in patents possess extremely high $G_{ij}$.

$$G_{ij} = \frac{P_{ij}}{\sum_{l \neq j} P_{lj}}$$

(3)

The three indicators constitute the technological strength (TS) of a company. The technological strength of company $i$ in $j$ field can be calculated by the following formula:

$$\text{TS}_{ij} = P_{ij} \times G_{ij} \times \text{PII}_{ij}$$

(4)

However, the classification methods in this paper also have some limitations. For example, all the patent citations are treated equally without drawing a distinction among the value of them. Furthermore, different reference patterns present unequivalent patent values (Chen, Lin et al. 2007). Although high-value patents such as patents cited by important patentees and beyond this technological domain or of different legal status are given a higher weight, delicate properties like that are not taken into consideration. In general, this paper holds that patent impact reflected by the number of patents and citations could generally represent the competitive situation among companies in a particular field and that a further study of the dynamic changes of leading companies’ patent development could be achieved with consideration of recent growth index.

Based on the downloaded patent data of communication industry from 1990 to 2013, a preliminary ranking and selection of enterprises according to their number of patents was made. After that, a further selection according to patent quality and growth indexes was made to figure out that there were totally 16 enterprises whose patents are among Top 5 in communication industry every year from 1990 to 2013.

3.2 Content Analysis of Patent Leaders’ Patented Technology in Communication Industry

After extracting and collecting high-frequency technical terms of the 16 enterprises’ annual patents, their annual technological hotspots were recognized. On the basis of the patent technology development of communication industry as a whole, a dictionary of patent technology for communication industry was built and the part-of-speech tagging, matching and extraction of technical terms contained in the titles of those enterprises were made. Lately, we made a description and analysis of the enterprises’ annual high-frequency technologies after selecting and ranking each company’s annual technical terms in the light of year and discussed the technological development of the 16 companies leading in communication patents during the 24 years.

It was found that high-frequency technical terms of a company presented an obvious similarity among neighboring years (regular technology period) while changed a lot at one or several points (abnormal technology period). However, during years following the technical terms tended to be similar again. Therefore, we attempted to divide the technical content cycle of each leading company according to the following methods: firstly, sequence all the technical terms contained in the dictionary of communication industry technology according to the order in dictionary of patented technology of communication industry; then counted the word frequency of technical terms occurring in every leading company in different years and made a zero-padding processing for those did not appear in dictionaries; finally made a hierarchical clustering of word frequency variation after standardizing all the technical terms. For a company, the technological emphasis is different in different years, which could be presented by the distribution of technical terms. A hierarchical cluster analysis by SPSS allows us to see more clearly the periodic changing tendency of a company’s technologies.
3.3 Analysis of Communicational Patent Leaders’ Participation in Standardization

A company participates in the formulation of industrial standards to a degree influenced by its internal technological capability (Leiponen and Bar 2008), meanwhile, a higher level of participation also makes it more likely for organizations to transform their technological superiority into global standards thus establishing a de facto standard globally (Bekkers and West 2009). Taking part in the formulation of technology standard is the best way to affect the choice of predominant standard in the future (Bousquet, Fomin et al. 2011). In fact, the development of different versions of Release reflects the development and changes of the patented technology standard of communication industry. The next sector is an analysis of the participation degree of leading companies in every Release during different periods in accordance with their participation in work planning.

Analysis of Patent Leaders’ Participation in Standardization in Terms of the Quantity of Involved Projects

Firstly, this paper drew all the assignee names (enterprises) that had participated in formulating standard for Release 7-13, and then made a second screening of the 16 communicational leaders based on 7 groups of data and finally analyzed the industrial leaders’ participation degree in terms of the number of standardization projects they have participated in. There are many projects undertaken by several companies jointly in standardization work, in that
case, the number of projects will be distributed in proportion to enterprises according to their ranking of participation degree. The proportion of patent leaders’ participation in 3GPP standardization work for Release 7-13 is displayed as the following Table 2:

</tbody>
</table>

As we can see from Table 2, the distribution of 3GPP standardization work conforms to the Pareto Principle, that is to say, a minority of enterprises take charge of the majority of projects while most enterprises take charge of a few projects or even not participate in the standard establishment at all. There are more than 300 company members in 3GPP, but only 58 of them have taken part in one or several projects of standardization work. The degree of participation is influenced by the internal technological capability of the company, and the weight of voting when participated in standardization is related to the company’s revenue in communication field (Leiponen and Bar 2008). Table 2 shows that 11 of the 16 leading enterprises have participated in formulating standards of R7-R13 at all. They mainly bear over 50% of the standardization work in Release 7-12 including a proportion of more than 60% in Release 9-11 standardization. Since Release 13 is still under way, the distribution among those enterprises has not been determined yet.

Information of Patent Leaders that Possess Standard Patents

The analysis of standard patents that leading enterprises possess could be seen from Table 3. As is shown in Table 3, there are 9 companies declaring to possess standard patents that are essential to carried standard in the 16 leading companies of communication industry. From Release 4 (2001) to Release 11 (2012), those 9 companies occupied more than 50% of the total number of standard patent in most years except for a slightly lower proportion in Release 4 and Release 10. Almost all the 9 enterprises have participated in standard establishment except LUCE and APPY.

4 The Role of Leading Enterprises in Industrial Technology Development

What part the leading enterprises play in the formation of technological paradigms was analyzed from two aspects, the patented technology content of the leading enterprises and their role in standardization of patented technology. Firstly, the role of leading enterprises in forming technological paradigms was defined by the similarity between their key patented technologies in each year and the contemporaneous patented technology hotspots of the whole industry. Specifically speaking, match the yearly high-frequency technical terms from communicational patented technology with the dictionary of communication industry technology and made a zero-padding processing for technical terms that do not appear in that year so that the industrial patents of each year can be represented as a feature vector consisting of 7147 technical terms of different frequency. Make an identical processing for the high-frequency technical terms of the 16 leading enterprises’ patent and we got a feature vector, consisting of 7147 technical terms, which represented the annual patents of a company. We got a correlation coefficient between the technical terms of enterprises and that of industry in that year by means of a correlation analysis. At the same time, after ordering the technical terms of both industry and leading enterprises in accordance with word frequency, we obtained those of high-frequency of which we made a comparison of the ‘Top 20 so as to analyse the relationship between companies’ key technologies and industrial technology hotspots from a qualitative perspective. How the analysis worked is displayed by Figure 3.
4.1 Leading Enterprises Provide Important Technological Base for the Formation of New Technological Paradigm

Comparing the key patented technologies of 16 leading enterprises from 1990 to 2013 with the patent hotspots of communication industry in corresponding year allowed us to learn about the variation trend of the correlation coefficient between patent content of the enterprises and that of industry during 24 years. Put the variation trend mentioned before together with that of the patented technology ranking of enterprises respectively and we got the results as shown below:
In general, the similarity of leading enterprises’ key patented technologies and the patented technology hotspots of the whole industry is basically consistent with the enterprises’ patent rankings. After further studying how the correlation coefficient between 16 industry leaders’ key patented technologies and communicational patented technology hotspots relates to enterprises’ ranking scores, it was found that for 15 enterprises, the consistency of their key patented
technologies and the industrial patented technology hotspots correlate significantly with their rankings in a moderate or higher level. In other words, there is a strong similarity between the patented technology content of 15 enterprises and the industry during the period when they led while a relatively weaker similarity when they did not. That means that leading enterprises’ patent content composes an important part of the industrial patent content and that compared with others leading enterprises’ patented technologies are more similar with that of the industry, which indicates in a degree that the patented technologies of leading enterprises have a significant influence on the formation of industrial technological paradigms.

In view of the high-frequency technical terms of leading enterprises, SMSU, for example, have involved most of the 1999-2008 technology hotspots of the communication industry since 2000. Its development of hotspot technologies is many years ahead of the industry especially for technologies about OFDM, safety and personal communication. The emphasis of SMSU technologies also changed since 2010, though technologies such as LTE, NFC (Near Field Communication), intelligence and portable terminals were consistent with leading industrial technologies. Besides, QCOM started to develop technologies like OFDM, content data and Mobile Terminal from 2000 to 2008, which was also ahead of the industrial technology content and similar with pioneering industrial technologies of that period. After 2009, QCOM changed its technological key points, in which technologies concerning LTE, NFC, WLAN (Wireless Local Area Network) and AP (Access Point) were consistent with leading industrial technologies of that time. As for APPY, since its entry into communication field in 2004-2008, it put the emphasis of technological development on digital camera module, cloud computing, touch screen, multimedia, portable electronic devices, music player, media storage, auxiliary equipment and Bluetooth rather than contemporaneous leading industrial technologies. Some technologies such as smart phones had not become leading industrial technologies until 2009 and others like cloud computing even not appeared as pioneering technologies until 2009.

It can be concluded from the above analysis that technologies of leading enterprises is ahead of the leading industrial technologies of the same period and compose an important part of contemporaneous technologies, thus providing an important technological base for the formation of a new technological paradigm.

4.2 Leading Enterprises Promote the Formation of Industrial Technological Paradigm by Technology Standardization

In view of the similarity between leading enterprises’ patented technologies and the industrial technologies of standard patent, enterprises that have participated in standard establishment generally have a higher level of similarity with industrial technical standard than enterprises that have not. The correlation coefficient between such leading enterprises as CANO, IBMC and LUCE that have not involved in standard establishment and standard techniques is far lower than that for leading enterprises which have involved in. This indicates to some degree that it is likely that leading enterprises have blended their own key technologies into the new generation of industrial technology standards during the participation in standard establishment so as to affect the formation of technological paradigm. The process can be displayed by Figure 5.
5 Conclusion

Since the combination of technology and standard is becoming more and more close, patent leaders tend to play an increasingly important role in promoting the development of industrial technology. With a study of the function mechanism of leading enterprises’ technology on industrial technology development, it is found that leading enterprises provide significant technological base for the formation of new technological paradigms and promotes the formation of industrial technological paradigm by technology standardization, which makes them a powerful driving force for industrial adjustment and upgrade as well as innovative development.

(1) Technologies of leading enterprises are ahead of leading industrial technologies of the same period and compose an important part of the contemporaneous pioneering technology thus providing important technological base for the formation of new technological paradigms.

(2) Leading enterprises of communication industry play a significant role in promoting the formation of both industrial technological standard and technological paradigms via active participation in standardization work and a large amount of standard patents in the process of industrial standardization.

(3) Leading enterprises blend their own key technologies into industrial technological standard so that they determine partial content of the industrial technological paradigms. After technological paradigms are formed, leading enterprises achieve a transformation from pioneering technology to leading technology, which makes the patent content of communication industry leaders an important part of leading industrial patented technologies.

The conclusions above are all drawn based on theoretical hypothesis and empirical studies of communication industry. The rule of industrial development this paper reveals is applicable to communication industry. At the same time, this research is expected to provide a research paradigm for technological analysis of other industries.

Abstract
Technological cooperation becomes necessary in extending technological application and improving market competitiveness, and thus, it is important to identify collaborative technologies that meet strategic purposes. This paper aims to construct a technological network based on the core terms derived from patent documents to help technology owners achieve such target. A four-step analytic framework is constructed, including: 1) community division, which allows the selection of cooperative technology to be controlled within a more relevant technical range; 2) indicator analysis that can be used to understand the technological situation within the community from three main aspects, i.e., degree, clustering coefficient and line weight; 3) the purpose of cooperation, which is an important basis for the selection of cooperative technology; and 4) technology selection, which is to combine cooperation purposes and indicator analysis to select technology. Finally, a case study on China’s artificial intelligence (AI) technology is conducted to demonstrate the feasibility of this method, and the findings will help decision making in related AI fields.

Conference Topic
Patent analysis; Social network analysis; Mapping and visualization;

Introduction
With the continuous development of science and technology, the degree of knowledge specialization is getting higher and higher. To improve the ability of technological innovation and market competitiveness, technological cooperation has received increasing attention (Tu, Mohler & Ma, 2017; Kotsemir, Kuznetsova & Nasybulina, 2016). In addition, it’s hard for an individual enterprise to bear high risk and huge capital investment requirement in the process of new product development, and technological cooperation can reduce the adverse impact of failure on enterprises.

With advantages in value-added information, structured data format and low acquisition cost, patent has been widely used to analyse modern technologies, such as technical information flows, technological trends (Segev & Kantola, 2012), technological innovation (Lee & Kim, 2010), and technological strategy (Ernst, 2003). Bibliometrics have been commonly used in patent analysis due to its simplicity and convenience (Bellotti, Kronegger & Guadalupi, 2016;
Landini, Malerba & Mavilia, 2015; Chen & Fang, 2014), but the shortage is that it heavily depends on bibliographic information, which doesn’t include detailed technology information (Yoon & Park, 2004). As a remedy, a content-based approach fills the deficiency by analysing detailed information extracted from text, and keyword-based analysis (KWA) is a representative method of content-based approaches. The combination of KWA and network models (Huang, Zhu & Guo, 2014; Stermitzke, Bartkowski & Schramm, 2008), known as keyword-based network, can directly reveal the relationships between keywords and help to analyse technologies within the theoretical framework of networks (Wu, 2016; Zhang, Shang & Huang, 2016; Choi & Hwang, 2014), and the engagement of advanced information technologies (e.g., machine learning) further enhances such ability in relationship identification (Zhang, Zhang & Zhu, 2016).

Community structure is a feature of networks. Node in a network can be divided into groups, and nodes in a group are tightly connected while node connections between different groups are sparse. Here group is called as community. Community in actual systems has significance meanings, and can help solve many actual problems. In social network, community may be based on human occupation, age or other factors (Girvan & Newman, 2001); in citation network, community may be divided according to research areas (Redner, 1998); in World Wide Web, different communities may represent different themes on web pages (Flake, Lawrence & Giles, 2002). Under this circumstance, indicator analysis becomes an important way to understand the topology of networks, and some common indicators include degree, density, compactness, line weight, closeness, clustering coefficient etc.

This paper proposes a method that identifies technological cooperation based on network community structure. Community division allows the selection of cooperative technologies to be controlled within a more relevant technical range and makes the selection result more accurate. We identify technological cooperation purposes into three categories, i.e., extending technology applications, improving technology level and identifying possible technological connection. Network indicator analysis is adopted to select cooperative technology. Different purposes need different indicators. This paper mainly conduct the following research: community division, indicator analysis, purpose of cooperation and technology selection. Finally, a case of China’s artificial intelligence technology is studied to illustrate the availability of the proposed method.

This paper is organized as follows: In the next section, we introduce the methodological framework, including patent collection, network construction, community analysis and identification of technological cooperation. A case study of China’s artificial intelligence technology is discussed in the following section to demonstrate the feasibility of our method. Finally, we draw some conclusions and discuss the future study.

Method

The proposed method is comprised of four steps: patent collection, network construction, community analysis and identification of technological cooperation. The process is showed in Figure1.
**Patent Collection**

This step aims to propose a search strategy and collect patents. To make a good search strategy, some necessary factors should be considered, including the features of patent databases, actual research purpose and time span. For example, special patent database does not reveal enough information about the legal status, the same family, the patent.

**Network Construction**

Before we construct keyword-based patent networks, keyword acquisition is required, i.e., extracting keywords from patent abstracts, filtering invalid words (such as number, academic terms and other basic words) and selecting a number of keywords as the research objects. According to a co-occurrence matrix, we construct a keyword-based network, where each node represents a keyword and the line represents the co-occurrence relationship between the two end nodes.

**Community Analysis**

Based on the network constructed in the above step, we divide the whole network into some communities based on the connection tightness between nodes, allows the selection of cooperative technology to be controlled within a more relevant technical range. Then, we adopt network indicators (e.g., degree, clustering coefficient and line weight) to explore each community, providing theoretical basis for technological cooperation identification.

1) Community Division

Intuitively speaking, community refers to a set of nodes, and the connections within a community are dense while the connections between different communities are sparse. Network community indicates a set of nodes that have some common attributes or some similar effects. The algorithm for community division is as follows.

\[
Q = \frac{1}{2m} \sum_{i,j} A_{ij} \left( k_i k_j \right) \delta(c_i, c_j), \quad \delta(c_i, c_j) = \begin{cases} 1, & c_i = c_j \\ 0, & c_i \neq c_j \end{cases}, \quad m = \frac{1}{2} \sum_{i,j} A_{ij}, \quad 1 \leq i,j \leq n \quad (1)
\]

Where \(A_{ij}\) is the line weight between node i and node j (1), \(k_i = \sum_j A_{ij}\) denotes the sum of all
the line weights connecting node i, $c_i$ and $c_j$ are the community indexes of node i and node j respectively, $m$ is the sum of all line weights of network and Q represents modularity, whose value is between [0, 1]-the higher Q value the better community division.

In the initial state, every node is a separate community, and the community number is n. Then, communities merge together one by one. The iteration ends when Q gets the maximum value.

2) Indicator Analysis

Before selecting a target technology, we need to understand the technology situation by analyzing nodes connection within the community, such as the influence and connection tightness of nodes, and node cohesion. Indicator which is used to analyze the relationship of nodes can be taken to research the above situations. Considering the diverse implications of indicators in handing diverse technological problems (Yan & Luo, 2016; Jeong, Kim & Choi, 2015; Koseoglu, 2016), we try to summarize certain common indicators and their technological implication in Table 1.
**TABLE1. Detailed network indicators introduction**

<td>The number of the shortest path passing through the node to the total number of the shortest paths.</td>
<td>Reflecting the effect and influence of nodes in the whole network. Used to measure the intermediary and brokerage capability of technology.</td>
<td>(Radicic, Douglas &amp; Pugh, 2015)</td>
</tr>
</tbody>
</table>
In our paper, we select indicators based on cooperation purpose, and different purposes will be analyzed with different indicators. Considering actual requirements on technology management and analysis, we specifically select three indicators in this paper, i.e., degree, line weight and clustering coefficient. Degree reflects the influence of a node, line weight expresses the connection tightness between two nodes and clustering coefficient corresponds to the cohesion of a node. The detail explanation of these indicators is given below.

- **Degree**
  In a network, the degree of one node means the number of direct links between the node and other nodes. High degree value means the node is highly linked with other nodes, indicating the technology reflected by this node is important. The calculation formula (Jeong, Kim & Choi, 2015) is given below.

  \[ d_i = \sum_{j=1}^{n} l_{ij}, \text{ where } i \neq j \text{ and } l_{ij} = \begin{cases} 1 & \text{if } w_{ij} > 0 \\ 0 & \text{otherwise} \end{cases} \]

  where \( w_{ij} \) denotes the line weight between node \( i \) and node \( j \), and \( d_i \) denotes the number of lines connected to node \( i \), and can reflect the importance of node in a large level.

- **Clustering coefficient**
  The clustering coefficient of one node denotes the extent of links between the neighbor nodes of a target node. A high value means the links between neighbor nodes is dense, which indicates the target node surrounded by strong connections is very important. This indicator measures the importance of a node by the density of its neighbor nodes' links. The calculation formula (Yan & Luo, 2016) is as follows.

  \[ cc_i = \frac{2l'}{k(k-1)} \]

  Where \( cc_i \) represents clustering coefficient of node \( i \), \( k \) denotes the number of lines connect to node \( i \) directly, \( l' \) denotes the number of lines existed in the \( k \) nodes, and \( k(k - 1)/2 \) denotes the number of possible links between those \( k \) nodes.

- **Line weight**
  Line weight describes the relationship between two nodes. In this paper, the value means the co-occurrence frequency of two technologies in the patent set. The definition of line weight (Barrat, Barthelemy & Pastor-Satorras, 2004) is introduced below.

  \[ w_{ij} = \frac{n_{ij}}{N}, \text{ where } i \neq j \]

  Where \( w_{ij} \) represents the line weight of node \( i \) and node \( j \), \( N \) denotes the patent number of patent set, \( n_{ij} \) denotes the number of patents which contain both technologies of node \( i \) and node \( j \). A high value of \( w_{ij} \) means node \( i \) and node \( j \) are highly related.

These indicators are used to select technological cooperation object, and different technological cooperation purposes need different indicator analysis. Next, we will introduce cooperation purposes.

**Identification of technological cooperation**

This step aims to select target technology based on the results from indicator analysis. To do that, we need firstly figure out the purpose of the cooperation.

1) **Purpose of cooperation**

In this paper, we mainly focus on three types of technological cooperation purposes, and the definitions are given below:

Extend technology applications
• The aim of the cooperation is to extend the application scope of own technology. The ideal cooperative technology should be those that are widely connected with other technologies.

Improve technology level
• Representing cooperate with professional technology to innovate own technology, which can improve the market competitiveness of own technology compared with similar technology.

Identify possible technological connection
• If technology a1 and technology a2 both connect closely with Technology b respectively, there is great possibility that a1 and a2 will connect tightly in the future. So, the cooperation between this two technologies is in line with technology development trends and easy to succeed.

2) Technology selection

Based on the above research of cooperation purposes and indicator analysis, we select different indicators to realize the three cooperation purposes, and realize the selection of cooperative technology.

In a community, the node with high degree value is widely connected with other nodes, which means this technology is easily to build connection with other technologies. Those technologies with high degree are good selection for extending technology applications.

Clustering coefficient indicates the relationship between node and its surrounding nodes. A high value shows strong cohesion, which means the surrounding nodes are highly connected and form a topic group. If one aims to improving technology level, the member technologies of the group are suitable to cooperate.

Line weight measures the connection tightness between two nodes. Technology couple with high value shows the close contact of existing connection, can be used to identify possible technological connection.

The above is the introduction to the method framework. We use indicator analysis to understand the technological information within the community. Then, based on cooperation purpose we select corresponding cooperative technology. Next, we take china’s artificial intelligence technology as a case to demonstrate the availability of the method.

Case study: China’s Artificial Intelligence

To demonstrate the feasibility of our proposed method, china’s artificial intelligence technology is selected as a case. Artificial intelligence (AI), a technical science, aims to research and develop theories, methods, and application system for simulating, extending and expanding human intelligence. The reason we choose China’s artificial intelligence is that China has the world's leading voice and visual recognition technology, and its research ability of artificial intelligence is impressive. Besides, according to two important reports of the White House released in October 2016, Preparing for the Future of Artificial Intelligence and The National Artificial Intelligence Research and Development Strategic Plan, China has surpassed the US in the total number of cited journal articles that relate to deep learning techniques in 2014. What’s more, on March 5, 2017, at the opening ceremony of the National People's Congress, Premier Li Keqiang announced that China would speed up the research and development of new industries such as artificial intelligence. This is the first time that China's highest national conference has incorporated artificial intelligence into government work reports. This shows that artificial intelligence has become the priority of China's economic agenda, and the government has decided to support its growth. China’s artificial
intelligence has indeed made great achievements, and technological cooperation will broaden this field’s future development.

**Data**

To study the development of AI in China, the patent set of Chinese AI technology was collected. The search strategy is “TS= ("artif* intelli*" OR "comput* intelli*" OR "deep learn*" OR "machine learn*" OR "big data" OR "cloud comput*" OR "pattern recogn*" OR "neural network*" OR "data mining*") AND PN= (CN*)”. As a result, 10,229 China’s patents between 2012 and 2016 were acquired from Derwent Innovations Index (DII).

**Result**

We draw a keyword-based network where nodes represent keywords and lines represent the co-occurrence relationships between two end nodes. Conducting community division, we got three communities displayed in Figure 4 (b1, b2 and b3 are the independent part of each community). Next, we combine figures and indicators analyse technology situation of each community.

![Figure 4. Community division result of the technology network.](image)

(a) shows the overall division effect. (b1), (b2) and (b3) are community1, community2 and community3 respectively.
TABLE 2 displays the results of degree and clustering coefficient analysis of three communities.
In degree analysis, we list out the top three technologies of each community. Comparing the degree values with community size, we find that in each community these technologies are almost all connected with other technologies, indicating these technologies are the best selection to cooperate with to extend technology application. From Figure 4-(b1), (b2) and (b3) we can find out the sparse nodes, and expand their technology application. The results are as follows:
- Community 1:
  Automatic control can cooperate with cloud calculation, internet-of-Things (IoT) or wireless sensing technology.
- Community 2:
  Hadoop architecture can cooperate with big Data, video recognition or real time.
- Community 3:
  Sensitivity analysis can select machine learning, neural network or data mining.
In clustering coefficient analysis, the top three technologies of each community are displayed. These technologies are highly professional, can promote own technology to have rapid growth. Improve own technology in the same type of technology in the competitiveness. From Figure 4-(b1), (b2) and (b3) we can identify the potential technological cooperation as follows:
- Community 1:
  Ultrasonic sensor can select to cooperate with automatic control.
- Community 2:
  Dynamic process algorithm can select to cooperate with image identification.
- Community 3:
  Feature selection algorithm can select to cooperate with Hidden markov model algorithm.

TABLE 3 reflects the result of line weight analysis, listing out the top 5 technology couples of each community. Figure 5 is the network diagrams of these technologies.
In community 1, Fig.5-(c1) is the corresponding network diagram of these technologies, where we can see that there are other connections between the six technologies besides the top 5 lines. For example, internet-of-Things (IoT) and wireless communication technology. For both of them are closely connected with cloud calculation, there are great possibility that internet-of-Things (IoT) and wireless communication technology can cooperate with each other and build close connection in future. After a similar analysis, we find in community 2 that pattern recognition and real time is possible close connection in the future and can
cooperate with each other. In community 3 machine learning and fuzzy algorithm, data mining and fuzzy algorithm are potential technology combinations.

**Discussion and Key Findings**

We constructed networks based on keywords extracted from Chinese AI patents, and divided it into 3 communities. In each community, we took indicator analysis to select cooperation technologies according to different cooperation purposes.

According to the connection tightness between nodes in the network, the network is divided into three communities. The contribution of community division is to refine the area of technical selection to a more relevant scope. We grasp the technical situation within each community by indicator analyse. When selecting cooperation partners, cooperation purposes are considered. This paper summarizes three kinds of cooperation purposes: extend technology applications, improve technology level and identify possible technological connection. Corresponding analysis indicators are: degree, clustering coefficient and line weight. Based on the above research, we can identify the following technological cooperation:

1) Cooperate with high degree technologies to extend technology applications, e.g., automatic control and cloud calculation in Figure 4-(b1).
2) Cooperate with high clustering coefficient technologies to improve technology level, e.g., ultrasonic sensor and automatic control in Figure 4-(b2).
3) Identify possible close technological connection by existing technology connections, e.g., pattern recognition and real time in Figure 5-(c2).

CONCLUSIONS AND FUTURE STUDY

In this paper, we propose a method based on network community to identify technological cooperation, mainly include community division, indicator analysis, purpose of cooperation and technology selection. This article is characterized by using community division and combining with technology purposes. Community division filtered out unrelated technologies and made the results more accurate. Different technology purposes adopt different network indicator analyses, according to the analysis results selecting technical cooperation object. Finally, we select China’s artificial intelligence technology as a case to demonstrate the feasibility of our method. This paper has following contributions: proposing a method to identify technological cooperation and benefit experts of technical cooperation identification. There are some limitations on our research. For example, in this paper, the network is divided into three communities. Applying other community division algorithm may get different results. Besides, this paper adopt three indicators based on research purposes, there are some other indicators can be used to analyse network topology, such as density, closeness and so on. Those indicators may have other new findings. In future, more accurate community division algorithm and more diverse indicator analysis should get further research.

Abstract
The major challenges of topic visualization in texts are to enhance, interpret, and explain the visualization results. Two strategies for enhancing and interpreting results of underlying topic visualization in texts are proposed. In order to overcome the limitations of visual display space capacity, the open coding method is introduced to assign terms to different categories, with each category corresponding to a visual space. In view of the difficulties in interpretability and understandability of the visualization results, this paper investigates the characteristics of context dependencies of the underlying topic and its terms, and puts forward a three-layer context model, which includes three levels, that is, domain context, topical context and linguistic context. The ideas and methods for constructing the context model in this study can be extended to other areas, such as text segmentation, automatic summarization and other text mining and knowledge discovery.

Conference Topic
Mapping and visualization

Introduction
Underlying topics can reveal main content of a text set. If underlying topics can be extracted and represented in the visual space, people can quickly obtain the key content of a text set. The hidden knowledge structure, mode and potential regular features in texts can be found and deep knowledge discovery can be realized.

A term is the smallest semantic unit in texts and clustering terms in visual space is an efficient way to visualize underlying topics. Due to the inner relationship among terms in texts in a specific domain, those terms expressing the same or similar meaning will show close spatial neighborhood relations in a 3D visual space. However, there are two difficulties in finding topics by the method of term clustering in the visual space at present:

The first is the limitation of visual spaces (Zhang & Zhao, 2013). Due to limitations of visual spaces (computer screen size), it is impossible to put all terms and underlying topics in the same space to present to the users. Conversely, if all the underlying topics and their terms are integrated in one visual space, advantages of the visualization method is weakened or even lost.

The second is the complexity and ambiguity when the visualization results are explained (Zhang et al., 2014). The underlying topic visualization is realized by using the method of transposed-vector-space to represent terms. But in the process of converting texts into matrix form, a lot of useful semantic information is ignored. The terms themselves are ambiguous in their meanings, which increase the complexity in interpretation of visualization results. Therefore, it is necessary to find a qualitative method to ensure correct interpretation and in-depth analysis of visualization results.

This paper aims to propose hybrid strategies to overcome those two difficulties. Research questions include: (1) how to overcome the limitation of a visual space that can only display limited number of terms? (2) how to reveal the true meaning of underlying topics and its terms profoundly?

Findings of this study can be used to: (1) reduce the number and size of objects in the visual space; (2) help interpret and understand the results of underlying topic visualization.
Related work
Topic visualization by clustering terms in visual spaces is used a lot in research on knowledge discovery in texts (Zhang, Zhao & Dimitroff, 2014; Zhang & Zhao, 2013; Zhang & Wolfram, 2009; Zhang, Wolfram, & Wang, 2009; Zhang et al., 2008). It is recognized that the limitation of visual spaces and the difficulty to interpret the visualization results are major problems and not addressed well until now (Zhang, Zhao & Dimitroff, 2014; Zhang & Zhao, 2013).

Methods
Two strategies for enhancing and interpreting results of underlying topic visualization in texts are proposed. One is to introduce coding technics into the process of underlying topic visualization. The other is to interpret the visualization results under a three-layer context model. Those two strategies are implied in underlying topic visualization of public company prospects.

Data sources
According to Corporation Law, Securities Act and Interim Measures for the Administration of Initial Public Offering and Listing on the Growth Enterprise Market, the issuer of initial public offering (IPO) must disclose all factors that may directly or indirectly cause significant adverse effects on operating conditions, financial conditions, sustained profitability and growth of an issuer. The relevant documents require the issuer to fully, accurately and specifically describe the relevant risk factors according to its actual situation. The issuer shall make a quantitative analysis of the risk factors disclosed and make a targeted qualitative description for those factors that cannot be made with quantitative analysis.
According to the Industry Classification Guidance for Public companies issued by China Securities Regulatory Commission on April 4, 2001, this study selected the computer application and service industry (classification code G87) as an sample for the analysis and all verbal contents in the chapter of “Risk Factors” in the prospectus of public companies in the computer application and service industry form the text set to be analyzed.

Underlying topic visualization
Texts were firstly represented as a term-document matrix and each item in the matrix is the term frequency. Then, a Multi-dimensional Scale analysis was executed to clustering terms in the visual space following the transition of the term-document matrix to similarity matrix. The software used here is SPSS of version 22.

Extending visual spaces by using coding technics
Aimed at addressing the first difficulty of underlying topic visualization, the open coding method is introduced to control the number of objects in the visual interface and realize the multi-layered visualization.
It is also necessary to design corresponding strategies of coding according to different situations while the coding technics are introduced into the process of underlying topic visualization (Zhang & Zhao, 2013). There are two coding approaches for text sets with different characteristics:
The first approach is to code terms after word segmentation. This strategy is applicable to completely unstructured free texts, like text sets composed of messages in online Q&A or other social media, chatting records in the instant messaging and others. These texts don’t have a clear text structure and often have no titles and even paragraphs. For this strategy, the object of open coding is terms and the task is to divide the terms obtained from the segmentation into several categories.
The second approach is to code texts before word segmentation. This strategy is applicable to text sets composed of weakly structured official texts, such as business plan, prospectus of public companies and other business or technical texts. This type of texts has large textual length, tight structure and clearly defined sub-title.

The first approach requires the deep participation of experts and the workload of coding is bigger; the second one just needs a small number of manual coding due to the use of the topic information of the text, and the workload of the coding is smaller. The advantages of introducing coding technics into underlying topic visualization are to control the number of terms and topics in the visual interface, solve the problem that the visual interface can only present limited objects and ensure the visual effect (Zhang & Zhao, 2013). At the same time, open coding is a classification environment and its disadvantage is that it is possible to divide the terms in the same underlying topic into different categories artificially.

**Interpreting visualization results under a three-layers context model**

After the underlying topic visualization for the topic related text sets, the underlying topic and its terms have been obtained. Only by taking full account of the underlying topic and the context of the term can we correctly understand the true meaning of them (Dey, 2000). On the one hand, the meaning of a term could be ambiguous, such as “Defense”, which can be a term expressed in the sports field, but also can expressed in the military field (Haghighi et al., 2009). Another example is “Flexibility”. For the separate analysis of this term, we do not know whether it refers to the elasticity in physics or flexibility in economics (Mei & Zhai, 2006). On the other hand, when the object of a term is different, its meaning will be different, such as “Size”. It can be the size of the enterprise, market size or staff size. Therefore, the underlying topic or terms must be interpreted in the context where they occur.

We proposed a three-layer context model include domain context, topical context, and linguistic context, which will be shown in the section of results.

**Results**

*Results of open coding of sub-titles and text under those sub-titles*

In this study, the theme of the target text set is risk factors of public companies in the computer application and service industry and the purpose of open coding is to divide the risk factors into several categories. Prospectus is a kind of business texts that is with complete format, and has clear sub-titles marking the corresponding fragment theme and representing the central content of the corresponding fragment. All section titles form the central theme. Therefore, the second approach of coding is adopted. The first step is to extract the sub-titles of all risk factors and form codes; the second step is to classify codes and name them; the third step is to form a category table.

A schema with ten categories were generated by coding and the ten categories are market risk, operational risk, financial risk, products and technology risk, investment project risk, internal management risk, inter-control risk, human resources risk, industry risk, and political risk. The original text is divided into many subsets by coding and terms in each sub text set can be visualized, clustered and displayed separately to achieve the purpose of controlling the number of objects in the visual interface.

*Results of underlying topic visualization*

Texts in the category of operational risk were selected to be visualized and analyzed. The results of underlying topics visualization are shown in Figure 1 and three underlying topics were found by term clustering.
Interpretation of the visualization results under the framework of context model

The result is interpreted under the framework of the three-layer context model which is shown in Figure 2.

The first layer is domain context. The scope of domain context firstly depends on the determination of research objectives, namely discovery of text knowledge of public companies; and then comes selection of the study object. This paper selects the public companies in the computer application and service industry as the object of empirical study. Public companies have many types of texts, such as prospectus, announcements, annual reports and others. Here prospectus is chosen as the target text set. At this point, the follow-up studies should consider issues under the context of the prospectus of public companies in the computer application and service industry.

The second layer is topical context. Prospectus is large in length and has many modules. The sections of risk factors in prospectuses of public companies in the computer application and service industry are selected to form the target text set. The first approach of coding is adopted here and ten categories were generated by coding. Terms included in each category will be clustered into a visual space. In our experiment, the category of operational-risk is the topical context for the analysis of visualization results.
The third layer is linguistic context. Terms in the same underlying topic and terms in the different underlying topics in the same visual space constitute the linguistic context. If there is a need for further research, you can return to the original text to locate a core term and get more profound conclusions through manual reading, analysis and comparison, generalization and summarization and other methods. Further explanation according to the linguistic context is given below:

Topic 1 primarily reflects the internal risk factors. One example is the company’s business concentration risk. Most companies in computer application services industry always adopt a “product specialization” style to focus on advantages of their products. But it also brings the over-concentration operational risk.

Topic 2 mainly reflects the seasonal risk. In China, government departments, the military, medium-sized enterprises, operators and other customers usually adopt budget management system and centralized procurement system. Generally, the project budget is approved in the first half year, tendering, procurement and construction process are executed in the second half year. The user market demand typically peaks in the second half year. Revenues are lower in the first half, and cash inflow from operating activities are mainly concentrated in the second half, while the R&D investment, staff salaries and expenses across months in a year are of equilibrium. This together leads to imbalance and unevenness in company’s profits and cash flows generated from operating activities.

Topic 3 mainly reflects risks from external environment. The first part is the risk of the instability in supply of raw materials and suppliers. The second part is the constraints of the business license qualification.
Discussion and Conclusion

In order to overcome the limitation of visual spaces, the open coding method is introduced to assign terms into different categories, with each category corresponding to a visual space. A large number of objects are divided into different visual spaces for display, which overcomes the space limitation and ensures the effect of visualization.

Aimed at the shortcomings in the interpretability and understandability of visualization results, this paper proposed a three-layer context model, including domain context, topical context and linguistic context. At the same time, this study also found that the first two contexts have been defined when determining the research objectives and data sources. The third context can be improved and enhanced in the research design part.

From the perspective of domain context, if the target text set is the business text set or technology text set, the corresponding strategies should be designed based on these characteristics. Because this kind of texts mostly has clear structure, titles and sub-titles representing topic content. If the target text set is the completely unformatted network health information text, such as questions and answers about diabetes on the online Q&A website, another coding strategy should be constructed. From the point of view of the topical context, the understanding of underlying topics shall be carried out under the subordinate major topic. In the view of linguistic context, more contextual information should be provided for target terms.

One limitation of this paper is the bias of its data source. This paper only uses formal Chinese text (prospectus) with more normative and rigorous text structure to verify the two strategies of open coding and the context model and doesn’t test free texts. In future work, more experiments will be performed on free text sets, such as text sets composed of message in online Q&A.

Abstract
In this study we tried to find a new way based on LDA to detect topics of projects and the papers produced by the projects to grasp the hot topics and topic evolution of the funding agency. We detected 5 hot topics of the projects on ocean acidification supported by NSF and articles produced by these projects based on LDA by computing subject-intensity. And we analyzed the evolution of topics of projects on ocean acidification supported by NSF. After comparing the topics we detected from projects and related papers by LDA with the recommendations proposed by the Ocean Carbon and Biogeochemistry Group, we find the topics detected by LDA is practical and effective. And some suggestions to detect topics of projects and articles with LDA are put forward.

1 Introduction

Topics of projects supported by national funding agency show research frontier and hot research topics of the field. Articles supported by the projects are presentation of the research progress. Some researchers like to find the status and hot topics by browsing the related projects and reading the papers supported by the projects. How to grasp the hot topics and the evolution of the research topics from the information of projects and their research output is becoming a critical task for researchers and funding agency. With the rapid growth of digital information, how to get the hot topics and grasp the tendency quickly and save time to direct to the related topics from large scale information is useful.

In this article, firstly, we try to find a new way based on LDA to detect hot topics of the projects supported by NSF and the papers written by the projects, analyze the research topic evolution of the projects supported by NSF. Then we compare the result of our experiment with some authoritative view of some professional broad to
test the validity of our method. At last, we make some suggestion to detect topics of projects and articles with LDA.

2 Literature Review

2.1 Analysis of projects supported by research Funding agency

According to metric analysis of scientific fund and their outputs, many researchers focus on statistics analysis of allocation of scientific projects (e.g. J.Ying, 2003), financial support (e.g. V.A. Markusova, 2010), subject field (e.g. D.Z. Zhao, 2010; G. Lewison & G. Dawson, 1998; S. Eckhousea, et al., 2008), regional and organizational allocation (e.g. L. Leydesdorf & C. Wagner, 2009; X.W. Wang, et al., 2012; V.A. Markusova, 2010). Some researchers carried out performance analysis of research funding by number of articles, number of citations (e.g. X.W. Wang, et al., 2010; P. Zhou, et al., 2012). These researches payed much attention to metadata indices and external characters of projects and articles to evaluate the performance of the projects. It’s hard to explore the research topic and evolution of research topic. Hot topics analysis and emerging topics detection have been an new and challenging field in scientometrics, C.W. Belter (2012) analyzed the research filed of articles supported by NOAA, to identify the topics of articles supported by the funding with co-words and bibliographic coupling. Few of studies relates to topic detection and evolution analysis of research projects with text-mining technology or LDA.

2.2 Detection topics with Latent Dirichlet Allocation (LDA)

Normally, identification and detection of topic are the basic of research frontier detection. K.K. Bun and M. Ishizuka (2001) used TF*PDF (Term Frequency * Proportional Document Frequency). H.X. Liu, et al. (2010) extracted topics with TF*IDF in their emerging trend detection. This method extracted words according to word frequency and syntax structure rather than the semantics of the topics. T. Hofmann (1999) proposed PLSI (Probabilistic Latent Semantic Indexing) as the first topic model. D. Blei, et al. (2003) proposed Latent Dirichlet Allocation (LDA), which is a generative model based on statistical foundations and which also tends to produce clearly interpretable output in a more robust manner. Several related, augmented variants of LDA have been developed in recent years (D. Hall, et al., 2011). These and other methods built on the foundations of LDA have come to be known as “topic models”. One key strength of LDA comparing with common document clustering methods based on term frequency or K-Means is that LDA explicitly represents each document as being generated from a document-specific mixture of multiple topics (a multinomial over words), which present somewhat semantic context, rather than single word. This flexibility tends to lead to more clear and interpretable topics. The models have generated significant interest because they create fine-grained, immediately interpretable topics that are robust against synonymy and polysemy. In
addition, generating topics and document topic assignments require virtually no human supervision (A. McCallum, et al., 2006).

L. He and F. Li (2012) extracted the topics of scientific documents with topic model, after computing the intensity and impact of the topics, they carried out research trend analysis. H. David (2008) mapped the changing history of ideas using topic models. Stanford Topic Modeling Toolbox (R. Daniel and R. Evan, 2009) can extract topics of documents, according to the map of documents and topics, time slices, theme of intensity change trend can be presented.

3 Data and Method

3.1 Procedure of extracting topics from document with LDA

In this study, we use LDA1 to extract topics of research projects. LDA posits that each document is generated as a mixture of topics where the continuous-valued mixture proportions are distributed as a latent Dirichlet random variable, and every topic is composed by a group of words with different probability. LDA get topics of the documents by iterative estimate. Given a document collection with D documents, assuming the document collection contain W words, K topics, the procedure of extracting topics from document with LDA is as below:

1. For each document d ∈ D, according to Dirichlet distribution \( \theta_d \sim \text{Dir}(\alpha) \), we get topic distribution parameter of document d, \( \theta_d \)

2. For each topic z ∈ K, according to Dirichlet distribution \( \phi_z \sim \text{Dir}(\beta) \), we get polynomial distribution \( \phi_z \) of topic z

3. For ith word of document D, wd,j, according to polynomial distribution zd,j~Mult( \( \theta_d \) ), we get topic zd,j, according to polynomial distribution wd,j~Mult ( \( \phi_z \) ), we get word wd,j

According to the procedure mentioned above, the model cannot get Dirichlet distribution \( \theta_d \) and \( \phi_z \) directly. In general we get the approximate parameter values with the method of parameter estimation, normally with Gibbs sampling algorithm based on Markova chain(Q.Z. Yao, et al., 2011; P.J. Zhang & L. Song, 2012). The value of \( \alpha \) and \( \beta \) should be predefined empirically, \( \alpha = 50/K \) (K means the number of topics of the collection of documents) and \( \beta = 0.01 \) is thought appropriate in experiment(Z.Z. Wang, et al., 2013; X.P. Zhang, et al., 2010).

LDA is a kind of unsupervised topic mining algorithm. D.M. Blei, et al. (2003) computed the most appropriate number of topics with perplexity when he put forward LDA, T.L. Griffiths(2004) used Bayesian method, some other researchers determined the number of topics of LDA empirically (e.g. J.P. Cao, et al., 2014; B. Wang, et al., 2015). All these studies evaluated the model from different views.

1 http://nlp.stanford.edu/software/tmt/tmt-0.2
3.2 Topic similarity

Topic similarity represents the degree of correlation between two different topics, generally using KL distance to measure the differences of two themes in different distribution (K. Cui, 2010). The representation of the word distribution $\phi_{k1}, \phi_{k2}$ of two different topics is as follows:

$$D(P(w|k1)||P(w|k2)) = \sum_{w=W} P(w|k1) \log \frac{P(w|k1)}{P(w|k2)}$$

The standard KL distance is non-symmetric. If the value is 0, it represents the two topics are exactly the same, actually the degree of correlation of the contents between the two topics should be symmetrical. So, we deform the KL distance in order to measure the differences of different topics’ distribution in the symmetric KL distance measure: $KL_s(A,B) = (D(A||B) + D(B||A))/2$.

According to symmetrical KL distance relationships, we calculate the degree of correlation between the topics of project and the topic of fund papers. Then we get the correlation $\psi_{k1,k2}$, $K1$ and $K2$ express different topics. This could be used to calculate the evolution of the topics of the project papers.

3.3 Topic intensity

Topic intensity reflects the popularity of the topic in the document, and its evolution can be measured by observing the changes of the topic over time. This paper adopted the method in literature of P. Wang (2011). According to the distribution of document topics, we give a weight to each document. The document which focus on fewer topics gets a higher score, and the one which has broad contents gets a lower score. Entropy is a good standard that can be used to calculate document weight. Finally, we combine with the weights of the document and the polynomial distribution of document’s topics to calculate the topic intensity.

$$\text{entropy}(d_m) = - \sum_{K=1}^K \theta_{m,K} \log \theta_{m,K},$$

$$w_m = 1 - \frac{\text{entropy}(d_m)}{\max\{\text{entropy}(d_1), \ldots, \text{entropy}(d_M)\}},$$

$$T_t(z_k) = \frac{\sum_{m=1}^{M_t} w_m \theta_{m,k}}{\sum_{m=1}^{M_t} w_m}.$$

$m,d$ represents the probability of the document $m$ belongs to the topic $K$, $M_t$ represents the number of documents within the period of time $t$, $T_t(z_k)$ represents the intensity of the topic $K$ in the period of time $t$. Through Slicing the topic intensity of document by years, both the topic concentration of the projects and the scope and variation trend of projects and papers supported by the projects can be observed. Combining with the topic similarities between the NSF projects and the paper supported by them, we can get the topic intensity of the papers supported by NSF fund in different topics:

$$T(z_k) = \frac{\sum_{m=1}^{M} \sum_{K'=1}^{K'1} \theta_{m,K'} \psi_{k,k'}}{M}$$
3.4 Data and preparation

We selected projects information funded by United States NSF and papers supported by the projects from Web of Sciences on ocean acidification as the experiment data. Ocean acidification is a phenomena which due to the absorption of excess carbon dioxide in the air caused the increase of ocean acidity or the decrease of PH. The current global ocean is in the fastest speed of acidification since 5500 million years. A paper published in Nature firstly discussed the problem which caused widespread concern in the scientific community (K. Caldeira, 2003), and ocean acidification became the hotspot of many international conference, such as the international symposium “Ocean under the conditions of high concentration carbon dioxide” (J.A. Raven, 2005) and so on. NSF is an important funding agency in the United States, which concerns on public health, food safety, water quality, environment, education and some other livelihood issues, and ocean acidification is one of the important funded branches with program code 1382. Considering the representativeness and practical significance, we collected the data on ocean acidification and detect the hot topics and the topic evolution in this field interested by NSF.

Firstly, we retrieved the projects with the search “((ocean* OR seawater* OR marin*) AND (acidif* OR (carbon* OR Nitro* OR sulf*) AND PH))” in the title and abstract of the awards funded by NSF. Secondly, we got all of the awards data containing program code 1382. Then, we merged the two parts and remove the duplicates as the first set. Meanwhile, we get the related papers supported by the funded projects with the similar search from Web of Sciences as the second set. The data instruction is shown in Table 1. The abstract information of funding awards contains the contents of the research topic, the research significance, research members and institutions, and broader impact and so on. Here we interested in research topics, therefore, it is necessary to clean data. This study reference the cleaning rules in publication of T. Chen et al. (2015), and remove the information which useless to the research topic. After artificial cleaning, it generates some independent text documents, then we clear the stop words and stem them, afterward we use LDA model mining the handled data. Refer to LDA model, it has to iterate 1000 times at most to get the best groups as the topics mining result. Then, we compare the different numbers of topics and determine the conspicuous groups to get the suitable number of topics with the method mentioned in publication of B. Wang et al. (2012).

4 Result

4.1 NSF projects and funded papers of ISI

As shown in Figure 1 which pictures the trend of the quality of NSF projects which divided into three groups: standard grant, continuing grant and fellowship and the total amount of funding from 2004 to 2016. The number of projects in 2004 and 2005 was still relatively small, but had increased significantly from 2006 to 2008 when nearly 20 projects were funded every year, until 2010 reached the highest. The number of projects in 2011 is the double of that in 2008, then NSF paid a high attention on ocean acidification in the next years and the trend keeps ever-increasing. As to funding types, the proportion of fellowship is increasing, and the number of standard grant kept 30 around every year, while continuing grant varied considerably relatively. The total amount of funding is higher in 2009, 2010, and 2012 than in the other years when it maintained the fluctuations in the level of $20,000,000. Abnormally, it had reached unprecedented levels in 2009 when the new U. S. President Barack Obama took over officially and the Federal Ocean acidifying Research AND Monitoring Act firstly began to implement in March. The implement of the act not only was the result of ocean acidification becoming more and more serious, but also made it highly concentrated.

Figure 2 shows the trend of papers of Web of Sciences funded by NSF from 2008 to 2016. It can be seen that the overall number is gradually increasing year by year except 2012 when the production may be resulted in the cut of funding and the number of projects in 2011. Above analysis roughly reflect the changes in projects and papers funded by the NSF organization each year, which is unable to figure out what the projects funded by NSF exactly focused, hence, the further study on the topics of the projects content is necessary.

Figure 1 the number tends of projects and funding of NSF
4.2 The intensity of NSF projects

We got 5 topics on ocean acidification based on the LDA topic model calculated and parameter optimization. Then, we pick up the top 15 keywords of each topic, abandoned the words which appear in three groups simultaneously and have no represented meaning, such as ocean, carbon and so on, finally show in Table 2.

According to the words groups of topic1, the main key words, including organ(ic), microbi (ology), reaction, cell, function, etc. After consult with some experts, we identify topic 1 is about the relationship between ocean acidification and the marine organic materials and the general marine biology. The concentration of seawater carbon is a crucial environmental parameter to the marine organisms. Some of the marine organisms need calcium carbonate in seawater to build shells and skeletons of
raw materials and many need keep the concentration of carbon dioxide in the extracellular fluid and water in a certain range in order to ensure the normal respiratory function. Acidification directly affects the sea creatures living conditions, due to diversely different biological effects, this topic focuses on the large scale observation and investigation of marine organisms and microorganisms, which can directly reflect the severe impacts of ocean acidification.

Topic 2 has the main keywords of dissolve(e), inorgan(ic), paramet(er), sample, alkalin(e), ion(ic), which basic covering the cue words of carbon dioxide measurement system elements, so is it as the topic2’s main theme. The measurement parameters of the ocean carbon dioxide system generally includes four factors: dissolved inorganic carbon, alkalinity, pH value, the equilibrium fugacity of carbon dioxide in water samples (A.G. Dickson, 1993; E.E. Bockmon, 2014). Changes of carbon dioxide content in the ocean influence the degree of ocean acidification, and the measurement of carbon dioxide system can evaluate the survival state of sea creatures, and the observation on biological activities in different carbon dioxide environment can predict the effects to marine biosphere caused by ocean acidification, and the experiment measurement on sample can provide practical solutions. Measurement of ocean carbon dioxide system is the beginning and important process of the research of ocean acidification. Without the measurement of carbon dioxide system there would be no accurate data sources for study and detection of the experiments, so do the research findings lose some persuasive.

Considering the main keywords in topic 3, such as sea water, isotop(e), observ(e), sediment, dissolut(e), atmosphere, it can be estimated topic 3 is about the application of isotope in the study of relationship between ocean acidification and climate change rate and global cycle of carbon and nitrogen, and at the same time, this topic contains the effects of the sedimentary and dissolved calcium carbonate to ocean acidification. The main theme of topic 4 is on the impacts of ocean acidification on calcification of marine creatures, which be inferred by the words of coral, reef, effect, affect, calcification etc.. It’s known that low pH value will affect the rate of calcification of marine organisms. As one of the most important livings in ocean, coral reef contains diverse organisms and has remarkable economic benefits. Ocean acidification does not only influence the activities of calcified organisms, and indirectly influence the flora and the fauna depending on them (O. Hoegh-Guldberg, et al., 2007; J.M. Pandolfi, et al., 2011). Besides coral reef, there are some other creatures with calcification, such as mollusks, echinoderms, fishes and so on. The responses of different species to ocean acidification are so different, and the study is beneficial and necessary to both economic and biological systems.

The subject of topic 5 is easily to be concluded by the words of model, ecosystem, climate, biolo(gy), data and so on which represent biological model construction, analysis and comparative of data model, the relationship and influence between ocean acidification and global ecosystem. Constructing model is an important means and method to study the complicated problems. There are a wide variety of biological species in the marine system and the different areas of ocean are not identical. Through the construction of marine biogeochemical model, data analysis and
comparisons of the similarities and differences of various species in different ocean zones (M.C. Leal, et al., 2015; G.G. Waldbusser, et al., 2013), more precise judgments and predictions on the rise of carbon dioxide caused by climate change will be made.

As discussed above, topic 2 is about data acquisition, topic 5 is the methods on studying the problem, and topic 1, 3, and 4 are about the different impacts of ocean acidification caused and causing, which were the habitats of marine organism, the economic benefits and climate change.

In order to test if our experiment detect the right hot topics of ocean acidification, we compared the 5 topics detected by LDA with 11 recommendations on ocean acidification research direction of the United States over the next 5-10 years proposed by the Ocean Carbon and Biogeochemistry Group(2009), established the ocean acidification subcommittee and chaired the ocean acidification research direction of the United States over the next 5-10 years. We found a certain corresponding relationship in the research content can be found. For example, topic 4 focuses on the effects of ocean acidification on calcification research, especially on the coral reef, while the 2rd and 5th recommendations are also advocated this topic. Topic 5 deliberates the data model on ocean acidification which also be seen in the 8th recommendation. Therefore, it can be considered that the topic clustering results of LDA model is a good way to express the main research contents of ocean acidification projects NSF funded.

According to the topic intensity formula above to calculate and draw the topic intensity variation of the projects funded by NSF, as illustrated in Figure 3.

As shown in the line graph, topics 2 and 5 are facing the decline trends overall and the downward trend of topic 2 is more obvious. In 2004 when the intensity ranked second, however it dropped to the bottom after 2009, indicating that the attention of NSF on the measurement of carbon dioxide system is weakening. The relatively smaller decline of topic 5 suggest that the construction of the model to simulate the response of marine ecology to ocean acidification is gradually reduced, meanwhile, the continuously high proportion indicting that topic 5 was still an important parts of NSF
projects. In contrast, before 2006 the strength of topic 4 was generally in a lower level, then gradually increased after 2006 and maintained at a high level in recent years. It suggests that the study on marine calcifying organisms to ocean acidification is a hot research topic of NSF funded nowadays. Although in several years topic 1 and 3 have abnormal performance, but the intensity changed little in the overall sight. Topic 1 reduced slightly in recent years, while topic 3 remained stable relatively, indicating that topic 3 is still under development. In the sight of the fluctuations of the intensity change, the volatility of the 5 topics presents large amplitude in the earlier years and gradually became small, which implies that NSF has been clear and steady on the direction of main topics of ocean acidification.

4.3 The intensity of papers supported by NSF of ISI

LDA model is used to mine the topic of the papers supported by the selected NSF supported of projects in Web of Sciences. After calculating the similarity with NSF projects, the intensity variation of the papers on the above 5 topics by years is shown in Figure 4.

![Figure 4 the intensity variation of the topics papers of ISI funded by NSF](image)

Observing the intensity variation of each topic, topic 2 and 5 stay on a low level in the most of the years and changed little, reflecting that papers related to these topics are relatively fewer. The output of topic 2 ranked in second in 2008 when it was principal areas of concern, but subsequently, it has been always in a low level. Topic 1 has been gradually declining. Combined with the changes in the number of papers every year, the output of topic 1 kept in a certain amount but not in an intensity scale. At the same time, it is apparently found that the intensity of topic 3 has varied apparently, it slowly raises from 2008 to 2012 and declines rapidly in 2013, then firms up a little in 2014 and 2015. In contrast, topic 4 remained sluggish growth in a certain extent, and it could be concluded that topic 4 outputted the highest proportion’s core papers.

Comparing the intensity of both projects and papers supported by NSF in WOS, the variation of papers’ intensity is consistent with the projects’. When the hot topics of some projects changed, the intensity of the papers’ topic followed. The intensity rank of topic 5 in the papers is lower than that in the projects, which represented that topic
5 had a relatively low yields, while the other topics is in the almost same rank indicates that the intensity of other topics in projects is consistent with that in papers.

5 Discussion and Conclusions

In this study, we apply LDA topic model to mine the main topics on the projects funded by NSF of ocean acidification. We also calculate the variation of the intensity of each topics by years, which shown the hotspots NSF paid attention to and the proportion arranged every year. Then we use the WOS papers about ocean acidification funded by NSF to measure the publication output of each topics and found some consistence with the funded awards.

The method used in this study has opened up a new perspective to analysis the funded award data, which not only reveals the hot topics of a certain subject, but also presents the trend of the topics evolution. The results are able to predict the proportion and funding trends in the future, and provide some references and supports for making plans or adopting policies.

Several suggestions in using LDA to detect hot topic and topic evolution are put forward. First, In the process of data, it is necessary to clean up and to eliminate the general stop words to exclude the useless information. Secondly, in the process of topic explanation, it is important to consult some experts or to make some preparation for the professional knowledge.

Some ongoing study have been carry out to compare the topics with projects in the same field supported by NSF and NSFC, that means to carry out experiment on Chinese with LDA to detect hot topics and topic evolution.

Bundle of sleeping-beauties:  
The case of Paul Hagenmüller and solid-state chemistry

Adil El Aichouchi1  Philippe Gorry2

Introduction

Paul Hagenmüller, and solid-state chemistry
Paul Hagenmüller (1921 – 2017) was one of the most well-known and influential French chemists of the second half of the 20th century. He is considered the father of solid-state chemistry (SSC) in France and head of a school at the University of Bordeaux. Solid-state chemistry, also referred to as materials chemistry seeks to synthesize new solid phase material and to study them by both chemical and physical methods (Hagenmüller, 1999; Teissier, 2010).

Sleeping beauty in scientific literature
In scientometrics, the phenomenon of delayed recognition has been well described since the pioneering observations of Garfield, and referred to today as sleeping beauties (SB). Van Raan (2004) defined SB as articles that go unnoticed (“sleeps”) for a long time and then, suddenly, receives a lot of citations by a “prince” (another article). Scientometrics offers three kinds of quantitative criteria: average-based criteria, quartile-based criteria and parameter-free criteria (Ke, 2015).

Objectives
Studying delayed recognition can be very useful to understand the dynamics of scientific change. The present work aims to study to what extend the phenomenon of delayed recognition have affected the birth, dissemination and autonomy of solid-state chemistry. We analyze the scientific production of Hagemuller’s body of work and the citation life of his publications looking for sleeping beauty. Then, we attempt to identify the relevant prince, and try to understand the reason for delayed recognition and awakening mechanisms.

Materials & Methods
To collect the publications of Paul Hagenmüller, we used Scopus® database. A collection of 646 publications and 13,676 citations were harvested until the 31st December 2015. Excel was used for statistics and calculations. Using Ke et al’s criteria (2015), the beauty coefficient (B) was calculated for all of Hagenmüller’s papers in order to detect top SB. The quantitative analysis was complemented by a historical analysis of SSC.

Results

Hagenmüller published his first paper in 1964 in Journal of Inorganic and Nuclear Chemistry. During his 38 years’ career, he published 620 original articles, and collaborated with more than 150 different authors. He published his last paper in 2002. His scientific work totaled 13,676 citations and reached 651 citations/year in 2015.

The calculation of the B coefficient using Ke’s equation for all of Hagenmuller’s papers reveals the existence of possibly 7 SB published between year 1965 and 1985 (Table 1), and awakened between year 1993 and 2010 (Figure 1 and 2).

These publications are related to 3 different research subjects: SB #1, 2, 4, 5, and 6 are related to sodium-ion batteries; SB#3 is related to sodium cobaltate and SB#7 to silicon clathrates. Citation histories of SB #1, 2, 4, 5, and 6 are aggregated in Figure 1, and in Figure 2 for SB#3 and 7. In both figures, reference line lt (black line); distance dt maximizing the awakening time (dashed line) and, awakening time (vertical line) are reported. Moreover, the publications trend per year of the related research subject is described for sodium-ion
batteries (Figure 1; black dotted line) and for sodium cobaltate and silicon clathrate research fields (Figure 2; dotted line).

**Figure 1.** Citation history of SB 1, 2, 4, 5, and 6 and publication trends.

**Figure 2.** Citation history of SB 3 and 7 and publication trends.

**Discussion**

**Sleeping-beauties dormancy and awakening**

The change in social situation and development of the battery technology might explain the awakening of first group of SB. Studies on Na-ion batteries have attracted significant renewed interests since 2010 because they are considered safer and are a lower-cost candidate for large-scale energy storage compared to lithium-ion. The same hypothesis can be formulated for SB#3 on sodium-cobalt oxides which is related to research on positive electrodes for lithium and sodium electrochemical. Studying clathrate-type phases of silicon and related elements were considered as simple crystallographic curiosities for a long time. The discovery of fullerenes renewed the interest in them (Pouchard & Cros, 2014), and one might postulate that SB#7 awakening was stimulated by the Nobel prize in chemistry awarded in 1996. We must stress that SB #3, 4 and 6 were published in French. Since Hagenmüller’s laboratory transitioned slowly from French to English as it has become the main language for scientific communication (Table 2), it is possible that the diffusion of those papers was limited by this choice.

**Table 2.** Hagenmüller’s articles language use

**Bundle of sleeping-beauties**

SB cluster have been described by Van Raan (2016) through co-occurrence word and concept map. Ke et al. (2015) also observed that papers belonging to the same topic exhibit remarkably similar citation histories. In parallel, Prince clusters’ and the need of multiple PRs to awake SB have been discussed by Teixeira (2016). In our case study, we would like to introduce the concept of “bundle” of SB as a cluster of SB related to one research field or an author, not necessarily through co-citations. Since SB is potentially associated to resistance to discovery and science paradigm shift, we might postulate that it would affect not only isolated publications but also related work from the same author or the same research field for which a consolidated B coefficient could be calculated based on the cumulated SB citations to ascertain the delayed recognition for the whole body of work (B coefficient 325,741).

Introduction

The Clarivate Analytics Web of Science (WoS) has served as a research dataset for more than 9,000 scholarly articles in the past 15 years alone—across a wide range of fields and disciplines from toxicology to computer science to economics. Scientists and scholars have been particularly interested in the WoS citation network, a massive graph containing billions of links that can proxy the structure and dynamics of not only scholarly communication, but knowledge diffusion, the evolution of fields, and the career lifecycles of individuals and institutions. To power these investigations, scholars are increasingly employing a number of compute-intensive methodologies, sophisticated big data infrastructures, and so called collaborative “discovery science” tools and techniques. Suddenly, in addition to deep, domain specific expertise, world-class computational knowhow appears to be a new prerequisite for analysis of scholarly data at the scale represented by WoS. While cloud-based computing and tools are more prevalent and accessible than ever before, harnessing these technologies remains both a challenge and opportunity for researchers and data providers (i.e., Clarivate Analytics and similar commercial data vendors and non-commercial aggregators). While the opportunities made possible by scholarly data at the size and scope of WoS for discovery and innovation are limited only by imagination, two general prospects come readily to mind. First, access to these data coupled with the appropriate computational and analytical capabilities opens up a wide range of funding and subsequent publishing opportunities in high impact venues. Second, data providers can pursue new business opportunities, including novel data access models, new types of analytic products, and new kinds of academic/industry partnerships. In this poster paper, we briefly explore 1) the new computational infrastructures that are being developed to enable collaborative research that leverages scholarly datasets such as WoS that are both big and proprietary; 2) some recent findings that have been made possible by these infrastructures; and, 3) new commercial offerings that have been enabled and demanded in response to increasing reliance on the WoS as a research dataset.

New Computational Infrastructures

Research leveraging big, scholarly datasets like WoS presents researchers with challenges related to the data’s size, inherently relational format, and sensitive (proprietary) nature. To overcome these challenges, researchers have developed a new generation of enclave supported, high performance, and cloud-based, collaborative research environments that are both big and proprietary; 2) some recent findings that have been made possible by these infrastructures; and, 3) new commercial offerings that have been enabled and demanded in response to increasing reliance on the WoS as a research dataset.

IUNI WoS Data Enclave

The Indiana University Network Science Institute (IUNI) acquired the complete set of Clarivate Analytics’ Web of Science XML raw data (Web of Knowledge version 5). The data was parsed and stored in a well-documented Postgresql raw database, entity-relationship diagram, database schema, and
Leveraging WoS in Research and Practice

Fostering Global Collaboration

Among others, IU started to use the IUNI WoS data to understand existing and foster global research collaborations. The world map in Figure 1 shows the co-affiliations of authors that listed “Indiana Univ” and at least one other non-U.S. institution as affiliation on 1,590 scholarly papers published in 2004-2013. There are 344 affiliation locations (not counting IU) and 641 co-affiliation links. Nodes denote author locations and are area size coded by degree with the exception of IU, which has 1,592 co-affiliation links. Links denote co-affiliations, e.g., an author with three affiliations IU, X, Y will add three links; the two links that connect IU with X and Y are drawn in red while the link between X and Y is given in green. Links are size coded by the number of co-affiliations with the top-three being Beijing, China (155), Eldoret, Kenya (115), and Pushchino, Russia (90).

Cloud Kotta

One platform specifically developed with WoS in mind is Knowledge Lab’s Cloud Kotta (CK). CK is a secure data enclave and analytics platform that serves the research needs of social sciences (Babuji 2016). By hosting CK in the Amazon Web Services cloud, the developers were able to take advantage of virtually limitless compute, cost-effective storage and the ability to implement a fine-grained security model ensuring the authorized collaborators could access both data and compute resources from any where in the world (Babuji 2016). Moreover, CK supports multiuser, rapid ideation and research iteration through a novel Python library that enables specific functions in an analysis code, written in a Jupyter Notebook to be seamlessly and securely submitted to the CK execution fabric (Babuji 2017). By allowing researchers to develop and share analysis code interactively over secure data like WoS, CK has removed the need for deep computational infrastructure expertise. The complete WoS XML dataset was ingested into a relational database housed in CK using a custom parser that has been made freely available on GitHub (see: https://github.com/alexander-belikov/wos_parser). The Cloud Kotta WoS database schema can be found on CK’s documentation pages (see: http://docs.cloudkotta.org/dataguide/wos.html). More about Cloud Kotta can be found at http://docs.cloudkotta.org.

Impact vs. Disruptiveness

Researchers at the University of Chicago’s Knowledge Lab and Northwestern University’s NICO have used WoS data going back to 1900 to study the relationship between team size and impact and the relationship between team size and disruptiveness. This work, currently under review, finds striking differences between the scientific output of large and small teams. Looking across all fields represented in WoS, small teams are shown to disrupt science, patents, and software with new ideas and opportunities, while large teams contribute to existing ones. Figure 2 shows the relationship between impact and disruptiveness of articles (left panel) indexed by WoS, patents (middle), and software (right). In all three spaces, there is a strong, inverse relationship between citations and disruptiveness as team size increases.
New Commercial Offerings

The value of the Web of Science as a search and discovery tool is well established at thousands of research institutions worldwide. But the commercial opportunities for the use of its high-quality metadata outside of the platform for big data studies are still emerging. When researchers need to study broad-scale trends in science, technology, and innovation, they very often turn to the Web of Science as the most comprehensive citation source to provide over 100 years of consistent, global publication data. Increasingly, user requests for this data take the form of custom reports, curated data sub-sets, and large-scale raw XML delivery. Clarivate Analytics is actively looking at compelling ways to meet these customer demands with new commercial products and data delivery choices. These options must balance scale and ease of use, with security and control over access to the proprietary WoS data. The lessons learned in the development of Cloud Kotta and IUNI WoS Data Enclave will very likely be instructive here, as they have proven their utility and leverage a mix of custom code built on proven commercial cloud services. Both self-service data access and secure use of analytical tools in a cloud “sandbox” seem like attractive features of these environments that could make commercial sense to meet the evolving expectation of Web of Science customers.

Introduction

After 70 years under the Soviet rule, in 1991 the Republic of Armenia has regained its independence. Soon, the republic was faced with a number of problems in nearly all areas, among them also in science. A sharp decline of the republic’s once huge scientific potential was marked. As a result of brain-drain and reorientation the scientific personnel involved in the research and development was reduced nearly 3-fold, while science funding was reduced by nearly 90% (Gzoyan et all, 2015). R&D institutions and organizations were rapidly closing or restructuring and reorganizing into business projects due to the brain-drain and lack of finances. The first two decades after the independence were the years of survival and adaptation for the Armenian science and scientific community (World Science Report, 1996; World Science Report, 1998).

Apart from the above-mentioned reasons, the R&D personnel also experienced subjective shortcomings: differences in Soviet and Western type education and methodologies, language difficulties, poorly equipped laboratories, etc. All the mentioned factors were hindering the integration processes in the scientific field.

The mentioned reasons and a general chaotic situation in the country resulted in the localization of the science in Armenia. The Soviet policy of “iron curtain” was preventing collaboration between the Soviet and Western scientists, among which also publications in Western journals, also contributed to this.

This localization resulted in the further growth of national journals. In the absence of any incentive to publish abroad, plus linguistic and methodological differences deter the Armenian scientists from publications in foreign journals. Thus, a huge percentage of the science made in Armenia was closed for the world. From 1991-2016 the number of publications in WOS from Armenia was nearly 17,000, which is only 10% of total publications.

This situation raised the necessity to create the national science citation index to assess the situation in the field of science and assist integration processes.

Armenian Science Citation Index (ASCI)

The Center for Scientific Information Analysis and Monitoring was established in 2010 with an aim of unification and integration of the Armenian Science into the World Science.

One of the main tasks of the Center was the elaboration of the Armenian Science Citation Index (ASCI) (Sargsyan et all, 2010).

The goals of ASCI are the following:

- To collect the publications of the Armenian scientists in one database;
- To collect all Armenian scientific journals in one database;
- To collect the publications of the Armenian scientists referred in the international databases;
- To select best journals based on bibliometric indicators.

Nowadays there are nearly 150 scholarly journals published in Armenia. They are mainly in Armenian with or without an English language abstract. Only 3 journals – Astrophysics, Journal of Contemporary Physics (Armenian Academy of Sciences), Journal of Contemporary Mathematical
Analysis (Armenian Academy of Sciences) are indexed in the Web of Science database. Despite some works towards the increase of the Armenian journals in the WOS, this number is not yet changed. The number of journals indexed in ASCI is nearly 50 with the time frame 2007-2016. The difficulties involved at this stage are the small staff involved in the work and that a huge part of the work is being done manually. There is a problem with finding the publications to be indexed; frequently their format doesn’t correspond to the portal requirements. 

Apart from working with the databases, the Center is also involved in dissemination issues, as the idea is not easily accepted by the Armenian scientific community and needs to be spread and explained. This work is being done on daily basis on state (state bodies), institutional (scientific organizations, institutions, publishing houses) and personal levels (researchers, editors, etc.).

As a result of developing ASCI and work with different stakeholders, we have noticed a considerable raise in the Impact Factors of the Armenian journals and their overall technical and quality indicators (investment of the peer-review system). Every year the number of journals considered in the ArmJIF (Armenian Journals’ Impact Factor) is also raised (Sargsyan et al 2013).

At the same time the Center is elaborating ASCI portal with its necessary tools and supporting databases having a prototype WOS portal. ASCI portal is a multi functional information system which analysis a complete bibliometric data, abstracts and citations from the Armenian scientific journals. Such known indicators as the number of publications, number of citations, their averages, Hirsh index, and Impact factor of the journals are calculated together with dozens of other metrics. ASCI portal will comprise an Armenian Journal Impact Factor (ArmJIF) and Armenian Data Analytical Tools (ArmDAT) to make necessary comparisons, analytics, etc.

Introduction
This study analyses the citation evolution of scholarly books based on the Book Citation Index (BKCI) from two perspectives: year of publication and discipline. We have selected all the scholarly books, which were collected by BKCI, published from 2005 to 2015. This paper is organised in this manner. In first section, we describe the annual variation about the publication quantity and citations of scholarly books in different disciplines. Second section is dedicated to analyse the citation frequency distribution. The last section presents the citation curve of scholarly books from the aspect of literature age.

Annual variation about the publication quantity and citations of scholarly books in different disciplines
The quantity of scholarly books shows an increasing trend in the early years and relatively stable in recent years and varies from disciplines. Scholarly books in Social Sciences, Arts & Humanities have been published in large quantities, but their citations are much lower. In contrast, in Life Sciences & Biomedicine, the citations of scholarly books are significantly higher than other disciplines, while the publication quantities are low.

Figure 1. Annual variation about the Publication Quantity in different disciplines

Figure 2 shows that the scholarly books which published in early years have more citations than the recent ones, and it also indicates the degree of influence from publishing year varies from discipline to discipline.

Figure 2. Annual variation about the citations in different discipline

Figure 3 reflects the zero citation rate of scholarly books. The diagram shows it presents an increasing trend. In early years, the zero citation rate rises slowly year by year, but in recent years, it increases rapidly. There is little difference between the disciplines although the proportion in Social Science and Art and Humanities are higher than other disciplines.

Figure 3. Annual variation about the uncited rate in different disciplines

Citation frequency distributions
The citation frequency distributions of scholarly books have shown the strong polarisation. The share of the lowest and the highest cited frequencies is over 60% and nearly 10%, which is much higher than the other citations intervals.
Across different disciplines, scholarly books in Life Sciences & Biomedicine and Physical Sciences performed better than other disciplines in the highest cited frequencies interval, while scholarly books which have the lowest cited frequencies are more likely in Social Sciences and Arts & Humanities.

Publication year is another important factor. Data in Table 1 is calculated using the formula below:

\[
D = R_I(y) - R_J(y) \quad \text{for } i \neq j, \quad y \in [0, 10] + \infty
\]

In the formula above, \( y \) means the publication year, \( R_I(y) \) means the citation frequency of the books published in year \( y \) received in year \( j \), \( R_I \) means the proportion of books which citation is \( bij \) since published.

We found that the earlier the scholarly books published the more citations it will receive, especially in Physical Sciences and Life Sciences & Biomedicine. The polarisation of citation frequency distributions is show much stronger in the earlier publication years in Social Sciences and Arts & Humanities.

Life-time curve of citations

Uncited Rate

Scholarly books in different disciplines reveal similar uncited rate characteristics. Most scholarly books would receive at least one citation in four years.

Citation Curves

Figure 6 indicates that the citations obtained in a given year varies significantly with the age among all disciplines.

Life Science & Biomedicine, and Physical Sciences, the citation frequencies increased rapidly since the book published, and when reach to the peak, the annual citations drop slowly year by year. However, the peak appears in different years between the two disciplines. The other three disciplines do not have obvious peak in the statistical period, the citations increase with the age.
Topic modelling based network maps in cardiovascular research

Introduction

Structural mapping and the detection of topics together with their dynamics within a given field of research remains a challenge within scientometrics. Journal-level classification systems do miss the required granularity and fail to adequately describe specific areas within research and so article-level information must be utilised, including lexical and citation data.

Previous studies have shown that using a hybrid approach, combining information from both lexical and citation data, produces more relevant findings at this level of analysis (Boyack et al., 2011; Boyack & Klavans, 2010; Janssens, 2007; Janssens, Glänzel, & Moor, 2008; Liu et al., 2010; Liu, Glänzel, & De Moor, 2012; Šubelj, van Eck, & Waltman, 2016). Thijs et al (2017) showed that combining similarities based on noun phrases extracted from titles and abstracts using Natural Language Processing (NLP), with bibliographic coupling similarities provided further insight into the topics studied and changes over time. Boyack et al (Boyack et al., 2011), when mapping two million publications from PubMed, also concluded that a hybrid technique using NLP and BC resulted in more accurate findings.

However, discrepancies between the lexical and citation based links remain present in the current approaches. The density and thus the underlying degree distributions deviate from each other. Due to quite common lexical expressions it is more likely that papers are connected than through the references to highly cited papers. Term frequency weightings like TF-IDF solve this problem only after the calculation of the similarity and after the application of a chosen threshold. Extending the list of stop words for removal might be suggested but the list of these common expressions can be long and contain meaningful phrases, removing them would in many cases destroy strong document links. In this paper, we propose an alternative approach for feature selection as an input to similarity calculations. We will use topic modelling in a large dataset as a mean to provide the necessary data to create lexical documents networks to solve the issue of higher density. The objective of this paper is to present the method and preliminary results obtained from applying Latent Dirichlet Allocation (LDA) to create a topic model and topic network map based on a large cardiovascular dataset.

Methods

Dataset and source

We obtained the publication meta-data in the cardiovascular field (2004-2013) from the Web of Science database, based on an in house license held between ECOOM and Clarivate Analytics. Of the 478,436 articles, letters, reviews and notes in the cardiovascular field that were identified, as previously described (Gal, Glänzel, & Sipido, 2016), 478,006 contained abstracts. We pre-processed the abstracts to extract noun phrases and term shingles using Stanford NLP (see Thijs et al 2015 for more details). We removed all copyright notices at the end of the abstract, all expressions containing numbers and all white spaces to reduce the overall list to almost four million unique phrases. We then removed the most commonly used phrases based on the h-core (those expressions -in a descendant ordered list- which rank is lower than their number of occurrences).

Topic modelling

Next, we applied Latent Dirichlet Allocation (Blei, Ng, & Jordan, 2003) to the document-term matrix using MalletR to obtain the beta and gamma for the topic-term and topic-document probabilities, respectively.
**Topic-document clustering**

The topic-document matrix containing the probabilities that a document is related to a particular topic is a very dense matrix but holding often very small probabilities in the cells. Straightforward salton cosine calculations would result thus in an almost complete network. Moreover, documents that have very small probabilities on all topics are very likely to form a densely connected clique with very high similarities. Those documents have to be removed from the set. In fact, we replace all probabilities below the topic average in the matrix by a missing value. Several documents will have such missing values on all topics and will become singletons in the document network instead of ending up in a strong cluster.

Next we use Locality Sensitive Hashing (Ravichandran et al 2005) for the calculation of the cosine similarity. The main advantage of LSH in this context is that through the use of randomization functions the actual calculation is only restricted to those pairs of documents that are very likely to be similar. Through this restriction we do not calculate cosines between pairs of documents with very low similarity as these links would be removed afterwards from the networks as they have a strength below a given threshold.

**Findings**

**Topic modelling**

In our preliminary review, the top groups of terms identified for each of the 200 topics, seemed to represent coherent topics in cardiovascular research or in methods applied in cardiovascular research. A limitation of topic modelling, however, is the need to define the number of topics to set apriori, requiring qualitative review to assess the validity, overlap and granularity of the topics.

**Table 1. Topic Model Overview**

<table>
<thead>
<tr>
<th>LDA</th>
<th>Description</th>

<tr>
<td>Average number of topics</td>
<td>6</td>
</tr>
<tr>
<td>with gamma&gt;0.01</td>
<td></td>
</tr>
</tbody>
</table>

*the number of topics is set apriori by the researchers

**Conclusions and next steps**

Next we will use community detection techniques like the Louvain clustering method and infomap to detect topic clusters in the documents. It is expected that the application of LDA for feature extraction will produce a network with properties more in line with bibliographic coupling based networks than using other lexical feature extraction methods. And that the topic detection is less sensitive to problems like resolution limit and degeneracy.

Introduction
Microalgae are considered one of the most promising sources for biofuels (Wijffels & Barbosa, 2010). However, this alternative to fossil fuel must overcome technological and economical barriers. To gain insights into the evolution of research on biofuel production from biomass, scientometrics characterization of biomass (Chen & Ho, 2015), waste recycling research (Garechana et al., 2015) as well algae and biodiesel patenting trends (Preiss & Kowalski, 2010) have been reported. These studies have highlighted the exponential growth of bioenergy research and the dominant position of the USA in this area. However, in many countries the invention of biofuel technologies slowed down by year 2008 (Albers et al., 2016). A first attempt to link the evolution of biofuel science with R-D expenditure has been published (Azadi et al., 2017) but, none of these previous studies embraced at the same time science, technology and economic indicators to describe the evolution of biofuel innovation.

The purpose of this work is to describe biofuel research and technology trends focusing on microalgae-based biosource through a multidimensional analysis to reveal influential factors (scientific, technologic, economic or environmental).

Materials & Methods
Literature search on microalgae and biofuel research was conducted in Scopus® database until 31/12/2015, with a query across the title, abstract or keyword fields in all types of records using a string of keywords associating biofuel and other synonyms (n=6), and the major species of microalgae (n=65). Patents with priority date before 31/12/201 were retrieved from the INPADOC family patents worldwide collection using Questel® software with the same search query used in Scopus®. Patent bibliographic data were analysed with the Intellixir® software, and metrics based on patent family. Press releases were searched within the Factiva® database across the title and abstract using a simplified version of the search query run in Scopus®.

Macroeconomic, and green indicators were gathered from the OECD statistics web portal: Gross Domestic Product (GDP, in US$/capita), biofuels patent (family number), environmental public investment (US$ Millions, PPP 2010). Other indicators, such as data in relation to the oil production was gathered from U.S. Energy Information Administration (https://www.eia.gov/), or the sunshine duration (hours by year for capital city) were retrieved for each country from U.S. National Oceanic & Atmospheric Administration (http://www.noaa.gov). Descriptive statistics were run for the different indicators and some inferential statistics were performed with the help of XLSTAT® software in order to describe association or correlation between science, technology, and other indicators.

Results

Science indicators
A corpus of 163,006 and 302,774 documents were respectively collected for microalgae and biofuel research fields. The intersection of these two sets gives a final corpus of 25,712 documents defining microalgae-based biofuel research field. This research domain took off in the ‘70’ followed by an exponential growth in 2010 (Figure 1; black line).

Figure 1. Microalgae biofuel innovation trends.

The contribution of different countries ranks US first, without any dominant position, along with
BRICS countries in the top 10 (Table1). The main publishing research institution is the Chinese Academy of science (data not show).

</tr>
</tbody>
</table>

**Table 1. The most publishing countries.**

**Technology indicators**

A collection of 2,992 patent families was retrieved. Microalgae-based biofuel innovation trend was measured based on patent filing priority date (Figure 1; dashed line). Then countries were ranked according to their patent family number: surprisingly, China came first, followed by US and Korea (data not show). In order to model the technology transfer efficiency, a linear regression was run to explore the relationship between the patent family number (Y) and publications number (X) as explanatory variable (Figure 2). While we can distinguish between high and low performing countries, the coefficient of correlation remains low ($r^2=0,542$) leaving us the existence of other independent variables.

**Macroeconomic & Environmental indicators**

Multiple regressions were run with various indicators (scientific, technologic, economic or environmental). An example of such analysis run on a sample of 10 countries (including DE, DK, FI, FR, IL, IT, KR, MX, PT, UK) is presented (Table 2): there is a strong correlation between the microalgae biofuel innovation (Biogas) and the overall patenting of a country (patent), sun exposure is negatively correlated with GDP/capita and research output (publications), and there is a moderate but significant correlation between green investment and oil production.

**Discussion**

Our results indicate that behind the steady increase of microalga biofuel publications over the last decade, there is some discrepancy with patent filing which could be linked to economic or policies issues. One might think that countries with important sun exposure in favour of microalga photosynthesis, would be research intensive while petroleum exporting countries would not be interested in. Our preliminary results show a more complex relationship between scientific and technological factors, and macroeconomic or environmental factors. This should be explored further through econometric modelling. Such analysis would be useful for both researchers and policymakers to understand research trends and green innovation policy incentives.

The Dissemination of the Concept of “Interventional Radiology” in Medical and Scientific Literature

Léo Mignot¹ and Philippe Gorry²

¹ leomignot@orange.fr
Centre Emile Durkheim UMR CNRS 5116, University of Bordeaux, 3 ter place de la Victoire 33076 Bordeaux (France)

² philippe.gorry@u-bordeaux.fr
GREThA UMR CNRS 5113, University of Bordeaux, Av. Leon Duguit, 33608, Pessac (France)

Introduction
Interventional radiology (IR) was born in the 1960s, at the interface of radiology and cardiology but its institutional recognition was late and incomplete. IR is still the subject of turf wars between different medical disciplines and it is not clear if this field will one day become an independent medical specialty.

Purpose
The aim of this study is to analyze the diffusion of the concept of "interventional radiology" using scientometric approach. The analysis of the history of the concept and its trends allows us to better understand how this medical field has attempted to institutionalize and to gain its autonomy.

Methods
A literature search on « interventional radiology » concept diffusion was conducted in Scopus and Factiva databases for medical science publications, and press releases respectively. Then, we analysed the resulting corpus (n=26655 documents) by conducting a bibliometric, network and descriptive statistics analysis with various analysis tools (Intellixir, Excel). Thus, we were able to examine the history of the concept and to identify the actors involved in the field (authors, journals, institutions and countries) in order to understand the institutionalization process of this medical field.

Results
The first article using the term “interventional radiology” was published by S. Wallace in 1976.

The distribution of keywords associated with the IR concept in publications reveals the predominance of endovascular techniques (angiography, angioplasty, catheters) and interventional cardiology, or “Medical Imaging” and cancer issues. Nevertheless, the temporal distribution of the publications suggests that the concept was rarely used in the literature until the 1990’s. Therefore, the founding fathers of the specialty are not the ones whom have popularized the use of the label “interventional radiology” in the literature (data not show). The growth of publications accelerated in the 2000’s, with a peak of public interest in the general press (Figure 1). The concept is mostly used in American (32%), European (34%) and Japanese (6%) articles. The use of the term in Chinese publications progresses from the late 2000s (Figure 2).

The top publishing institutions are mostly American and British ones (Table 1): the notable exceptions are the University of Seoul (2nd rank), Tokyo University (6th rank) and Toronto University (10th rank).

The two mains journals of the fields are the JVIR and the CVIR, but they account less than 10% of the total IR publications (Table 2).

Discussion

Analysis of publications reveals that the emergence of IR concept in the scientific literature took place several years after the birth of the specialty. Indeed, IR is an example of delayed recognition invention: it is born with the invention of angioplasty by Dotter in 1964, and the diffusion of the concept was contemporary of the awaking of his landmark paper on angioplasty (Gorry, 2016). Thus, the concept was not promoted by the founding fathers, but by new entrants. For example, C. Dotter – who is commonly known as “the father of intervention” (Payne, 2001) did not promote the concept of IR in the literature until 1981. Moreover, if Wallace (1976) is the first to use the term IR, he rarely used it during his long and productive career (10 articles among 382). We can assume that the structuring of the field by scientific societies helped to build a research community and to develop a sense of belonging to the IR field.

The main IR scientific societies have only been created 10 to 20 years after the first medical developments of the specialty (Table 3). This may also explain in part why the emergence of the concept in the literature was so late.

The specialty tried to gain its scientific autonomy, founding its own journals in 1978 (CVIR) and 1990 (JVIR). But, it is a partial failure: these 2 journals account for less than 10% of IR publications.

The appearance of department entitled “interventional radiology" can be seen as another attempt of empowerment and institutionalization. This process can be interpreted as an attempt to legitimize interventional radiology. It is also an identity claim sustained by the proclamation of a clear membership in a medical specialty. More generally, the publications mobilizing the concept of IR focus mainly on endovascular procedures, medical imaging and cardiology. Those overlaps could explain why most of the IR articles are published in the fields of radiology and cardiology. It could also be explained by the desire to communicate the results in journals of those disciplines and to ignore the disciplinary boundaries.

Today, IR still remains a heterogeneous field with unstable borders. The specialty has not reached a full scientific autonomy and its institutionalization process is still ongoing. This partial failure of institutionalization of the IR field could partly be explained by the initial hybrid position of the specialty, which emerges at the crossroads of different disciplines (radiology, cardiology, surgery) (Becker, 2001).

Through the case of IR, this study contributes to our understanding of the nature and history of interdisciplinarity and how it works. It must lead us to be careful to scientometrics indicators and analysis.

Introduction

Journal impact factor has become an important standard to judge the quality of scientific publications over the years, and it also influences the other evaluation system. However, it also subjects to some criticisms. More and more journals adopt the form of publishing online in advance so that readers can browse the latest scientific research in the first time, while more and more researchers will also publish their research results in some open access database, such as some social networking sites. The online publication of the journal has a lot of ways, such as the publication would like to publish some papers or a brief description of the papers on their website in the first time, these papers often are high-quality or current hot topic. These measures can attract the reader's attention to the journal content; Another form is the journal submitting the papers to the database before the date of publication in print form, then readers can retrieve the papers in databases. Nature, Science, Springer, and Elsevier have already used the "AOP", "Express", "online first", and "Inpress" date information, which are generally earlier than the publication date in print form. We only research the online publication ahead of print, which submitted to databases earlier than the date in print. We want to discuss the relationship between online advance publication and Journal Impact Factor.

Data and Methods

In this research, we estimated 284 journals’ Impact Factors during 2012-2015, and we also estimate journals’ online-to-print lags and Lag-corrected Impact Factor. We refer to the method proposed by Tort A B. While Tort A B’s paper only select 61 journals under the “Neurosciences” category, and limit a lot of conditions. So the conclusion cannot be extensive convincing. But we have richer and more general data from every category to verification the influence of advance online publication on Journal Impact Factor.

Journal Selection

We first considered all 3375 journals which we retrieved in Springer database (https://link.springer.com/search?facet-content-type=%22Journal%22). We only reserved 184 journals and excluded other journals from this list because of (a)we only analyzed journals that publication is not zero during 2010-2016,(b)we only analyzed journals that we can retrieval Journal Impact Factor and citation frequency in the Journal Citation Report (JCR) database published by ISI (http://webofknowledge.com/JCR).

Estimation of Online-to-print Lags for Selected Journals

Online-to-print lag was computed as the difference between the online appearance date of an article and its official date of publication, as obtained from Springer records. Mean online-to-print lags for journals were obtained from all published articles in a given calendar year.

**Figure 1. Online-to-print Lags**

Estimation of Journal Impact Factors

Take 2015 impact factor as an example, the 2015 impact factor is defined as the number of citations in 2015 to articles published in 2013 and 2014 divided by the number of articles published in 2013 and 2014.

Estimation of the Lag-corrected Impact Factor

To calculate the lag-corrected impact factor index, we also take 2015 Lag-corrected impact factor as an example. The 2015 Lag-corrected impact factor is defined as the number of citations in 2015 to articles published in 2013 and 2014 divided by the number of articles online appearance in 2013 and 2014. For example, since the average delay period for the journal is three months, papers that published between April 2013 and March 2015, actually would be retrieval in advance. So these articles are online from 2013 to 2014.
Results
We analyzed 284 journals, and the proportion of online publication ahead of print was 52.11%, 66.20%, 66.20%, 66.55% and 69.01%, so we consider that the online-to-print Lags has been on the rise in the past few years. According to statistics, it found that the 284 periodicals of the average delay in the distribution of 0 to 18 months, and delay month showed a gradual increase in the trend. The current journals online advance published has become a more extensive phenomenon.

Figure 3. Journals online-to-print Lags statistics

We first calculated 284 journals’ Lag-corrected Impact Factor. Then we calculated Lag-corrected Impact Factor gradient to study change. The delay month is negatively related to Lag-corrected Impact Factor gradient. If the delay month longer, the Lag-corrected Impact Factor gradient would be smaller, in another hand, Lag-corrected Impact Factor would be decrease.

$$\text{Lag-corrected Impact Factor gradient} = \frac{\text{Lag-correctedIF} - \text{IF}}{\text{IF}} * 100$$

Formula 1. Lag-corrected Impact Factor gradient

We found that Lag-corrected Impact Factor small or unchanged proportion of the total number is greater than 75%, that means if a journal always publishes their papers online in advance, its Impact Factor would be inflated.

Figure 4. 2015 Journals Lag-corrected Impact Factor gradient and delay month distribution.

We found that the bimonthly journals and quarterly’s proportion of the lag-corrected impact reducing is large, while the annual is basically unchanged. Because bimonthly journals and quarterly usually have short and timely publishing period, online publication ahead of print would have effect on impact factors. While annual have longer publishing period, so the effect is weaker. Comparing with Tort A B’s research, some results are similar, such as delays between online and print publication of articles increased steadily over the last years and online-to-print delays would be influence JIF. But we also have the difference. We found that JIF would not always increase, even though a journal always publishes their papers online in advance. Considering the current method of JIF calculation, which is mainly based on the date of publication in print form, despite the fact that most journals now make their articles available online before that date. Because we found that journal online-to-print Lags may affect impact factor, we suggest that calculation of JIF should consider the date of a paper’s online appearance, not only the date of the publication in print.

Introduction

Although there are significant advocacies in favour of Open Access (OA) mandates in the U.K., there are less evidence on how gold OA research (OA from publisher) draws altmetrics compared to green OA (OA from authors or repositories). Numerous research has examined conventional citation advantage of OA, indicating contradicting results (see annotated bibliography regularly being updated by Wagner since 2010). However, there are a few studies on advantages of research access models on altmetrics such as Mendeley readerships and Twitter uptakes (Adie, 2014; Alhoori et al., 2015). Therefore, as a follow-up study current research aims at comparing research impact across access models (Maleki, 2015) in a more OA-intensive country. The research is a large-scale evidence indicating whether and how altmetrics is influenced by various OA models, particularly journal papers accessible through Digital Open Access Journals (DOAJ), PubMed, and ArXiv.

Method

In order to address research question, 413,770 UK journal articles with Digital Object Identifier (DOI) out of 466,640 articles published between 2011 and 2014 was exported from Scopus. Scopus was used due to its broader coverage of Open Access publications. To identify papers’ subject and OA status in DOAJ, source index of Scopus was used. PubMed availability of papers was identified using DOI converter in nlm.nih.gov. In order to examine availability of ArXiv preprints, arXiv IDs was extracted by software developed to submit DOIs through arXiv API. Tweet count and Mendeley readers was collected using software program Webometric Analyst (lexiurl.wlv.ac.uk). All data was collected in June 2017.

Findings

Table 1 indicates that proportion of PubMed-indexed papers were just over three times (34%, 140,548) as much as articles published in OA journals (11% 47,376 articles), whereas the UK articles in Health Sciences were predominantly available through PubMed (60%). ArXiv, however, was used relatively low in Physical Sciences (only 11%, 16,738).

In order to compare means of speculated metrics (see Table 1) Mann-Whitney test was initially used, indicating that all access types significantly showed higher impact compared to non-accessible articles, despite mean readership impact of preprint-provided papers in ArXiv (20) which had slightly, but significantly less readers than non-ArXiv (24). There was a minimal but significant difference in mean Scopus citations to OA and non-OA papers, whereas both PubMed (24) and ArXiv (23) papers advantaged almost twice as many citations as non-PubMed (12) and non-ArXiv (14). Readerships were more numerous than citations while on average PubMed papers (41) were bookmarked almost double that of non-PubMed (21). Similarly, mean readerships of OA (34) was significantly above, but not much more numerous than non-OA (27). Mean non-ArXiv readerships (24) was above ArXiv (20), however. Finally, papers in PubMed (6), OA journals (5) and ArXiv (2) had significantly more average tweets than non-PubMed (1), non-OA (2) and non-ArXiv (1) all significant at p < 0.0001.

<sup>a</sup> UK journal articles (2011-2014) in Scopus with DOIs; <sup>b</sup> Only Health Sciences; <sup>c</sup> Only Physical Sciences; ** significantly higher mean than counterpart category at p < 0.0001 (e.g. OA vs. non-OA); <sup>R</sup> Access type with significant positive coefficient in regression model
As shown in Figure 1, there was a relatively moderate, but significant and slightly decreasing Spearman’s correlation between formal citations and readerships (C-R) of publications in all access forms, probably due to falling number of citations accrued by more recent papers. Correlations for PubMed papers (at around r = 0.6), which is above non-PubMed (changing between 0.5 and 0.6) was the strongest, and correlations in OA journal articles are also marginally above non-OA (both around 0.6). However, the reverse is seen in arXiv where correlations between citations and readerships in physical science (about r = 0.6 for non-arXiv) did not rise with arXiv preprints (around 0.5).

On the other hand, correlations between citations and tweeter counts (C-T) was the weakest in all access models ranging between 0.1 and 0.3, while only slightly fluctuating over years. Despite low correlations, the broadest difference is made by PubMed access, while arXiv and OA journals also had a slight rise of tweets in line with citations.

In contrast to correlations with formal citations, there are increasing correlations between readerships and tweeter counts (R-T) over the period given, which probably reflects the increasing users of Mendeley and Twitter engaging online with academic articles.

Discussions

In order to model the uptake of papers through three access models an ordinary least squares regression analysis was conducted after data was normalised using natural log of metrics plus 1. Findings of regression showed that PubMed accessibility was significantly positive predictive of citations (standardised beta = .143, standard error = .009), readerships (b = .210, e = .005) and tweet uptakes (b = .365, e = .010). Also, consistent with Mann-Whitney test, ArXiv was positive indicative of citation (b = .117, e = .009) and tweet uptake (b = .311, e = .010) but not readerships (b = .015, e = .005). However, OA journal articles only had a significantly positive tweet uptake (b = .106, e = .011) but significantly negative citation (b = -.019, e = .010) and Mendeley impact (b = -.017, e = .006), which could be due a distribution shift occurred in normalized data as means and medians were relatively close in two groups. All regression results are significant by 95% confidence interval at p < .001.

Advantage of metrics for PubMed articles and only tweets for OA articles was also seen in a previous research (Maleki, 2014), however, results are completely inconsistent in that current research denies readership advantage of ArXiv available research and rather favours citations and tweeter uptake for ArXiv preprints.

Conclusion

Repository (PubMed) and author provided (ArXiv) access models generally seem to be more successful than OA journal articles in terms of impact, due to more impact on formal citations and readerships. OA journal articles constantly showed a benefit of tweet uptakes but not significantly more citation or readership impact. Therefore, there are promising aspects of impact for research available at PubMed, both formally and informally. Articles of scientists of Physical Science in the U.K. which are highly read, however, seem not to be available on arXiv.

A scaling approach to tackle the heterogeneity of HEIs

Introduction

The assessment of the performance of Higher Education Institutions (HEIs) at the micro (institutional), meso (regional) and macro (country) level is an important and recurrent question in the higher education’s policy debate. The modernisation agenda for Higher Education in Europe (European Commission, 2016) identifies the relevance of creating effective governance and funding mechanisms for higher education among the five key priorities for this sector. It is underlined the importance to ensure greater flexibility and autonomy for institutions to specialise more easily, promoting better educational and research performance while fostering excellence within higher education systems.

Different models of governance (Agasisti and Catalano, 2006; Capano et al. 2015) are applied by policy makers trying to improve the systemic performance of Higher Education. However, the analysis of the performance of HE systems is far from being easy to deal with. One of the main critical issue to address properly the assessment of the performance, in a multi-level (systemic) perspective, is the consideration of the heterogeneity of the HEIs involved.

Among the heterogeneity factors of HEIs, the disciplinary specialization or subject mix is considered one of the most relevant (López-Illescas et al. 2011, Daraio et al. 2011).

Main objective of the study

Recently, Bonaccorsi et al. (2017) extend the results of Ruocco and Daraio (2013) to the evaluation of bibliometric indicators of Social Sciences and Humanities (SSH) and propose a scaling approach as a tool for indirect qualitative-quantitative comparative analysis across heterogeneous disciplines. In this paper we (i) demonstrate that the distributions of total enrolled students (ENR STUDENTS) of European HEIs in four main fields of education (ENG, MED, NAT, SSH) follow a Log-Normal:

\[ f(x) = \frac{1}{\sqrt{2\pi}x} \exp\left\{ -\frac{1}{2\sigma^2} \left[ \ln \left( \frac{x}{\xi} \right) \right]^2 \right\} \]

and the rankings (in percentile, then with a maximum value equal to 100) of ENR STUDENTS have been fitted with a cumulative Log-Normal distribution:

\[ F(x) = 50 + 50\text{erf}\left( \frac{\ln(x/\xi)}{\sqrt{2}\sigma} \right) \]

where:

\[ \text{erf}(.) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \]

These functions depend on two parameters, the scale factor, \( \xi \), which is a kind of exchange rate to compare heterogeneous categories of students (namely ENG, MED, NAT and SSH), and the parameter \( \sigma \), or shape parameter, that should be close to one if the compared categories are similar, that is, in the case of universality of their underlying distribution. See Figure 1.

Table 1 shows the results of the estimates, obtained by applying a non-linear fit algorithm (Levemberg-Marquardt). For each field of education (ENG, MED, NAT, SSH), the table shows the value of the estimated scale parameter \( \xi \), its Standard Error (S.E.), the standard deviation (\( \sigma \)) and its S.E.; and normalizations before running systemic performance assessment and comparison.

Data

The data analysed come from the European Tertiary Education Register (ETER) which is a database that provides a core set of data on 2,239 HEIs in 31 European Research Area countries for the years 2011-2014. Most ETER data can be freely downloaded from the project website (http://eter.joanneum.at/imdas-eter/).

Method and results

Following Ruocco and Daraio (2013) the distributions of the total enrolled students (including ISCED 5 to 7 students, average 2011-2013), called ENR STUDENTS hereafter, aggregated in four broad fields of education ENG (Engineering and Technology), MED (Medicine), NAT (Natural Sciences) and SSH, have been assumed as a Log-Normal:

\[ f(x) = \frac{1}{\sqrt{2\pi}x} \exp\left\{ -\frac{1}{2\sigma^2} \left[ \ln \left( \frac{x}{\xi} \right) \right]^2 \right\} \]

and the rankings (in percentile, then with a maximum value equal to 100) of ENR STUDENTS have been fitted with a cumulative Log-Normal distribution:

\[ F(x) = 50 + 50\text{erf}\left( \frac{\ln(x/\xi)}{\sqrt{2}\sigma} \right) \]

where:

\[ \text{erf}(.) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \]

finally the statistics of the reduced Chi-square and the Adj. R-square.

![Figure 1. Cumulative scaled distributions of ENR STUDENTS by field of education (ENG, MED, NAT, SSH). The figure shows the distributions (Eq. 2) of ENR STUDENTS by fields of education divided by their respective scale parameters, ξ, whose values are reported in the legend of the figure.](image)

The scale parameter ξ, acts like a kind of exchange rate to compare the heterogeneous categories of students. The standard deviation (σ) estimated are all close and around one, showing that we are in presence of universality. Finally, it is worth noting that we have a very high fit for all the considered categories, as all the Adjusted R-Squares are almost equal to one. This result confirm that ENR STUDENTS have a Log-Normal distribution across the different fields of education considered. Figure 2 illustrates the obtained fit.

![Figure 2. Fit of the cumulative distributions of ENR STUDENTS by fields of education.](image)

Discussion and conclusions

The results of this analysis show that to make appropriate comparisons it is important to consider the heterogeneity of the disciplinary mix of education. The estimated scale parameters by field of education represent sound thresholds for comparing the different categories of enrolled students among HEIs and at the country level.

The scaling approach we propose in this paper could be an interesting tool to analyse and tackle the different sources of heterogeneity of HEI systems included in multi-level models of performance where country level statistical data are combined with micro-level institutional data. It is worth then to further corroborate and apply the scaling approach proposed here to implement appropriate normalization strategies in multi-level systemic performance evaluation models.

Bibliometric Research of Faculties based on Local Databases

Veslava Osinska¹ Piotr Malak²

¹wieo@umk.pl
Nicolaus Copernicus University, Torun (Poland)

piotr.malak@uwr.edu.pl
University of Wroclaw, Wroclaw (Poland)

This research is sponsored by Polish National Science Center (NCN) under grant 2013/11/B/HS2/03048/Information Visualization methods in digital knowledge structure and dynamics study.

Introduction

The state of under-representation of the humanities and social sciences in global databases such as Web of Science and Scopus has become permanent and detrimental. But for scientometric research on mezzo (institutional) level local databases can successfully substitute world indexes. Authors present a case study of gathering and visually analysing of unstructured data deriving from NCU Website. Cleaning and processing the data allow to identify metadata which describe academic activities connected with organizing different events at University. Another data source is University bibliographic database Expertus, the most complementary information resource concerning the publications of employees. This way, two different activities: publishing and organisational one can be compared for each faculty or equivalent division and thus evaluate collective impact in academic environment.

Data and metadata

Data collecting

Application form accessible at University Website https://www.umk.pl/badania/konferencje/ allows to collect such metadata about conferences as: Date, Title, Faculty, Organiser(s), Place, Leader, Secretary, Description. Downloaded data due to HTML format required semiautomatic cleaning. The relatively small records quantity \( N = 1344 \) allowed for quick estimation of similarities and relationships. Due to number of organizing units (Organiser(s) field), an asymmetric matrix has been created for the quantitative representation of the intensity of cooperation in conference organizing. Asymmetry is caused by unequal roles of the organizer and co-organizer.

Data aggregation

All identified University units (over 300) were grouped into the main categories corresponding to 17 Faculties and one additional, General. Thus, for publishing and organisational activity, cumulative data divided into 18 categories was obtained. In order to compare the received visualizations with the generated image according to the Web of Science data, the next level of grouping faculties into scientific areas was performed. Ultimately, in our study we involved domains, such as:

- humanities,
- natural science,
- life sciences,
- medicine/clinical sciences,
- engineering and technical science,
- social sciences.

Analysis

Graphs, maps and diagrams were used in the visualizations. To illustrate the dynamics of activity in the areas of conference organization area chart is used as the most effective in the trend study (Fig.1).

Figure 1. Dynamics of faculties publishing per year.

The band width exposes publication quantity each year for each faculty. It allows to observe all changes and parallel to capture information which is the most effective unit for analyzed period. For comparison local and global databases, ring charts were used. Figure 2 presents domain structure for three data sources. As mentioned before, standardized categorization was applied. All domains colored by scheme, which is available at InCites reports: https://incites.thomsonreuters.com/. Outer ring at Fig. 2 shows the best representation of publications for humanity and social sciences according local database –Expertus.
The visualization of social activities working on joint ventures (conferences, symposia, seminars) can be accomplished by using graphs (Garfield, 1994). We used the legible kind of graph – circular network layout (Fig. 3). Band width indicates the intensity of cooperation in organizing conferences. This way we discovered the close relations in such kind of activity between faculties (for example history and political science).

In order to prove this observation NLP techniques were used. Texts of conferences description were processed by Ward’s clusters analysis (1963) and visualized - the result we can see on Figure 4. Dendrogram presents faculties similarity based on texts clustering. Visualisation results confirmed previous assumptions according relationships between organizational units.

The set of metadata predisposes for extending mapping and broadening the perspective of study.

We can also carry out geomapping and provide analysis of foreign cooperation of University. We can compare publishing versus mobility for each year, but all maps exceed the scope of current work.

Figure 2. Domain structure of publications of University employees according three databases.

Figure 3. Co-organizing local events by different faculties.

Figure 4. Co-organizing local events by different faculties.

Summary
Authors present analytical possibilities of local database in confrontation with global scientometric indexes. Humanity and social sciences became visible on science map based on local data. Visualisations techniques were chosen according datatypes and analysis purposes (Osinska & Malak, 2016). Thus, circular graph shows cooperation between units, area chart – dynamics, ring diagram – comparison and structure and dendrogram – close and far similarity. Authors proposed publishing activity of scientists to complement by alternative one - organisational and this way to broaden evaluation framework.

Abstract
This paper is to reflect the China’s international collaboration in science during the period 1995-2015 and to discover the dynamics and the channel of international collaboration between China and the main scientific and technological powers. USA, Japan, Germany, UK, and France are chosen the international target countries to compare, the collaborative data of Big 6 are retrieved in Web of Science, and some descriptive statistical analyses are given. The data show that China’s share of internationally co-authored papers is still considerably lower than that of the other main countries. The numbers of collaborative papers in five nations have grown much faster than the numbers of non-collaborative ones. In China collaborative papers grow only slightly faster than non-collaborative ones, especially over the latest years. China’s international collaboration in science has obvious disciplinary preferences, focusing mainly on traditional fundamental disciplines. Overseas Chinese play an extremely important role in mainland China’s international collaboration, providing an optimal channel to overcome linguistic and cultural barriers.

Keywords

Country-level studies

Introduction
By the end of the fifties in the 20th century, Smith (1958) noted a trend towards more and more multiple authorship. This led Price (1963) to predict the demise of the single-author article. Although this prediction has not come true, the number of single-author articles has indeed steadily declined. Wuchty et al. (2007) confirmed the general increase of the influence of teams in science, including that by this phenomenon the process of knowledge creation has fundamentally changed over the years. Scientific collaboration can be described as a process by which scientists with common interests work together to create new knowledge (Katz, 1994, 1997; Coccia & Wang, 2016). It is generally accepted that team work increases quality and productivity and hence the received number of citations, although collaboration does not necessarily lead to success, such as a lot of citations. (Figg et al, 2006; Glänzel, 2008; Elango et al, 2015). Generally speaking, nowadays a scientist is not anymore an isolated actor but one member, among many, of an international research team, working together to discover the rules of nature and society (Cronin, 1982; Finardi & Buratti, 2016). Due to differences in research accumulation during investigations there
are always leading teams and followers (Zhou & Bormman, 2015; Ma et al., 2016). If researchers collaborate with the leaders, knowledge and technical barriers are reduced and this helps them to reach the research front. Yet, leaders too may benefit from collaborating, as increased manpower can greatly accelerate the development and diffusion of new knowledge, new technologies and new methods.

Developing countries can greatly extend their scientific productivity and strength, in the same time increasing the visibility of their researchers, by collaborating with leading countries (Rigby & Edler, 2005; Jonkers & Tijssen, 2008; Zhou et al., 2009; Ynalvez & Shrum, 2011; Wagner et al., 2015). Collaboration gives, moreover, direct access to complementary knowledge or skills, unique sites and facilities, and shares costs and risks (Kim, 2005; Birnholtz, 2007; Haustein et al., 2011). Starting as a developing (or at least a not-yet-fully-developed) nation China’s science and technology has increased considerably during the latest twenty years. The exponential increase in the absolute and relative number of WoS papers bears testimony of this fact (Jin & Rousseau, 2005). Yet, outstanding scientific and technological discoveries are not distributed evenly over countries, regions or provinces (or states) within a country (Wang et al., 2005; Zhou et al., 2009). By studying international collaboration we intend to obtain a better insight in the position of China with respect to other big countries.

We would like to add one more point, namely that collaborative research may not only lead to publications but also to patents (Chen et al., 2013). This aspect is not the topic of this paper. Hence, the main purpose of this article is to describe China’s position in the international fray, restricted to its output in scientific papers.

**Data and Methods**

The articles jointly written by several authors reflect scientific and technological collaboration. Consequently international collaboration is reflected by articles jointly published by authors in different countries. Articles co-authored by Chinese scientists in the context of international collaboration are mainly published in international journals. Zheng et al. (2012) mentioned that in domestic journals only 1.5% of the publications are the result of international collaboration. Hence, if one wants to study China’s international collaboration as shown by published articles one must make use of an international database. Consequently we use Thomson Reuter’s Web of Science (WoS). Publications are restricted to the article and review type.

The United States, the UK (taking care of the fact that the UK consists of England, Scotland, Wales and Northern Ireland), Germany, Japan and France are, together with China the countries producing the most articles. They will be referred to as the Big 6. In 2015, the total articles’ number recorded in WoS is 2,632,093, and the number produced by the Big 6 is 1,529,243. Nowadays we focus on these six countries. Taking the names of the chosen countries as retrieval terms, the retrieved data are divided into two groups: international collaborative papers on the one hand and non-international collaboration on the other (authors are all from China, including single author papers).
By choosing the above mentioned countries we expect to grasp the main trends and characteristics of international collaboration with special emphasis on the role played by China. Furthermore, we explore the dynamics of international collaboration and try to find the optimal path for China’s scientists when it comes to participation in international scientific and technological endeavors. Occasionally we will refer to papers written as the result of an international collaboration as “co-papers” (as a short-hand).

Because of this aim, the WoS data set of articles and reviews in 1995-2015 are retrieved. Besides all papers (of article and review type), we also consider separately the collaborative papers, written in collaboration with the main countries with which these countries collaborate the most. Articles by overseas Chinese are especially collected as well as the fields in which collaboration occurs. Data were collected in September 2016.

**Results**

*International collaboration trends of the BIG 6 countries*

Taking the name of Big 6 as retrieval terms, the retrieved data are divided into two groups: international collaborative papers, of which the affiliation consists of two or more than two countries, and non-international collaborative one, of which the affiliation only one country. The full counting is recorded every one year since 1995, and the growth rate is calculated respectively. The calculation results are shown in Table 1.

</table>
The data in Table 1 show that, except for China, the growth rate of international collaborative papers is much faster than the growth rate of non-collaborative ones. What could be the reason for this phenomenon?

When a society matures, the division of labor and in particular the numbers of practitioners engaged in scientific and technological research may stay constant, leading to a stabilization of its scientific and technological output. In order to maintain their international position developed countries must adapt their scientific policies and try to increase their attractiveness for foreign scientists, heavyweights as well as average ones. These and other factors must be optimized to maximize scientific and technological output. Supported by a national R&D policies, international collaboration promotes scientific development and progress, leading to prosperity in the collaborating nations. For these reasons developed states have vigorously strengthened international collaboration over the past twenty years. Promoting scientific and technological collaboration has become an important point in the research policies of most countries all over the world.

In contrast, China is not yet a fully developed country, and its society is changing at full speed. On the one hand, the number of practitioners engaged in scientific and technological activities in China continues to increase, and the number of scientific papers maintains a sustained high growth. On the other hand, there is no doubt that it is a good choice to promote scientific and technological development through international collaboration. Therefore, all Chinese papers (internationally collaborated or not) maintained a double-digit growth during the recent 20 years. Furthermore, while China’s growth rate of non-collaborative papers tends to decrease after the peak in 2003; its international collaborative papers kept a sustained strong increase, and its growth rate is also higher than that of the other five nations. But until 2015, China’s scientific output(330,927) is still only about half of that of USA(646,528). As a not-yet-fully-developed country, it is of great importance for China to develop a sound scientific policies and to promote scientific research, including international collaboration, to follow or even lead world trends.

The role played by China in international collaboration

In international collaboration, the ranks of authors in the byline of papers usually reflect the contribution of participants, reflecting role differences in collaboration. In particular, the corresponding author is often the person responsible for the research project. Therefore, by analyzing whether an author in collaborative papers is the corresponding author or not, the scientific contribution of authors in such papers can be analyzed. In this section, we investigate if China undertook either a leading role or

Table 2 shows that the proportion of corresponding authors in China’s international collaboration is over 50%, and staying relatively stable in 2007 and 2011. Of course, the simply descriptive statistical data only give us some superficial impression, and the in-depth analysis need to use panel analysis tools to reveal the rules.

Which role did China take in the collaboration with the five other important nations? Table 3 shows that in collaboration with major scientific and technological powers, the proportion of corresponding authors is slightly lower than the average of China in 2007 and 2011, especially in collaboration with Germany and France. Therefore, in order to enhance China’s capacities in international scientific and technological collaboration, the proportion of corresponding authors needs to increase.

How does the role differ according to discipline? Based on the SCI 22 subjects/disciplines we determine the proportion of corresponding authors in international collaborative papers for the years 2007 and 2011. The data shown in Table 4 reveal that in 2007, the following disciplines have a proportion of corresponding authors higher than the average (54.0%): agricultural sciences, chemistry, computer science, engineering, environment / ecology, geosciences, materials science, interdisciplinary, physics, plant and animal science. In the following disciplines the opposite is the case: clinical medicine, economics and business, immunology, molecular biology and genetics, neuroscience and behavior, social sciences (general). But in 2011, there are some changes. The following disciplines have a proportion of corresponding authors that is higher than average (56.2%): agricultural science, computer science, engineering, environment/ ecology,
geosciences, materials science, physics, plant and animal science, and space science. Some disciplines in which this proportion was higher than average in 2007 are now below average and vice versa. The collaborative counts of disciplines have doubled from 2007 to 2011; however, in terms of collaborative roles, in particular in terms of playing the leading role some disciplines, such as clinical medicine, immunology, molecular biology and genetics, and neuroscience & behavior, still show room for improvement.

**Overseas Chinese play the role of bridges in international collaboration**

The connecting role of countrymen or former countrymen working in other countries has been studied in several publications (Webster, 2004; Jin et al, 2007; Jonkers & Tijssen, 2008). When it comes to Chinese scientists we will use the term overseas Chinese referring to those scientists who are of Chinese descent, but have joined other nationalities, as well as those Chinese which temporarily work and study in other nations. Among the 38,327 Chinese international collaborative papers in 2011, there
are 25,995 papers including overseas Chinese, about 67.8%.

The proportion of overseas Chinese collaborative papers in 22 disciplines (Table 5) shows that in some disciplines, such as physics (75.1%), interdisciplinary studies (74.2%), immunology (73.5%), materials science (73.5%), molecular biology and genetics (73.2%), and computer science (72.2%), the overseas Chinese are very active, often leading the collaboration. Even in some disciplines with a lower proportion of overseas Chinese collaborative papers, such as plant & animal science (50.4%). In sum, the overseas Chinese have a very strong role as a bridge in international collaboration with mainland China.

### Conclusion and discussion

This article analyzed the trends of international collaboration in science and technology using six leading nations (the United States, China, Japan, Germany, UK and France) as case studies. These data retrieved from the WoS show that the numbers of collaborative papers in five nations have grown much faster than the numbers of
non-collaborative ones. This means that the major scientific and technological nations focus on their own research capability while further promoting science and technology through international collaboration. The numbers of collaborative nations are continuously growing all over the world, but especially in China.

As a not-yet-fully-developed nation, China is playing an increasingly important role in international collaboration. Numbers of collaborative or non-collaborative papers have experienced a breakthrough growth. China’s international collaboration in science and technology has obvious disciplinary preferences, focusing mainly on traditional fundamental disciplines. Overseas Chinese play an extremely important role in mainland China’s international collaboration in science and technology, providing an optimal channel to overcome linguistic and cultural barriers. It is no surprise that China's S&T policies support and facilitate such collaborations.

Collaboration is an optimal strategy to promote science and technology

Why does the data show sharply increasing patterns of international collaboration in recent years?

In researchers’ level, collaboration is intrinsic needs in their careers. Everyone want to publish instead of perish, especially to publish in high level journal, such as *SCIENCE* or *NATURE*. Many data have verified the fact that partnering with collaborators anywhere can help them do the research, and even more importantly, get their papers accepted, especially partnering the prestigious professors. In earlier stage, the collaboration has taken place in colleagues, supervisor and students, even different institutes. With the support of IT, the collaboration gradually spread more remote distance, such as different states or nations. It can be called bottom-up pattern, which is driven by the researcher himself and is a self-organized process. The limitations of this pattern are stochastic and non-planned, but it is a critical factor to promote the sharp increment of collaboration, whether the local collaboration or international one.

International collaboration in science and technology besides being an effective way to boost productivity also promotes prosperity in the world. No nation, developing or developed, has enough resources to match its needs in science and technology. Therefore international collaboration has become an important aspect in scientific policies. We even claim that it is the optimal path to acquire needed resources. This is obvious in the case of Big Science projects such as CERN’s Large Hadron Collider (LHC).

Developed nations often have first-mover advantages in research and have enough resources to attract talented, excellent intellectuals from all over the world to participate in international collaboration. Due to their strength, they can be more selective with respect to the nature of their collaboration. In order to reach the research front of a discipline, developed nations have paid a lot of attention to increase their own scientific and technological capabilities, while promoting international collaboration and formulating appropriate international collaboration strategies.
Due to limitations in scientific and technological conditions it is impossible for developing or non-developed nations alike to carry out comprehensive research in all disciplines. Hence they have to formulate suitable strategies focusing on their best disciplines on the one hand, and promoting their other disciplines through international collaboration. Generally, developing nations often have an advantage in the number of human personnel, so that they have manpower to offer when collaborating with developed nations. Such collaborations may accelerate the development of science and technology in the world.

Therefore, international collaboration in science and technology is an optimal way to reallocate scientific and technological resources on a global scale. Every country sees international collaboration as a tool to develop its own R&D strength. This collaboration can be call top-down pattern, which is an optimal strategy driven by government policies. Not only the developing countries, such as China, but some developed ones, such as UK, have formulated some planning to promote international collaboration in science and technology. The impressive characteristics of this pattern are the target-oriented and the planned, and it can be used to interpret the preferred collaborative disciplines, institutions, and countries.

20 years ago or earlier, it is difficult to seek a collaborator in remote distance, especially different countries. It is the main thing that the advent of the internet has given more convenient condition to promote collaboration during the past two decades, especially the international cooperation. With the development of the Internet, scientific and technological collaboration in an international context has become easier. Gone are the days of hand written letters, difficult intercontinental telephone talks and an occasional long travel. Nowadays colleagues living on the other side of the globe are as close for discussions as a colleague working two stages higher in the building.

All of these, not only the needs of single researchers but the governmental policies and context changes of information techniques, together promote the international collaboration in science and technology. The bottom-up practices of collaborative needs in scientists have accelerated the increment of collaborative papers and settled the micro-foundation of collaboration, the top-down collaborative policies formulated by the government have facilitated the policies context, and the information techniques, particularly the internet, have eliminated the spatial barriers of communication and collaboration in long distances. The prosperities of international collaboration are due to the harmonious function of above factors.

*Ethnic ties are a bridge to optimize collaborative channels for China*

For developing nations, it is an important issue to seek an international collaborative partner in science and technology. Yet there exist many barriers to collaboration, such as culture, language, funds and policies. It is known that building on ethnic ties is an optimal channel to eliminate such barriers (Jin et al., 2007).

The ‘Overseas Chinese phenomenon’ (Jin et al., 2007) in China’s international
collaboration has developed from a deep social basis over many years. Chinese scientists leaving China, permanently or temporarily, are embedded in traditional Chinese culture, writing the same language, and having close social relations with China. These factors form a strong social basis binding overseas Chinese to a country with which they share many characteristics. This social basis is also where the opportunity lays for overseas Chinese to carry on international collaboration with China. From the foreign country’s perspective, the presence of a significant community of ethnic Chinese makes it easier to collaborate with scientists in mainland China. Indeed, Jonkers and Tijssen (2008) conclude that while countries may lose human capital when Chinese or other ethnic groups return to their homeland (a phenomenon referred to as “return brain drain”) they may also gain in terms of scientific linkages.

Furthermore, the government of mainland China has formulated several specific policies regarding overseas Chinese, such as *The Recruitment Program of Global Experts*, *Introducing Talent intellectuals Planning*, *Yangtze River Scholars Program*, *Thousand Talents program*, and so on. These programs attract outstanding overseas Chinese persuading them to return to their homeland.

Such ethnic ties are of a homophilic nature (McPherson et al., 2001), referring to the phenomenon that similar groups have more frequent contact than un-similar ones. On the one hand, we notice that overseas Chinese scientists establish emotional contact through family, relatives, teacher-student relationship and former collaboration, making future collaboration easier; and on the other hand, based on ethnic ties, this collaboration can enhance the prestige of participants in mainland China. In fact, this phenomenon may not only exist for Chinese, but also for other ethnic groups such as Indians and Koreans.

BIBLIOMETRIC ANALYSIS AND RANKING OF LIBRARY AND INFORMATION SCIENCE (LIS) RESEARCH AND PUBLICATIONS IN AFRICA

Okon E. Ani1 Eucharia Okwueze2

Introduction
Bibliometric analysis is a method that is used to describe patterns of publication and national and international strengths and biases in areas of research within a given field or body of literature such as library and information science (LIS) (Aharony, 2011). Johnson (2011) explained that many bibliometric studies enumerate the extent and scope of scientific communication amongst scholars/researchers. According to Ocholla and Ocholla (2007), bibliometric studies are widely used to inform policies and decisions in political, economic, social and technological domains affecting information flow and use pattern within, between and outside institutions and countries. Thus, bibliometric studies are essentially used in evaluation of research and publications in all areas of human endeavors to support decision making by policy makers in governments, organizations/institutions (universities), academic departments and individual scholars/researchers. Furthermore, bibliometric analysis is significantly used in the ranking of research and publications (Meho and Spurgin, 2005) and this has become popular especially in the universities and other academic and research institutes with emergence of different rankings organizations within the past one or two decades (Ani, 2015). Barik and Jena (2016) opined that bibliometric study is focus on evaluation of research performance of authors, institutions/universities, countries or regions in variety of disciplines. Publications counts and citation analysis are two major methods that are used in bibliometric studies. Ocholla and Ocholla (2007) described citation analysis as a tool that is used as quantitative measure of the quality of research and publications.

LIS is a discipline that is fast growing in terms of research and publication globally. Although bibliometric analysis and ranking studies in LIS have a long history in developed countries (Meho & Spurgin, 2005); in Africa, bibliometric studies are limited and insignificant in Africa in spite of the widely applications of these studies by policy makers to support research and publications in line with the emerging global rankings of universities (Ocholla & Ocholla, 2007). Onyancha (2007) vividly captured the poor state of LIS research in Africa by expressing the fear that there is general concern among LIS scholars concerning the growth and development of LIS research in Africa in relation to global perspective. Thus, this present study is intended to fill the knowledge gap in bibliometric studies and would therefore expand the scope of literature in LIS in Africa.

Objectives of the Study
The study was guided by the following objectives:
1. To rank LIS research and publications in African countries in global perspective;
2. To rank LIS research and publications in Africa by country, and
3. To determine trends in LIS research and publications in Africa.

Research Method
The Web of Science databases published by Thomson Reuters were used for the study. The study was limited to the used of Social Science Citation Index (SSCI) and Arts and Humanities Citation Index (A&HCI). The data for the study were obtained by conducting an advanced search using Web of Science Category, WC=Information Science and Library Science, with articles as the document types, all languages in terms of selection of language of publication of the journal articles. The period of the study was limited to 2010-2016 to depict current state of research globally and in Africa in particular. The data obtained were analyzed globally and by African countries based on the objectives of the study.

Results and Discussion
The results of the study are presented and discussed in this section based on the objectives of the study. Ranking of LIS research and publications in Africa in global perspective
The results of the study showing ranking of LIS research and publications in Africa in global perspective are presented in table 1. The results revealed that Africa is not represented among the top 10 countries globally in LIS research and publication in all bibliometric indicators that are used in this study (publication counts and citation...
analysis: total citations, citations per article and h-index). Earlier study by Sin (2005) has confirmed this finding that Africa is not represented among the top 10 productive countries in LIS research and publication. Analysis of the results showed that USA is significantly leading globally in LIS research and Africa is only represented in the global ranking among the 20 top countries by South Africa in LIS research and publication in number 19 positions with publication counts of 364.

Ranking of LIS research and publication in Africa by country

The results of the study showing the rankings of LIS research by publication counts in Africa are shown in table 2. The results in table 2 revealed that South Africa and Nigeria are the foremost countries in LIS research in term of publication counts. The findings of the study are consistent with previous studies that affirmed South Africa and Nigeria as the leading countries in LIS research in Africa (Aharony, 2011; Onyancha, 2007).

Ranking of African countries by citation analysis

In table 3, African countries are ranked by citation analysis and the results revealed that South Africa is significantly leading other countries in the number of total citations (1006), followed by Nigeria (229), Kenya (106), Ghana (90) and Uganda (90). South Africa (15) is again leading in h-index, followed by Nigeria (7), while Tunisia (7.58) is the most ranked African country in terms of citations per article and is followed by Ethiopia (7.00).

Trends in LIS research and publications in Africa, 2010-2016

The growth, progress and development of different fields of knowledge are usually determined by annual publication outputs in a given field (discipline) over a period of time. It was therefore pertinent to examine the trends in LIS research and publication in the study. The results of the study are presented in figure 1. The results showed an increasing trend in general or overall annual publication outputs in LIS research in Africa; but analysis by individual country using the three most ranked countries (South Africa, Nigeria and Ghana), showed declining and fluctuating trends. In South Africa, there was an increased in annual publication output until a decline was set in 2015-2016. The declining and fluctuating trend in annual publication outputs was apparent in Nigeria. Similar declining and fluctuating trend was also observed in annual publication output in Ghana. In the case of Nigeria, a recent study by Ani, Ngulube and Onyancha (2017) affirmed fluctuating and unpredictable trend in the annual publication output in LIS research in Nigeria.

Conclusion

LIS is a vital discipline that has been developed globally to support national and international development. In view of the importance of LIS in socio-economic development, the field has been transformed from its traditional role of information storage, dissemination among others. However, and in spite of the rapid growth, progress and development in LIS research globally, scholars have decried the poor state of LIS research and publication in Africa (Mchombu, 2002; Ocholla & Ocholla, 2007; Onyancha, 2007). The findings of this study have therefore made significant contributions to the literature of growing concerns on the need to promote LIS research and publication in Africa in line with the global trend. The findings of the study have revealed that Africa is not represented among the top 10 productive countries in the world in LIS research and publication, but is however, represented by South Africa in the 19th position among the top 20 productive countries in the world. Thus, South Africa is one of the leading countries in LIS research and publication in the world and Africa in particular. The rankings of African countries in LIS research and publication, however, revealed that South Africa (364) and Nigeria (165) are significantly leading other African countries in publication outputs. Although, the results of the study indicated general or overall increase in annual publication outputs in LIS research in Africa; the trends in annual publication outputs by the three most productive countries (South Africa, Nigeria, and Ghana) were found to be declining and fluctuating.

Keyword
Co-occurrence analysis, Ternary co-occurrence, Co-word matrix, Weighted CLSVSM, Clustering

Introduction
Resource aggregation is an effective way to solve the question of too many resources. Literature aggregation can be realized by the clustering of the feature vector of literature. It is very important to use the semantic information to express the vector fully. The most basic vector representation is the vector space model (VSM) (Salton, 1997), this model assumes in-dependency between the vocabulary terms and ignores all the conceptual relations between terms that potentially exist; The Generalized vector space model (GVSM) (Wong, Ziarko&Wong, 1985) excavates the co-occurrence information of words, but it cannot extract the semantic information fully. The semantic vector space model (SVSM) (Song, Liang&Soon, 2014), excessive relies on ontology or the language database. The co-occurrence latent semantic vector space model based on the binary information (CLSVSM) (Niu&Qiu, 2014) is used to proceeding literature aggregation. The result shows that the model is better than the VSM. But we find that researching the binary information only is not comprehensive. As a consequence, we introduce the ternary information.

Ternary CLSVSM
The co-occurrence latent semantic vector space model is mainly realized by mining the latent relationship between terms. Latent relationships include synonyms, antonyms and near-synonyms. This passage is mainly based on the research of binary co-occurrence. Next, we will study the model from the following three aspects: the representation of co-occurrence matrix, the calculation of the relative strength and the weighted CLSVSM.

The Representation of Co-occurrence Matrix
In this passage, we present a ternary co-occurrence layer matrix with algebraic method. We can use this matrix to calculate the co-occurrence frequency. Definition1: Given document sets D and its document - term matrix A (only 0,1), let \( t_j \) be the j-th column of A, we define co-occurrence frequency of the j-th term \( t_j \) and all term pair \( (t_i, t_k) \) is the j-th layer of ternary co-occurrence as follow:

\[
C_j^{(3)} = C_j^{(1)}(t_j) = (\text{diag}(t_j) . A)^T \cdot (\text{diag}(t_j) . A)
\]

Explication: We calculate \( \text{diag}(t_j) . A \) first. In calculation, we use \( \text{diag}(t_j) \) to modify the matrix A.

If the diagonal elements of \( \text{diag}(t_j) \) contain 0, that is, the term \( t_j \) at least in one document does not appear (might as well be k), at this time the k-th row and the k-th column elements are 0. According to the matrix multiplication, the k-th row the elements of the \( \text{diag}(t_j) . A \) are all 0. On the contrary, If the diagonal elements of \( \text{diag}(t_j) \) are all 1, the result of \( \text{diag}(t_j) . A \) is A.

For example:

\[
A = \langle t_1, t_2, t_3, t_4, t_5 \rangle = \begin{bmatrix}
1 & 1 & 0 & 1 & 0 \\
0 & 1 & 1 & 0 & 0 \\
1 & 0 & 0 & 1 & 1 \\
1 & 1 & 0 & 1 & 1 \\
1 & 1 & 1 & 0 & 0
\end{bmatrix}
\]

\[
\text{diag}(t_1) . A = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1
\end{bmatrix} \begin{bmatrix}
1 & 1 & 1 & 0 & 1 \\
1 & 1 & 1 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0
\end{bmatrix} = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1
\end{bmatrix}
\]

1825
The Relative Strength of Ternary Co-occurrence

We can also use the following method to calculate the ternary co-occurrence frequency. Let \( c_i, c_{ij}, c_{ijk} \) respectively be the frequency of terms \( t_i, t_j \) and \( t_k \). Let \( C_{ij} \) be the number of documents that including at least one of the three terms. Contrasting the promotion of the addition formula in the probability theory, for the three events A,B,C, let P be the probability of occurrence of events, then we define \( P(A \cup B \cup C) \) as follow:

\[
P(A \cup B \cup C) = P(A) + P(B) + P(C) - P(A \cap B) - P(A \cap C) - P(B \cap C) + P(A \cap B \cap C)
\]

We can infer the calculation formula of the ternary co-occurrence frequency:

\[
c_{ijk} = C_{ij} + C_{jk} + C_{ik} + C_{ijk}
\]

Definition 2: Given binary co-occurrence matrix C, we can define the relative strength of ternary co-occurrence \( b_{ijk} \) of any three terms \( t_i, t_j, t_k \) as follow:

\[
b_{ijk} = \frac{c_{ijk}}{\sqrt[3]{c_{ij}c_{jk}c_{ik}}}, i, j, k = 1,2,\ldots, m
\]

The Weighted CLSVSM

In the new CLSVSM, we consider combining with binary and ternary co-occurrence information, and give the ternary greater weight.

Definition 3: Given the binary co-occurrence relative strength matrix B, the ternary co-occurrence matrix \( C^{(3)} \), the j-th floor ternary co-occurrence matrix \( C^{(3)}_j \), the j-th floor ternary co-occurrence relative strength matrix \( B^{(3)}_j \),

\[
C^{(3)}_{ij} = \sum_{t_i} \sum_{t_j} \sum_{t_k} c_{ijk} = (\text{diag}(t_i), A) \cdot (\text{diag}(t_j), A)
\]

We find that the second diagonal elements of \( \text{diag}(t_j) \) is 0, therefore the second row of \( \text{diag}(t_j)A \) is 0. \( C^{(3)} \) is the co-occurrence frequency matrix of the first term \( t_i \) with other terms. Obviously, the matrix is a symmetric matrix. The element of the second row and the third column is the co-occurrence frequency of the terms \( t_1, t_2 \) and \( t_3 \).

We define the new co-occurrence latent semantic vector space model based on binary and ternary as follow:

\[
\phi(d_i) = \tilde{a}_i = (q_{i1}, q_{i2}, \ldots, q_{im}) \in \mathbb{R}^m
\]

\[
q_{ij} = \begin{cases} 
\max_{t_i} \left\{ b_{ij} \right\}, & \text{if } a_{ij} = 1, \\
\max_{t_i} \left\{ b_{ij} \right\} + \frac{1}{3} \left( \max_{t_i} \left\{ b_{ij} \right\} \right), & \text{if } a_{ij} = 0, \text{max}_{t_i} \left\{ b_{ij} \right\} = 0, \\
0, & \text{otherwise}
\end{cases}
\]

Where, \( I_{ai} = \{ j | a_{ij} = 1 \} \) is the indicator sets of \( j \).

The new document - term matrix is defined as:

\[
Q = \begin{pmatrix} 
q_{i1} & q_{i2} & \cdots & q_{im-1} & q_{im} \\
q_{i3} & q_{i4} & \cdots & q_{im-2} & q_{im-1} & q_{im} \\
& & \ddots & \vdots & \ddots & \ddots \\
q_{i,n-2} & q_{i,n-2} & \cdots & q_{im-n+1} & q_{im-n+1} & q_{im-n+1} &q_{im-n+1} & q_{im-n} & q_{im-n} & \cdots & q_{im} \\
q_{i,n} & q_{i,n} & \cdots & q_{im-n+2} & q_{im-n+2} & q_{im-n+2} & q_{im-n+2} & q_{im-n+1} & q_{im-n+1} & q_{im-n+1} & \cdots & q_{im-n+1} & q_{im-n+1} & q_{im-n+1} & q_{im-n+1}
\end{pmatrix}
\]

Conclusion

This paper we researched the ternary CLSVSM and gave the experimental design. We showed that, in the Chinese literature, the clustering effect of the weighted model was better but in the English literature, the two clustering effects were equivalent. In this paper, the representation of the ternary co-occurrence layer matrix can be extended to the multiple co-occurrences, but it should be noted that the frequency of the multiple co-occurrence will decrease rapidly with the increase of multiple numbers. The multiple co-occurrence phrases are also rapidly decreasing. In the subsequent study, we will try to find a way to directly represent the ternary information and explore the scope of the model.

Abstract
Based on the review of the research achievements of the relationship between science and technology, using scientometrics and network analysis method, taking the database of CNKI and SCI as data source, this paper studies quantitatively the Promoting effect of scanning tunneling microscopy (STM), the specific new technology, on science development. We research the mechanism of STM permeating each area of science research fields, including the influence of STM on science knowledge structure, STM improving the science research field and the evolutionary dynamic process of hot spots in scientific research under the promoting of STM. We also study the role of STM in promoting other relevant technologies’ growth and development. The aim is to reveal how science and technology promote each other and develop in parallel. This study predicts the emergence and development of the future science research field according to burst detection under the influence of STM.

Key words: Relationship between science and technology; scanning tunneling microscopy (STM); promoting each other; developing in parallel

Conference Topic
Science of science

Review of the relationship of science and technology
The relationship between science and technology has long been one of the most important issues in many disciplines. Especially in this Big Science age, the relationship is becoming more complex and closer, and at the same time their boundary is becoming even more obscure. The correlation between science and technology, science and science, technology and technology should be further studied from a new systematic viewpoint. The relationship between science and technology has become a hot topic for present scholars. For example, many scholars are exploring this relationship on macro-level using qualitative method, such as discussing whether science and technology evolved independently or together (Rip, 1992; Nelson, 2004; Barnes, 1982; Lin, 2014). This chapter explores essence of science and technology.
through analyzing the historical process of science and technology development (Gui, 2009; Guo, Guo & Shi, 2007), studying the mutual association patterns of science and technology, and their common knowledge origins (Cao & Wu, 2013; Narin, Hamilton & Olivastro, 1995), and by researching the relationship between science and technology in the context of modern economic and social development (Ju & Liu, 2004; Huang, 2002).

Contemporary quantitative analysis is another method used in this study. Especially literature quantitative analysis is used frequently in this field. In their long development process, science and technology have interacted, and depended on each other. In this process, science has provided the theoretical foundation for technology development and the intellectual preparation for technological innovation. The needs and advances in technology has provided new research subjects, research tools and exploration methods for science as well (Tan & An, 2007). But meanwhile, science and technology, as two different stages in the whole process of human learning have big differences in categories, presentation forms and evaluation standards. The mainly presentational forms of scientific achievement are academic papers, and technology innovations are mainly carried out as invention patents. That is to say, papers and patents are the knowledge carriers of science and technology achievements respectively. Mutual citation between these documents has not only reflected the inherent relevance of their knowledge, but also shown the direction and process of the knowledge flow. By researching the various indicators, contents and inter-reference features of papers and patents, we can reveal the relationship of science and technology in a quantitative perspective as well as the relation of the mutual penetration, interaction and mutual promotion between basic researches and technical innovations. Through exploring the reference links of papers and patents in specific fields, we can analyze the inherent interaction mechanism of science and technology from a micro-perspective.

The reference between patents and papers is bi-directional. In other words, papers can be cited by patents as well as patents do. To some extent, patents referencing to papers has reflected how research achievements are applied to technological invention. Through analyzing the characteristics and laws of the patents referencing to papers, we can reveal the science research’s effects on technology innovation. The specific indexes used to measure the patents referencing papers mainly contain time distributions, regional distribution, periodicals distribution, as well as subject analysis and subject categories. Carpenter MP and Narin F. applied the analysis of patents referencing to papers in researching the relationship between science and technology earlier (1983). Based on the SUPTO data from 1987 to 1996, Tijssen studied the relationship between science and technology with the analysis methods of social network (2001). Combining patents citations analysis methods with econometric models, Van Looy B found that there was a strong correlation between science and technology (2003). Other scholars explored their relationship’s features through analyzing the patents referencing to papers in specific subjects fields. For example, Narin studied the citation relationship between patents and papers of bioscience, and found that the more advanced the technology was, the further closer to basic sciences it was (Narin & Noma, 1985). Zhao Zhiyun etc, who conducted an empirical study on Chinese biotechnology, found that the basic research and technology was closely linked and the relation between them was becoming closer over time (Zhao & Lei, 2013).
Papers referencing to patents has reflected how technology has affected scientific research. Through the law of paper citing patent, the relationship of basic research to technological innovation can be demonstrated from another perspective, and the impact of technology on science can be measured. For instance, through analyzing the references of SCI papers to USPTO patents, Glanzel W and Meyer M have built internal relations between science and technology and pointed out the significant difference of science and technology’s relevance in different subjects (Glanzel&Meyer,2003). However, by contrast, there are few examples of quantitative research on relation of science to technology, through analyzing the references of papers to patents. The main reason is that citation papers on patents tend to be too few to query, and the shortage of data might statistically affect the credibility of the results of analysis. Yang Zuguo and Chen Hong etc. have explored the status and laws of China's patent technology being used for scientific research by collecting the data of scientific papers citing Chinese patents, and by analyzing them. In their conclusion, they pointed that due to the few sources of statistical data, the statistical analysis conclusion had some limitations (Yang, Chen & Zhu, 1999). According to the data of papers and patents citing each other, Wu Feifei and partners built two relationship networks: science citing technology and technology citing science, based on the citation data of papers and patents citing each other. Combining the relationship networks with social network analysis methods, they analyzed the interaction of science and technology, and identified the science and technology fields with high network centrality. Through the cross-influence between disciplines and technology fields, they explored the transference between scientific knowledge and technological application. But their analysis of the data of papers citing patents is based on basic data used by Glanzel W in 2003 (Wu, Huang & Shi, 2013). The promotion of technology over science has long been recognized, it is well known that technology development promotes science research, yet there is weak quantitative research for this. Application of new technology provides new ways of observation and experiments, offering new materials for science research; this causes scientists to conduct further research and achieve new breakthroughs in basic scientific research. This is one aspect of the technology driving science development. At the same time, technological development provides new contents for science research, and the application of new technologies might also bring several new problems which have to be resolved. And then all those stimulate further science research. In addition, the natural paths of technology improvement indicate its limitations, while these limitations demand that research enlarges its areas and defines new directions. This is another aspect of technology driving science development. Therefore, the development and breakthrough of modern science often occurs after a crucial improvement of technology. Without the application of technology, science will be difficult to develop. For example, the invention and improvement of experiment instruments plays an important role in science progress, and brings the potential for major breakthroughs in science development. In 1995, the United States National Science Foundation organized an academic conference, and renowned biologists, technical experts and relevant managers attended the conference. The main purpose of this conference was to discuss the impact of emerging technologies on bio-science development. At the conference, speakers thought that if the rapid development of bio-science was achieved, new technology must be combined with the bio-science research
In this study, we start with a specific technology, scanning tunneling microscopy (STM), to study the effects of a specific technique for science research using different analysis methods of patents citation in papers. Taking STM as an example, we investigate how this technology has improved science development, and its impact on each subject. In 1981, Gerd Bining, Heinrich Rohrer and their laboratory staffs of the Zurich laboratory in International Business Machines Corporation had successfully developed one novel surface analysis instrument for the first time in the world --the scanning tunneling microscope. The scanning tunneling microscope helped people "see" the atoms on the objects’ surface, and it could even identify approximately 1% of one atom’s square. Because of the important application of this microscope, their emergence has extended into plenty of new fields, nanotechnology included. This new area has rapidly penetrated into the research of each subject and promoted their development. So the scanning tunneling microscope was recognized as one of the top ten science and technology achievements of the 1980’s by the international science community. Therefore, Gerd Bining and Heinrich Rohrer, the inventors of the scanning tunneling microscope, and Ernst Ruska, the electron microscope inventor, shared the physics Nobel Prize in 1986.

Data source and methodology

We used the published STM-related academic papers as samples. The theses of domestic journals were chosen from CNKI database, and the theses of foreign journals were from the SCIE database of Thomson Web of Science. Using "scanning Tunnel microscopy", "tunnel scanning microscope", "STM", "scanning tunneling microscope" as retrieve terms, we searched the CNKI database and found that the earliest literature appeared in 1985. So we set the period between 1985 and 2015 for investigating, and got 2,223 related articles altogether. In this context, we would like to call the four keywords above-mentioned together as "Scanning Tunneling Microscopy". Searching with the retrieve formula of TOPIC= (SCANNING TUNNEL* MICROSCOP*) AND ADDRESS= (PEOPLES r CHINA) in SCI database, we got 2,485 articles in total. As it is shown in Graph 1, the retrieved documents in two databases were distributed over time. It can be seen that CNKI papers presented a wavelike rising trend before 2001 and then declined rapidly. The publication of SCI papers started in 1989 and grew swiftly and violently from 2005. One of the possible reasons is that a great number of papers associated with the scanning tunneling microscope had started contributing to international journals since 2005. Accordingly, in order to make the data mutual-complement, we combined the two databases and analyzed them in this study.
Currently, there are abundant software and technological means used for Scientometrics and Bibliometrics research, and each of them has its own unique style, advantages and disadvantages. We can choose different software functions based on different contents. For instance, the calculation function of UCINET is powerful, and it can output the calculated data and results to software like NETDRAW for Visual display, but UCINET requires the raw data to be presented in matrix format. When applying UCINET for central calculation and visualized network construction of data, firstly we convert data into BIBEXCEL format by using the CITESPACE conversion function. Then we construct the matrix format for UCINET analysis by BIBEXCEL. One distinctive feature of CITESPACE is to explore the dynamic evolution of research progress and frontiers in specific fields. CITESPACE can detect the burst words from numerous titles, abstract, descriptors and identifiers through BURST DETECTION algorithm, and analyze the evolutionary process and progress of science based on the swift changing trends, rather than the frequency of words only. Therefore, we have conducted the research with appropriate technological means depended on the contents in this paper.

The osmosis of STM technology to science research

The analysis of application breadth of STM technology

STM technology is widely applied in interdisciplinary studies, which was deeply rooted in quantum mechanics, soli-state physics, chemical physics, electron physics, mechanical engineering and cybernetics. The subjects scope of this technology application is comprehensive. We analyzed the quantity of achievements of STM being applied in various disciplines. Using the standards of subjects classification of SCI and CNKI database, 2,223 references with the theme of STM were retrieved from CNKI. They belong to 40 different subject areas, of which the key fields are shown in Figure 2. Moreover, the 2,485 papers retrieved from the SCI database belong to 43 fields, of which the main subjects are shown in Figure 3. By contrast, the disciplines of the papers collected by SCI are more dispersive and
more concentrated. 60% of them are on the topics of physics and chemistry. It is demonstrated that the impact of STM varies in the development of different subjects. In terms of these disciplines’ categories, physics, biology and chemistry belong to the recognized discipline of natural science; instrumentation, industrial, engineering, materials science, metallurgy and metalworking, industrial technologies and equipment, organic chemicals, inorganic chemicals, electricity industry belong to the engineering science and technology disciplines; radio-electronics belongs to information science and technology disciplines.

Figure 2. The subjects distribution of STM-related theses from CNKI database

Figure 3. The subjects distribution of STM-related theses from SCI database

The detection about the speed of STM permeating into various disciplines

The invention of new technologies will promote the development of disciplines in many ways. Some of them are revolutionary, while some are mildly progressive. In modern science research, new technologies have become one of the most important forces of science development. We have analyzed the permeation speed of STM into interdisciplinary studies. In other words, we have studied the speed of various disciplines responding to STM technology. Our research is conducted with retrieve data of CNKI database, according to the time of when those theses were published in this database. We use both the invention date of STM technology, and the lag time when various disciplines papers has been firstly published, as the indexes. Therefore, we can make the following definition: for a certain subject A, assuming the time of the first published paper of STM as T, the invention time of STM as $T_0$, the lag time of subject responding as $\Delta T$, then $\Delta T = T - T_0 + 1$. Accordingly, we have calculated the measure results of lag time that various subjects responding to STM technology, and listed the top 14 of the most productive disciplines concerning the published papers in Figure 4. As Figure 4 shown,
the left axis expresses the lag time that various disciplines respond to STM technology. The right axis represents the amount of subjects containing STM papers. As figure displayed, in these 14 disciplines, the fastest one responding to STM is technology instrumentation industry, lag time was 5.3. In April and May of 1985, Dai Daoxuan, Shen Hong have published the paper “scanning tunneling microscope”, “the work law and progress of scanning tunneling microscope”, introducing the concepts and principles of STM to this discipline. Generally, the reaction speed to the technology and the literature volume about this technology are positive correlation. The faster a subject reacts to the invention of STM, the more literature it has. Yet, there are also exceptions, such as metal science and metal craft. The STM technology was introduced and applied to this subject in April 1988, by Yan Qing, on Iron and Steel Research Journal. With the reaction speed ranking in the fourth place of various subjects, its literature volume was ranked seventh. On the contrary, the reaction speed in the field of radio electronics was slow. In February 1989, Chen Yufeng introduced the concept of STM, eight years after the invention of the STM technology. With the response lag time ranking seventh in various disciplines, its literature volume grew rapidly, and was ranked fourth in the total amount of literature of all subjects.

Figure 4. The comparison of response speed to STM technology in various disciplines

Measure of STM technologies on the role in promoting science and technology
Brooks had proposed that if we can make a map out of all the known knowledge nodes, then the map will reflect the structure and relationship between scientific knowledge (Brookes, 1981). Knowledge element is not only the smallest knowledge node, but also a set of the keywords and subject headings (Wen, Hou & Gong, 2007). Professor Liu Zeyuan pointed out that, under certain conditions, a key unit of knowledge may play a genetic role in determining the knowledge evolution and mutation in the specific fields (Liu, 2010). In the following study, using the high frequency key words in data retrieve results as the object, we have discussed the underlying knowledge structure of STM-related scientific findings, and the dynamic evolution of the research focusing on the main area of knowledge. This chapter has revealed the promotion of STM technology for scientific development and the impact on new technologies.
**Analysis of knowledge structure in STM-related research fields**

We have classified the top 60 high frequency key words in the two databases, and have discovered that the keywords of microscope series implements are scanning microscopy, optical microscopy, scanning electron microscope, scanning near-field optical microscope, scanning tunneling microscope, atomic force microscopy, transmission electron microscopy, scanning probe microscopes, microscopy, microtechnique. Following the STM technology invention, people have improved this technology, have enabled it to work under vacuum, low temperature, magnetic fields and other specific conditions. Meanwhile, based on the principle of STM, a series of new scanning probe microscopes have been invented, such as, atomic force microscopy, scanning capacitance microscopy, scanning near-field optical microscopes, scanning near-field acoustic microscope, scanning near-field thermal microscopy, scanning electrochemical microscopy. These new inventions of the microscope provide a powerful tool for exploration on various specialties of substance surfaces and interfaces. And furthermore, they have accelerated the development of the microscopic manufacture technology and microscopic observation technology.

After the invention of the STM technology, nanotechnology, the frontier science studies substance of 0.01~100nm-scale, has introduced to the public. Nanotechnology is using STM for nano-level analyzing on material surfaces, including the manipulation of atoms, molecules and etching on the surface of those. Among all the investigated keywords, words associated with Nano are Nano, nano-materials, Nano-electronics, nanocrystallization, Nano-sciences, nano-technology, nano-science and technology, carbon nanotubes, nano-scale, gold nanoparticles, Nano-fabrication and nano-structures and Nano-devices, Nano-biology, nano-particles, nanowires, carbon nano-materials.

The advent of STM technology dramatically promotes the development of surface science, and offers powerful supporting technology for surface atoms array, single crystal surface structure and surface structure research. It also provides an objective theory basis to the questions of the basic issues, such as “Where is atom? How does it move?”. Keywords associated with the material surface are surface structure, surface topography, surface roughness, matter surfaces, metal, silicon and graphite surfaces; and there are keywords of material structure and scale: single-layer, molecule, single molecule and single atom, hair, Atomic layer, Atomic scale, atomic level. In addition, retrieve related data. Within the SCI database, there are more keywords for characterizing specific substances, such as copper (CU100, CU110, CU111), carbon (C-60, CARBON, CARBON NANOTUBES, CARBON-MONOXYDE), Silicon (SI (001) SI (100), SI (111), SILICON) etc. There are three high frequency names of the data retrieved in CNKI database, one is the famous physicist Richard Feynman, the Prize winner who is the first one to put forward the concept of nano-Nobel. One is a chemist, C-60 discoverer, Smalley. And the third one is the nanotechnology expert Bai chunli, the first man who has invented STM in China. No discussion about the STM technology without referring to the academician Bai’s work in China. In 1988, China's first STM with a micro-computer control, data analysis and image-processing system has been developed, leading by Bai chunli. The research team, led by Bai chunli, has successfully developed China's first atomic force microscope (AFM) later. The successful development of STM and AFM has enabled China to
join the advanced ranks in these fields in the world. In addition to the development of those instruments, Bai Chunli is also engaged in the study on STM application. As one of the pioneer researchers, he has applied STM to nano-research field, and has achieved outstanding results. Following the lead of Bai Chunli and other researchers, the STM has flourished in the area of surface analysis in China. And his work also furthers and deepens the application of STM in scientific research (Zhang, 1991).

Furthermore, we have used keywords to analyze the hot spots evolution and co-occurrence networks. Keywords co-occurrence networks are built based on the co-occurrence strength of keywords. By investigating the networks, it is expected to explore the connections between different areas, and study the knowledge structure in the fields of science. In the keywords co-occurrence networks, each keyword is a node on the network. Network connection represents the concordance between the keywords. Then, we have analyzed the centrality of network nodes, and have revealed the status of every node in the whole knowledge structure network and its relationship with other knowledge units. There are three main indicators of measure centrality: centrality of degree (DEGREE), centrality of mediation (BETWEENNESS), centrality of closeness (CLOSENESS).

The Degree centrality index is to measure the of the relations between nodes on the web. The more nodes one can get connected to on the web, the more connection of this node is. That shows the node is in the centre of the web. Degree dedicates the position and influence of the nodes on the web. Higher Degree means the node is closer to the web’s core position, and more likely to control and affect the activities of other nodes. By contrast, lower Degree means the node is further away from the web’s core position and hardly ever interacts with others. Ones like this has little effect on other nodes. What the Betweenness measures is, to what extent does one node locate in between other nodes’ "middle" of the web. That is to say, to what extent the node is others’ "intermediary". Nodes like this played the role of bridge in the web. Betweenness shows the degree of the rule that one node perform in the circulation of the web. The higher betweenness one node is, the more crucial position it is in the circulation of knowledge and information on the web. Closeness is the sum of the shortest distance from one node to others on the web. Lower closeness means one node can connect to others through a shorter distance and less depends on others. The smaller Closeness expressed the stronger ability for one node to get ride of others’ control, in other words, the node is more dominating.

Chart 1 shows that the calculations of Centrality of top 25 keywords whose various centrality indexes are high. The calculations dedicated that the rank of Centrality’s calculations was different from the rank of the keywords’ frequency. Practically, some keywords with low frequency ranking has a high Centrality ranking. For example, the frequency ranking of the word “microscope” came out in the 9th place, while it ranked third in the calculations of Betweenness. Moreover, there are other keywords like these, which had significant differences in words frequency and Betweennes. Such as the Atomic lattice of carbon atoms, molecule, micro-robots, Micron Technology, organic thin films, small size effect, copper etc. And the rank of all Centrality indexes of various keywords is very diversity. Keywords with three Centrality
indexes all ranked in top 25, such as scanning tunneling microscopy, nanotechnology, optical microscopy and scanning probe microscopy. And the keywords, ranked in top 25, only with the calculations of Degree and Betweenness indexes included surface structure and surface morphology, single molecule, Silicon, nano-materials, Nano- and nano-fabrication. The keywords, ranked in top 25, only with the calculations of Betweenness and Closeness indexes, included biological molecules and biological macromolecules, carbon atom, Micron Technology, micro-robots, small size effect and Atomic lattice. And the keywords, ranked in top 25, only with the calculations of Degree and Closeness indexes, included nanotechnology, probe scanning microscopy, life science and material surface, tunnel effect. As shown in Picture 5, it is the web structure of the top 40 high frequency keywords ranked in Degree relevant graphic, through the visualization function of the UCINET.

Figure 5. The web structure of keywords at high frequency

The analysis of research fields about STM related hot spots

Next, we have analyzed the changes of the research on STM-related hot spots through studying the burst keywords. The burst terms of one theme refer to the words or phrases of this theme, whose frequency changed swiftly in one period. Burst terms is the mark of the sudden booming of the hot topic in the research area, as well as the significant measurement of the research direction (Chen, 2004). Compared to the traditional ways of high frequency words analysis, the burst of keywords frequency is more suitable for exploring the transform of research hot spots, and the new trends of research development. When analyzing the burst terms by detection technology and arithmetic, we have used the BURST DETECTION of CITESPACE. This function measures the deeper changes, basing on the burst information of keywords’ frequency, during a period of time.

Figure 6 illustrated the situation of the top 20 keywords with strongest citation burst. There were ten keywords had direct correlation with Nano, out of the top 20 keywords. In terms of burst strength, the strongest one is Nano technology with the strength up to 19.09; the second is atomic level with the burst strength up to 11.16 in the period of 2005-2009. From the time, the keywords having burst before 1995 mainly consisted of atomic scale, optical microscopy,

**Figure 6. Top 20 KEYWORDS with Strongest Citation Bursts**

**Research Conclusions**

There is a close and complex relationship between science and technology. When it comes to conducting quantitative analysis of the relationship of the two, quite a few scholars have revealed how science supports and promotes technology through the citation analysis of patents to theses, and have discussed how technology has accelerated scientific research by citation analysis of theses to patents. In this text, we started with a specific technology to study the rule of how the new technology -STM- has permeated various disciplines of science research. We have also studied the structure of science knowledge under the impact of this technology and how the dynamic evolutionary progress of scientific research hot spots followed this technology. Therefore, in this text, we have conducted a quantitative study using the data of the documents retrieved from the databases of CNKI and SCI and reached several main conclusions below: Literatures associated with STM first appeared in 1985, and kept developing at a stable and swift speed, referring to the disciplines of natural science, engineering science and technology, and information science and technology. STM permeated various disciplines at different speeds, and different subjects also responded to STM discrepancy. Generally, the reaction rates of each
subject to technology had changed in the same direction as that of STM relevant documents. From what we have known of documents about STM, STM was born in the land of quantum mechanics, solid state physics, chemical physics, electronic physics, mechanical engineering, and Cybernetics. Meanwhile, the new technology promoted the emergence of relevant disciplines and also promoted the advance of new relevant technology. STM advanced the appearance and development of the technology associated with microscopy which included atomic force microscopy, SNOM, scanning probe microscopes, scanning electron microscopes, transmission electron microscopy. At the same time, STM also brought rapid progress of research into nanotechnology and surface science. In this field, it can therefore be seen that science and technology not only affect and promote each other, but have also developed along independent paths.

In the co-occurrence web of keywords’ structure, based on the calculations of web Centrality, in indexes of scanning tunneling microscopy, nanotechnology, scanning probe microscopy, and the three Centrality of optical microscopy ranked at the top. The noteworthy keywords are Atomic lattice, micro-robots, small size effect and biological macromolecules. Though they are sorted out of the keywords list of high frequency, the Betweenness and Closeness of these keywords is ranked in front, occupying an important position in the structure of the keywords co-occurrence web. We conducted the research on the hot spots study fields associated with STM technology and found that the burst keyword were MBE, Graphene, quantum computers in recent years. So we can forecast that research associated with these keywords should be the current research hot spots, science breakthroughs and new technological growth in the future.

Abstract
Archival Appraisal Theory (AAT) is a fundamental theory of Archival Science, which has been undergoing substantial changes since 1990s. Using the research methods of Scientometrics and the related Knowledge-Mapping tool, this paper analyzes the citations between AAT journal articles and those from other disciplines, identifies the related AAT research hot spots, and summarizes the developments of AAT from 1990 to 2016. We use the study results to extrapolate the trends of AAT developments in the past almost three decades through a macroscopic view. The discoveries could be used to augment and tune Archival Science in order to meet the emerging demands for more applicable and effective theories and methods for appraising modern archival works.

Conference Topic
Citation and co-citation analysis, Mapping and visualization, Social network analysis, Science of science

Introduction
Archival Appraisal Theory (AAT) had been invented as a result of the developments of modern archival works. The theory itself concerns various concepts such as value, utilization, appraisal, simplification, and benefits in appraising archives (B.L.Craig, 2004). Archival characteristics of files and the characteristics of archival management are reflected in AAT (N.Brubach, 1996). Using the research methods of Scientometrics and the related Knowledge-Mapping tool, analysis on the developments of AAT from 1990 to 2016 is made in this paper. Various AAT developments are identified and summarized, and we discover five trends of AAT developments through a macroscopic view.

Archival Appraisal Theory and Its History of Development

What is Archival Appraisal?
Archival appraisal is the practice to identify and assess the values of archives, in order to identify the valuable ones to hand over to an archival institution and to discard the worthless ones meanwhile. Archival appraisal directly determines whether or not an archive should be preserved or destroyed, and the determination itself is the most important and difficult aspect of archival management. (Duranti, 1994; Williams, 2006; Avery, 2010; Cook, 2011).

Developments of Archival Appraisal Theories
A. “Age determination theory”: In 1901, German archival scholar Mays McConnell put forward the notion that “elderly archives should be respected” and he proceeded to set an arbitrary amount of time
for their preservations before destructions. McConnel, for the first time, also raised the idea that the provenance of an archive should be among the most important appraisal criteria. (Fishbein, 1970; Carnicheal, 2004).

B. “Administrative official determination theory”: In the 1920s, British archival scholar Hilary Jenkinson proposed that the archival workers ought not to be involved in the appraisal and destruction of archives. Instead, they should be done by administrative officials (Finch, 1984).

C. “Function appraisal theory”: In the 1930s, Polish archival scholar Carlin Sharansky proposed that the importance of the producers’ positions and their functions in a governmental hierarchical system should be used to decide the values and retention periods of the archives they produced (Boles, 2005; Harris, 2007).

D. “Archival dual values theory”: In 1956 American archival scholar T. R. Schellenberg, known as “the father of archival appraisal theory”, published his iconic work, the Principle and Technology: Modern Archives, and he proposed that public archives should have two different values: the value to government bodies producing the archive, “the first value”, and the value to the users of other government bodies or individual users, “the second value”. Specifically, the first value reflects an archive’s administrative value, the legal value, the financial value and the technological value, while the second value reflects its evidential value, information value and intelligence value. The administrative officials from the government body producing an archive should be responsible for appraising the archive’s first value, whereas its second value should be determined by archival workers (Francis, 2007).

E. “Utilization determination theory”: In 1960s and 1970s, American archival scholars Fez, Bridgetown, Clifford and Finch proposed that historians’ actual and expected utilizations of archives should be the most important criteria for archival appraisal (Ngulube, 2001; Hurley, 2005).

F. “Social analysis and function appraisal theory”: In early 1980s, German archival scholar Booms advocated that an archive should reflect the social values in its formation period. He also argued that these values should be indirectly determined through understanding of its creators’ functions rather than be directly determined through the study of the social public opinions during the period (Behrnd-Klokt, 2009; Pearce-Moses, 2005).

G. “Literature strategy theory”: In mid-1980s, American archival scholar Seymour Wales advocated that the starting point of archival appraisal shall no longer be the examination of an archive but the analysis of the backgrounds in which the archive was produced, especially as a response to the frequent changes of the archive-producing government bodies in modern society (Kurtz, 2004).

H. “Macro-appraisal strategic theory”: In late 1980s, Canadian archival scholar Terry Cook proposed that a variety of factors should be taken into consideration for archival appraisal such as the social structure, archival formation process, creators and their functions (Cox, 2005; Hensen, 2004).

Data Sources and Research Methodology

Data Sources

The Institute for Scientific Information (ISI) started to publish Science Citation Index (SCI) in 1964, and ISI brought an integrated system of academic information resources named “ISI Web of Knowledge”. The core of this system is “Web of Science” (WOS) through which ISI’s three most famous citation databases, Science Citation Index Expanded (the SCIE), Social Science Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI), can be directly accessed. These three citation databases cover the most important and influential research achievements in the world.

The journal articles from the above three databases of WOS were accessed with a default time span from January 1st 1990 to November 21st of 2016. The information retrieval was centered on the topic of “appraisal”, and the query was “Subject = appraisal or appraise, publication time = 1990-2016, select Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI), Lemmatization = on, documental type = article”. 20720 articles were retrieved as a result. However, many of the journals articles containing the keywords were irrelevant to archival appraisal research.
For example, an article from an archeology journal containing the keyword “appraisal” may only mean to describe and evaluate the new discoveries from an archeological excavation site and hence does not contribute to archival appraisal research. In order to eliminate such noises, the retrieval results were refined, and eventually 14470 articles were selected as source literatures.

Research Methodology

The interactions between different disciplines are reflected in the citations linking their articles. An article from one discipline citing the research results or study methods introduced by the articles from another discipline shows that the latter discipline informs the first one, which may use the cited results and methods to broaden and/or deepen its own research.

Such analysis is called Citation Analysis, a research method frequently employed in Scientometrics. Making use of graph theory, fuzzy sets, statistics and logical methods such as inference and induction, it analyzes citations on research objects, such as academic journals, conference papers and authors in order to forecast and evaluate the trends of scientific developments.

Knowledge-Mapping is the graphical display of the development processes and the structural relationships of scientific knowledge (Wasserman, 1994; Waaijer etc, 2011; Chen etc, 2002; Anderson, 2008). It makes use of visualization technologies to sort out and describe the relationships between scientific knowledge and the related patterns of knowledge evolution (Newman, 2001; Yan etc, 2012). The developments of AAT in the last thirty years are visualized using VOSviewer1.4, the Knowledge-Mapping drawing tool, in this paper.

VOSviewer, written in the Java programming language, runs on most operating system platforms (Eck, 2010, 2011). It is the primary tool for analyzing a Scientometrics networks. The program can be used to create maps of publications, authors, or journals based on a co-citation network or to create maps of keywords based on a co-occurrence network. The maps are created using the VOS mapping technique and the VOS clustering technique. VOSviewer can be used to view and explore the maps as well. It can show a map in various different ways, with each emphasizing a different aspect of the map.

Results

Analysis 1: Contributions of AAT Related Research Articles by Countries

Table 1 shows that based on the total number of AAT related research articles produced by countries, USA and UK were the ones that are the most active in AAT related research with them together being responsible for more than three fifths of all the articles published during the period. Canada and Australia are also noticeable countries that had highly active AAT related research with each of them accounting for more than 8% of the articles published during the period.

Table 2 lists the frequency statistics of the disciplines citing AAT. It shows that AAT has been cited by many disciplines and thus it has impacts on those disciplines by varying degrees. Figure 1 is a mapping of the relationships among disciplines having cited AAT. The size of a ball on the map is proportional to the number of instances of citing AAT in the related discipline. Figure 2 is the density map of disciplines having cited AAT. Figure 1 and Figure 2 show that the top two disciplines (that cited AAT the most) are Business & Economy and Psychology, which are followed by Social Science, Health Care Sciences & Services, Environmental Sciences & Ecology, etc.

The knowledge mapping of research focuses from the disciplines citing AAT

A keyword reveals the research focus of a scientific research, and the higher frequency one keyword has, the more attention its research focus received. Table 3 lists the frequencies of specifically cited AAT research focuses from the disciplines having cited AAT. Figure 3 is the mapping of relationships among research focuses. Figure 4 is the density map of research focuses from disciplines citing AAT. According to Table 3, Figure 3 and 4, the No.1 research focus is PERFORMANCE, at a frequency of 6092, which is commonly found in the disciplines of Business & Economics, Human Resource Management, and Psychology. It follows that AAT has been applied to management evaluation theories, where PERFORMANCE is a high frequency word. The second research focus is MODEL, which has been found in many disciplines, at a frequency of 4661, and those disciplines normally took advantage of AAT to build mathematic models in order to solve practical problems. The third research focus is BEHAVIOR that has been found in Psychology, at a frequency of 3040, and it follows that AAT have been employed by psychology to study behaviors.

The Knowledge-Mapping of research focuses from disciplines cited by AAT

Table 5 is the frequency statistics of research focuses from disciplines cited by AAT. These research focuses are almost the same as those in Table 3, but there are some differences in the ranking of the focuses. The data in the table suggests that the development of AAT is closely related to the developments of other disciplines with AAT continuously interacting with other disciplines to improve itself to meet their needs. Figure 7 and 8 are respectively the mapping of relationships between research focuses from disciplines cited by AAT and the density map of these research focuses.

Figure 7. The mapping of relationship between research focuses from disciplines cited by AAT

Figure 8. The density map of relationships between research focuses from disciplines cited by AAT
Conclusion

The development trends of AAT in the past almost three decades can be extrapolated, and the conclusions can be made, based on the analysis on the disciplines and their research focuses that have cited AAT and been cited by AAT.

Trend 1: the declining influences by Historicism

The emergence and development of archival science was closely related to the study of History. So to speak, archival science in the early stage can be considered as a by-product of History study. The influence of historicism even spurred the formation of “Utilization Determination Theory” of AAT, which regards historians’ actual and expected utilizations of archives as the most important criteria in archival appraisal.

However, the influence by Historicism on AAT has been declining in the past almost thirty year and this trend can be reflected in the table of frequency statistics of disciplines cited by AAT. It shows that the influence on AAT by History study has declined (currently the sixth in the rank of disciplines cited by AAT) and is no longer the most influential discipline to the development of AAT. In the meanwhile, the standards of AAT have become more diversified. Moreover, since the emergence of electronic archives, the attentions paid to electronic archival appraisal exceeded those paid to content (historical paper documents) appraisal. The establishment of “Double Point Theory” for electronic archival appraisal demonstrated the weakening of Historicism in guiding AAT developments. In addition, archives’ properties as technological devices have become popular research focuses of AAT.

Trend 2: the regression to Function Appraisal Theory

Since late 1980s, with the astonishing increase of archival quantities, growing complexity of archival types, and the fast growing applications of archives, archival researchers have been gradually convinced that archives should reflect the societ al values that influenced the archives’ productions. As a result, the ideological basis of archival theory has undergone a fundamental change from being a national theory to being a societal one. However, later on, the focuses of archival appraisal have gradually shifted from an archive’s complex societal values (and the social problems or trends they intent to convey) to the archival provenances shown by the functions of archival creators. The analysis would emphasize on the functions of archival creators, their activities and interrelationships in those activities, and their importance (standings) in business, etc. This new trend, albeit based on the same concept behind the old “Functional Appraisal Theory” (FAT), demands a large body of knowledge from other disciplines to assist archival appraisal, such as Public Administration, Information Storage and Retrieval. The table of frequency statistics of disciplines that have cited AAT and been cited by AAT shows the trend that Public Administration, Information Science & Library Science have been more important than History as far as the influence on AAT is concerned, confirming partially the regressions to FAT.

Trend 3: the predominant popularity of Provenance Principle (PP)

PP is a way to “compartmentalize and manage archives on their provenances to the organizations producing those archives”. It means archival workers arrange and classify the archives according to archival provenance and must stick to the principle that “Do not disperse the archives from the same provenance, and do not mix up the archives from different provenances”. In view of archival value, the principle emphasizes that the archival preservation value should be appraised based on the creators’ functions and the functions of the archives they create. PP had been derived from principle of “Respect General Archives” that originated in France in 1841. The appraisal standards and approaches based on PP are simpler, more objective and practical, hence is an important criterion to judge archival value.

PP made it possible that the applications of AAT to different disciplines. According to the data collected from 1990 to 2016, we could arrive at a conclusion that the disciplines citing AAT and cited by AAT are widely distributed, it shows that all those different disciplines were applying AAT to their own research fields using a variety of different AAT methods, and the methods used depend on the different disciplines and organizations that produce those archives. It reveals that PP is indeed a highly important, or in other words predominant, component of AAT.

Trend 4: the practicalization of appraisal standards

In the past thirty years, the practicalizations of archival appraisal theories has grown to be more
obvious. This trend can be shown in two aspects as follows:

First, the criteria of archival appraisal have been made more favorable to practical application and systematization. In face of the rapid rise of archival quantities, it is very important to make a prompt decision on archival appraisal in time. The procedure for archival appraisal instructions has been made to further detail the storage time of archives in order to facilitate archival appraisal workers to utilize specific methods in a prompt manner. This development trend can be reflected on the research focuses from disciplines that have cited AAT and been cited by AAT, such as the keywords of ORGANIZATIONS, SYSTEMS.

Second, archival appraisal is the main measure for archive optimization. Among a huge collection of files and documents, only a small part of it could be worth being conserved permanently as archives. Therefore, it is essential to control the size of archival collections and to guarantee their qualities at the same time. Archival optimization means to obtain the best proportional relationship between the size of an archival collection and its quantity of information, in other words, how to conserve the maximal amount of necessary information with the minimal size of archival collection. This development trend of archival appraisal can be reflected on the keywords in the articles of collection optimization in AAT, such as MODEL, STRATEGIES, VALIDITY, and QUALITY.

Trend 5: the increasing emphasis on utilitarianism

The keywords of PERFORMANCE and SATISFACTION enjoy very high rankings in the research focuses from disciplines that have cited AAT and been cited by AAT, and it follows that the emphasis on AAT’s utilitarianism (for the utilitarian benefits to the organization that applies AAT) has received more attentions and become an important criterion of archival appraisal.

In addition, evaluating an archive’s value given the cost of conserving it, archival workers try their bests to maximize the benefits applying AAT and minimize the cost. The phenomenon shows that the idea of emphasizing benefits in archival appraisal work has been widely accepted. Archival appraisal is no longer limited to basing itself on subjective demands or on objective properties, but it would also rather be skewed to achieve the optimal benefits in different scenarios and for different disciplines.

Thoughts

The development of AAT is both a dynamic and a regular process. We studied this observation and used the study results to discover the trends of AAT developments in the past almost three decades. These discoveries could be used to augment, tune and enrich Archival Science in order to meet the emerging demands for more applicable and effective theories and methods for appraising modern archival works.

Abstract
This paper proposes a new patent classification method that accounts for both time inflation and application year. We compare the annual citation increment of patents and classify the patents into four types: dominant, precocious, admirable, and late-recognized. Substantially different citation curves were obtained for different patent types. Additionally, early citation history was highly related to the probability of a patent being classified as important.

Keywords
Patent classification, citation analysis, patent analysis

Conference Topic
Patent analysis

Introduction
A patent can be considered a tangible form of an invention or an innovative technology. Among all the indicators employed to measure innovative performance, patent citation and its extensions are the most efficient measurement of patent quality (Breitzman, Thomas, & Cheney, 2002; Costas, van Leeuwen, & van Raan, 2010). When a patent’s technology is based on previously granted patents, these earlier patents are cited in the later patent. If the technology in a previously granted patent is widely used by later inventions, its importance is higher than those that have fewer citations. Thus, a patent’s number of citations indicates its impact or importance.

Long-term forward citations indicate the importance of a patent and its contribution to subsequent research. Younger patents tend to have fewer citations than older patents (Hall, Jaffe, & Trajtenberg, 2001) because of their shorter exposure time. In addition, Hall, Jaffe, & Trajtenberg (2001) proposed that the number of citations a patent receives may be high for reasons other than patent quality; this phenomenon is named citation inflation. When measuring patent quality, different application date and citation inflation may cause citation inequality.

Studies have investigated the distribution of citations during a patent’s life cycle. The shape of the citation distribution is termed the citation age profile, and it can imply knowledge flow, the utilization of knowledge, and the duration of a technology’s life cycle (Mehta, Rysman, & Simcoe, 2010). Patterns of citation durability, aging, and obsolescence vary for different patents (Costas et al., 2010; Glänzel & Schoepflin, 1995; Line, 1993).
Citation inequality caused by time factors should be considered when citations are used to measure patent performance. Most of the current research measuring patent performance has considered only the citations a particular patent receives during the first few years after it was issued (Blind, Cremers, & Mueller, 2009; Breitzman et al., 2002). However, counting citations from only these first few years may overlook the potential impact of patents that are less cited at first but then become highly cited after a long period (van Raan, 2004). Fabry, Ernst, Langholz, & Köster (2006) introduced an impact-factor-like indicator and assigned more weight to citations received in the last two years in their research that was used to position the innovative power and patent strength of companies in the health and nutrition industry.

Various studies have aimed to utilize patent citations in the evaluation of the innovative performance of a single patent, patent assignee, company, or country. However, when examining patent citations as an indicator of patent quality or impact, most studies have failed to account for the time factors of patent citations. Patents applied for in different years may have been examined using the varying policies of intellectual property agencies, and patent application can differ because of the industrial environment during different periods. Comparing patents of different ages is unfair because older patents tend to accumulate more citations. Although there are plausible solutions to managing citation truncation caused by time factors, a comprehensive measurement methodology has not yet been developed.

Numerous studies have employed patent indicators in a diverse analysis; however, the single value represented by patent indicators can only reflect the aggregated performance of a patent until the time at which the analysis is performed. For example, the 2015 accumulated patent citations contain all the citations received by patents up to 2015 if patents of different ages are not distinguished. Therefore, comparing patents of different ages using the 2015 accumulated citations will result in a bias toward older patents and thus an incorrect examination. Moreover, if only static patent indicators are employed—including the accumulated performance during the analysis interval, which does not differentiate the citations gained in each time segment—some interesting behavior of patent may be ignored and the effectiveness of the evaluation will be limited.

In this study, we evaluate patents using their annual patent citation increment, and these values are compared for patents with the same application year. We further propose a classification method for use in future research.

Data
In this preliminary paper, we applied our classification method to patents classified as Information Storage patents by Hall, Jaffe, & Trajtenberg (2005) using the United States Patent Classification (USPC). These USPC included Dynamic Magnetic Information Storage or Retrieval (360), Static Information Storage and Retrieval (365), Dynamic Information Storage or Retrieval (369), and Electrical Computers and Digital Processing Systems: Memory (711). To avoid citation inequality caused by different application years, we compare citations within the same application year. However, in this preliminary research, we only employed 1-year data—grant patents applied for in 1995—to verify our proposed classification method. Citations were counted if a citing patent was applied for from 1995 to 2015 and granted before October 12, 2016, the day we collected our data from the United States Patent and Trademark Office Patent Full-Text Database.
Method
To evaluate the importance of patents during each year, we first divide a patent’s citations by their citation year. For each cited year $y$, we calculate the citation percentile rank and further separate the patents into two groups depending on whether the patents received more or fewer citations than the citation threshold $C_{th,y}$, which is the citation of the chosen percentile in the year $y$.

The following three patent characteristics were considered:
(i) Importance ($g$): the number of times a patent’s annual citations were higher than the citation threshold $C_{th,y}$;
(ii) Stability ($d$): the maximum number of continuous years that a patent received more annual citations than the citation threshold $C_{th,y}$;
(iii) Most influential time ($m$): the age at which a patent received its maximum number of citations.

Figure 1 illustrates the classification method used in this study. If a patent has a significantly higher $g$ than the average (i.e., $g > g_{th}$, where $g_{th}$ is the average of $g$ plus one standard deviation of $g$), we recognize it as an important patent (i.e., dominant). These important patents are separated into two subgroups: stable and unstable. Stable patents are highly cited for a significantly longer period than are others (i.e., $d > d_{th}$, where $d_{th}$ is one standard deviation higher than the average of $d$). For the unstable patents, their citation peak is determined, and they are divided into three subgroups. If their age of maximum citation is significantly larger than those of others (i.e., $m > m_{above}$, where $m_{above}$ is one standard deviation larger than the average of $m$), we term it “late-recognized.” If its citation peak occurs significantly early in its life cycle (i.e., $m < m_{below}$, where $m_{below}$ is the average of $m$ minus one standard deviation of $m$), it is termed “precocious.” An “admirable” patent has $m_{below} < m < m_{above}$.

Result and Discussion
Choosing the Percentile Threshold
To determine the threshold used in the subsequent analysis, we first employed four thresholds (top 1%, 5%, 10%, and 25%) and observed how the classification changed as the threshold was varied (see Table 1 for the results). We discovered that the top 1% threshold was too severe to satisfy and most patents were not recognized as important or stable; this threshold thus resulted in the smallest $g_{th}$ and $d_{th}$. However, we do not expect a dominant patent to remain in the top
1% of cited patents only for a few years. Thus, the top 1% and 5% thresholds could not meet our needs.

### Table 1. Critical indicators for the different thresholds.

Through the critical indicators, the classification results also changed as the threshold varied. As the threshold was gradually changed from top 1% to 25%, more patents were classified as important patents (i.e., dominant, precocious, admirable, or late-recognized; Table 2). However, we noticed that the number of admirable patents increased by a larger amount than did the other important patent types, indicating that a severe threshold will limit the classification result to patents that are extremely important.

Figure 2 plots the average citation curve of the four patent types when the four thresholds were used. The gray regions in each plot indicate the citation threshold $C_{th, y}$. When the threshold was top 1%, the annual citations of the citation threshold was higher than even the average of annual citations of dominant patents. Furthermore, we could not separate precocious patents from admirable patents when we applied this threshold. These results indicate that top 1% is not a suitable threshold because it is excessively severe for classifications and can result in the omission or misclassification of some patent types. When the top 5% threshold was used, all four patent types were identified and their characteristic citation curves obtained. However, the citation curves of most of the important patents were still lower than the gray threshold region, and the shapes were strongly affected by the dominant patents. Thus, top 5% is also not a suitable threshold for the classification of these patents. The curves of the top 10% and top 25% thresholds are different from the citation curve for the dominant patents. Both top 10% and top 25% are suitable threshold choices. In the following discussion, we analyze in detail the classification of patents using top 25% as the citation threshold $C_{th, y}$. 
Classification Result

Only a few patents were classified as important patents, as indicated in Table 2. Even if top 25% was used as the threshold, only 19% of patents were recognized as important. However, we noticed that most important patents were stable and classified as dominant. We also discovered that although the citation of most patents peaked approximately five years after application, there were a relatively small number of precocious patents, the citation of which peaked significantly earlier than others.

In Figure 2, the difference in the average citation history of each patent type can be clearly distinguished. The average citation curve of precocious patents peaked early and soon decreased to the average. The dominant patents were not only highly cited for a long period but also gained more citations than other types. The annual citation of dominant patents was two times the annual citation of other important patents on average and more than three times the annual citation of the average citations of all information storage patents. The late-recognized patents have a flat citation curve that is slightly higher than the average and the threshold during the first half of their life; subsequently, the citation curve suddenly increases by a factor of approximately two. After these late-recognized patents were recognized, their citation curve was similar to that of dominant patents but approximately half the amplitude. The average citation curve of admirable patents is similar to the theoretical citation curve of patents, with a peak approximately 5–7 years after the patent’s application.

When the top 25% threshold was employed, most of the average citation curves of important patents (except for the precocious patents during their late life) were higher than the threshold. This indicated that our classification method successfully recognized important patents.

Figure 3 illustrates the classification distribution for four top cited patent groups. For patents having its accumulated citation rank as top 1%, which had a total number of citations larger than 285, we discovered that all were classified as dominant patents. As the accumulated
citation changed from top 1% to 25%, the proportion of dominant patents decreased. Less than half of the top 25% accumulated citation patents were dominant patents. Figure 2 illustrates that the average citation curve varied from type to type. Figure 4 further examines the citation curves of the four types of patent for patents that received the equal number of accumulated citations ($C_{total} = 82$). The patent types in Figure 4 were classified using 25% as the citation threshold $C_{th, y}$. Although these patents had the same number of accumulated citations at the time the data was collected, their citation curves vary distinctly.

Figure 3. Classification distribution under different total citation thresholds.
In the current patent system, assignees must pay maintenance fees to extend the legal status of their patents. Therefore, it is essential to know if a patent is worth maintaining before a fee is paid. If only the total number of citations a patent receives is used to evaluate that patent, some crucial patent information might be missed.

Patent assignees must decide whether to pay the first maintenance fee 7.5 years after the patent was applied for; thus, we attempted to examine the years during which a patent received fewer citations than the citation threshold $C_{th,y}$ during its first 8 years and used our method to classify the patents (Table 3). We discovered that if a patent received fewer citations than the threshold for more than 5 years, it had a small probability (<10%) of being classified as an important patent later in its life cycle. The results presented in Table 3 may help patent assignees to decide whether to pay maintenance fees.

Conclusion

In this paper, we propose a new patent classification method that accounts for time inflation and application year. We compare the annual citation increment of patents applied for in the same year. Thresholds are defined for the identification of significantly highly cited, stable, early cited, and late-cited patents, and they are classified into four types: dominant, precocious, admirable, and late-recognized.

We first investigated the classification results when one of four citation thresholds was employed: top 1%, top 5%, top 10%, and top 25%. We discovered that the top 1% and 5% citation thresholds are too high for most patents to pass. The citation curves obtained when these two thresholds were used were also strongly affected by the dominant patents. Therefore, top 10% or 25% is recommended as the citation threshold when our proposed classification method is employed.

The average citation curves obtained using our classification and the citation curves of selected patents that had the equal number of accumulated citations revealed that the citation curves of different classification types differ significantly. If only accumulated citations are considered, crucial information can be missed.

Our analysis of patent performance in the first 8 years and our classification identified that if a patent has fewer citations than the threshold for more than 5 of its first 8 years, it has a relatively low probability of becoming an important patent. This might help assignees predict the performance of their patent and decide whether to maintain it.

Is the Gap in Scientific and Technological Strength Between G7 and BRICS Becoming Smaller or Larger?

Yuan Junpeng  Gao Jiping  Su Cheng  Zhai Lihua  Wang Haiyan  Pan Yuntao

junpengyuan@gmail.com

Institute of Scientific and Technical Information of China, Beijing (China)

Introduction
Science and technology in emerging economies is undergoing rapid development. As a result, the question arises of whether the gap in scientific and technological strength between emerging economies and developed countries is becoming smaller or larger. Although there are many ways of studying scientific activity systematically, scientometric analysis provides a well-proven means of achieving this goal (Garfield E. 1979). Although numerous lists of highly cited articles have been compiled across a variety of scientific fields, few have included articles from all fields (van Raan 2017, Siddiqi and Usman 2017, Terekhov 2017). The present study was an in-depth scientometric analysis of data. It aimed to identify and analyse the 1000 most highly cited articles and evaluate the research performance of the G7 and BRICS countries. It is hoped that this study will stimulate useful discussion among scientists and research managers about research directions and provide insight for policy and funding decisions.

Dataset and methods
Since the reformation and opening up of its economy in 1978, China has undergone rapid development. The Web of Science (WoS) database was used to compile a citation history of papers for the period 1979–2008. Based on these articles and citations, the top 1000 highest-impact articles in every discipline were selected as the dataset. To measure scientific output, we adopted as indicators the total number of articles, total citation rates, citations per article, and numbers of domestic and international articles. To examine collaboration, we chose as an index of international articles, the international cooperation rate to assess the role of international collaboration in high-impact articles.

Analyses and results
We consider whether a country’s stage of economic development and its S&T level can affect the production of its highly cited papers. Do S&T levels lead to or result from numbers of highly cited papers?

Characteristics of G7 countries’ highly cited papers
Domestic articles are taken to be highly cited papers that were written entirely by authors of one particular country. Analysis of the G7’s domestic papers in 22 disciplines can be used as an indicator of the S&T capability and impact of the G7 countries in various disciplines. It can be seen that domestic papers of the G7 accounted for the majority of the papers in all the disciplines: except for the fields of space science, clinical medicine, agricultural sciences, and mathematics, those proportions were greater than 70%. The proportion of G7 domestic papers to all domestic papers in the discipline of general social sciences was more than 90%

Because it provides access to a wider range of facilities and resources, collaboration is encouraged at a policy level. It enables researchers to participate in networks of cutting-edge and innovative activity. The international cooperation rate can reflect the G7 countries’ status of participation in international scientific and technological cooperation. The international cooperation rate of G7 countries in the 22 disciplines is shown in Figure 1.
than the number of such papers from 1999 to 2008. This is in keeping with the principle that in the G7 countries papers published earlier tend to be cited more often.

Characteristics of BRICS countries’ highly cited papers

In terms of the number of papers in the various disciplines, there was a large gap between the rankings of the five BRICS countries and the G7 countries. Table 1 lists the total number of articles and the ranking by discipline of the BRICS countries.

Table 1. The total number of articles and ranking by discipline of the BRICS countries (1979–2008)

</table>

The economic strength and S&T capacity of the BRICS countries made substantial progress over the period from 1979 to 2008, and the number of SCI papers of the five countries also increased rapidly. It is evident that the highly cited papers in the BRICS countries were mainly the result of international cooperation. In terms of the average international cooperation rate among the BRICS countries, chemistry was the discipline with the lowest rate; the average rate amounted only to 16.67%. The next lowest were pharmacology & toxicology and mathematics. The other disciplines showed an average rate of greater than 50%. Notable was the rate of 100% in economics & business, immunology, and multidisciplinary, which indicates that the highly cited papers produced by BRICS countries in these three disciplines were entirely the result of international cooperation. Compared with the figures for the G7 countries, the average rate for chemistry and pharmacology & toxicology was also low among the BRICS countries.

Conclusion and discussion

The present study was designed to analyze the published articles that attracted the most citations in the G7 and BRICS countries. Some valuable insights can be gained through this restricted approach.

1) The United States was the world leader, followed by the United Kingdom, Germany, and Japan. There was a significant gap between Italy and the other G7 countries.

2) In terms of the number of papers in the various disciplines, there was a large gap between the rankings of the BRICS countries and the G7 countries.

3) There was a world trend toward domestic research in terms of highly cited papers. The papers in the majority of disciplines in the United States were based on independent domestic research. The United Kingdom, France, Germany, and Italy placed greater emphasis on international cooperation, and Japan and Canada had different tendencies toward international cooperation in different disciplines.

4) The highly cited papers among BRICS countries in economics & business, immunology, and multidisciplinary were produced entirely by international cooperation.

5) The growth rates were high in 13 disciplines in Germany and 12 disciplines in Japan. In the United Kingdom and France, the growth rates were high in eight disciplines. Finally, the United States had high growth rates in five disciplines, and in Canada and Italy growth rates were high in four disciplines.

Abstract

Evidence based policy studies provide rationale for developing polices and mechanisms for strengthening research and innovation ecosystem, and for creating strategic roadmaps and new business models. This is becoming critical in science-intensive research areas like nanotechnology where the traditional models of innovation do not work. Taking this as a premise, the paper investigates the contemporary research and innovation trends in nanotechnology. Along with traditional bibliometric indicators, standard activity and product development are examined to provide a deeper insight of nanotechnology research and commercialisation.

Findings confirm with current studies of exponential increase in research papers and aggressive patenting activity in this field. Patenting and linkages between various technology classes/sub-classes and the role of instruments in development of this field shows new insights behind nanotechnology development. Interesting evidence emerges from research activity in production methods which is linked to scalability and commercialisation. Standard making shows how it is a strategic activity with domaination by a few countries. The paper concludes by highlighting the need for examining both macro and micro trends to capture the direction of translation and commercialisation in an new and emerging technology like nanotechnology.

- Science policy (on different levels)
Introduction

Nanotechnology is seen as the key emerging technology of the 21st century. Radically novel properties that materials demonstrate at the nano-scale (10-9 meter) promises to revolutionize many industry sectors. Nanotechnology has potential for mitigating developmental challenges in water, health, environment among others. Nanotechnology in the last decade or so has attracted global attention due to these promising possibilities leading to articulation of dedicated mission mode programs, roadmaps and other policy instruments by different countries (UNESCO, 2016). Liberal funding had surrounded the various policy initiatives (Battelle, 2013). Advanced OECD countries are major players, however unlike other emerging technologies many newly industrialised and emerging economies have also emerged as influential players. UNESCO (2015) analysis provides good evidence based support the above fact. Research articles in particular demonstrate emerging South economies strong presence. However, patenting activity which is a reflection of a country’s competitive strategic asset shows emerging countries still have a long way to go to match the innovation leaders. As this report shows leading producers of research articles are ranked as China, the USA, India, South Korea, Germany and Japan. However, the order changes when one looks at number of patents per 100 articles. The USA takes the lead with 44, followed by Japan (30), South Korea (27), Germany (22). It is only 2.28 for China, 1.67 for Brazil, 1.61 for India and 0.72 for Russian Federation.

Nanotechnology has made substantial global impact primarily due to the strong public push by different countries (Bhattacharya et al., 2014). Almost no other field has obtained as much public investment in R&D in such a short time as this field. Along with advanced countries, BRICS and other scientifically proficient countries such as Mexico and Taiwan are making huge investments in this field specifically in development of new and improved nanomaterials. Sophisticated instruments have been created that provide advanced tools for engineering nanomaterials.

Nanotechnology at the present stage of commercial development is primarily acting as an enabling technology. Engineered nanomaterials are being embedded to improve the quality of existing products. Different market forecasts for nanotechnology show the market dominance of nanomaterial production. A good estimation of nanomaterials market comes from the second regulatory review on nanomaterials by European Commission (2012). It estimates the nanomaterials market at the global level at around 11 million tonnes, with a market value of roughly 20 Billion Euro. Application domains where nanotechnology is making significant impact are primarily products containing nanomaterials as intermediary products (i.e. functional components such as biosensors or light emitting diodes) or end user products (eg. Nano silver socks or solar cells) whose performance is enhanced by the specific properties of the nanomaterials.

Nanomaterials distinguish itself due to its size which gives it novel properties. However, it is a technical challenge for producing and storing nanomaterials in bulk quantity as the material quickly changes to normal size due to high reactive property a material has at the nano level. Thus, unlike other technologies, nano-scale provides new challenges that make the translation from laboratory to commercialization difficult (Kurva and Mahajan, 2012). The production techniques developed in a laboratory has to be scalable and industrially viable. Distinguishing the issues that emerge from influential studies on nanotechnology innovation and commercialization provides a useful lens for understanding the trends and design effective policy mechanisms.

Assessment of nanotechnology research and innovation based on bibliometrics has been an active area of research. One highly cited article by Roco (2011) gives a long term trend of nanotechnology development. A recent study by Karaulova et al. (2017) shows development
of this technology in Russia and identifies a series of factors that may help to explain Russia’s limited success in leveraging its ambitious national nanotechnology initiative. Hullman (2007), Ghosh and Krishnan (2014), Darvish (2016) among others showed the development of this area and to what extent emerging countries have been able to assert their position in the global stage. Another set of literature available is in analysing relevant set of bibliometrics data in specific application domain like nanobiotechnology Takeda et al. (2009) and clean energy (Wang et al., 2014), graphene (Shapira et al., 2012). Comparing nanotechnology research profile of different countries is visible across various reports and research articles capturing the contemporary trends of that period. Some recent articles that provide contemporary trends include Liu et al. (2017), Gorjiara and Boldock (2017). Some of these indicators include comparing national publication output and impact, international collaboration output and share, contribution and impact of Institutions and impact of journals and patent filings. Some of the scholars have also used sophisticated methods like foresight studies, data-mining and social network analysis to map the structural characteristics and future prospects of this area (for example, Kostoff et al. 2007). Lux research, European commission and various national reports provide important indications of market and commercial trends. Inspite of rich repository of the various studies we find that majority of them have centered on indicators constructed from publications and patents (we call them conventional indicators). The limitation is that they capture more the upstream end of the innovation value chain and thus it calls for revisiting the conventional indicators and also expanding the types of indicators to capture the downstream end of the innovation value chain and the emerging market. The paper attempts to address this limitation by examining research and patent trends that have more relevance to innovation and commercialisation and also examine standards and emerging products in this area.

Methodology

Four proxy indicators namely research publications, patents, standards and products were taken to capture the research, innovation and commercialisation trends in this field. Indicators based on publications provide an important indication of progress in this technology as mastering this technology and developing applications is contingent upon advanced scientific research. In this context, it is important to examine research activity in different nanomaterial and production techniques as they influence downstream activity. Patents help us to judge the inventive ability and a possible indication of developing novel products/processes. Standard making in emerging technologies is a strategic activity as products/processes evolve around a standard. This indicator is generally overlooked inspite of its high significance. Nanotechnology being an enabling technology at this stage, it is difficult to capture the products that have high functional enhancement through nanotechnology. This is an important caveat which should be kept in consideration while capturing nanotechnology based products.

The data for this study was captured through various methods. Publication data was downloaded from Science Citation Index Expanded (SCI-E). Search string defined by Arora et al. (2013) was applied in the title and/or abstract and/or keyword field to capture nanotechnology publications. Thomson Innovation Patent database was used for this extraction of nanotechnology patents. Search string was based on Technology classification provided by the International Patent Classification (IPC) for this field. Standard activity was captured through close reading of various technical documents including International Organization for Standardization (ISO), World Watch Institute (WWI 2006), etc. Woodrow Wilson International Centre for Scholars’ Project on Emerging Nanotechnologies database (www.nanotechproject.org) was used to capture nanotechnology based products in the major
global markets. This database tracks nanotechnology products globally and thus gives a global view of nanotechnology products, industry sectors where nanotechnology is making an impact and also helps to analyse different country’s activity and impact.

Results

Patenting Trends

Patent applications provide an indication of ongoing inventive activity in this field and also an indication of how innovation is taking shape. Patent filing through the Patent Cooperation Treaty (PCT) is the most preferred route for multiple filing in different patent office due to cost effectiveness, ease of multiple filing, establishing and extending priority among others. Nanotechnology patent filing in the PCT is thus a good reflection of global inventive activity in this field. USA being the major market for high technologies has become an obvious choice for global firms to patent in the US patent office for exploiting their invention. Thus a further informed view can be obtained by examining the application trends from US patent office. These considerations led to the examination of nanotechnology patent filing in these two patent offices.

![Figure 1. Year wise Trends in Nanotechnology Patent Applications](chart)

Patent filing shows steady upward growth in the PCT. However, in the US patent office, the shape of patent filing shows erratic changes from 2010 onwards. There would be multiple factors behind this change. Patenting in nanomaterial carbon family particularly graphene and to some extent in CNTs have shown sharp upward trend from 2009 onwards. Also for the first time in 2009 it was observed that investment by industry sector exceed public investment in advanced OECD countries (Battelle, 2012). US market appetite for next generation technologies may have contributed to the sharp upward trend in the USPTO. Can it be that the expected promise of nanotechnology application is not happening and this is having implications for filing patents in the US patent office which is a costly process? Or as the field is consolidating and there is deliberate intervention to focus on commercially and strategically important inventions? Or are their other causal factors behind this decline in patent filing?

It is important to look at the patenting activity in three nanomaterials fullerenes, carbon nanotubes (CNT) and graphene. These three nanomaterials primarily CNT and graphene are most preferred material for enhancing functionality of different products.
CNT provides high strength to weight ratio, electrical resistance and easy penetration through walls which makes it important for applications like light-weight materials, electric cables, solar cells and fabrics. Graphene has similar properties like CNT but shows more promise due to its unique single layer hexagonal lattice configuration. Thus it is increasingly being used in photovoltaics, sensors, optoelectronics, energy storage devices and ultrafiltration devices. Fullerenes acts as a semiconductor, conductor and superconductor under specific conditions and possess ability to form compounds with many different sorts of material with applications in organic photovoltaics, antioxidants, biopharmaceuticals, polymer additives and water purifiers.

Table 1 demonstrates further the technology classes in which patents have been filed in the PCT and the USPTO.

</table>
Patenting activity in different technology classes clearly demonstrate that majority of technology classes cover nanomaterials with increasing activity observed in carbon based nanomaterials. Analysis of the overlapping classes in many patent provides evidence of this. B82B has maximum linkages with C01B31/02 (452 in PCT and 284 in USPTO) showing the active inventive activity in carbon based nanostructures. Also B82Y shows maximum linkages with CO1B31/O2 (170 in PCT and 147 in USPTO) implying the active inventive activity in use or application of carbon based nanostructures.

Table 1 shows that an active area of patenting is in development of scanning probe instruments. Continuous development of sophisticated instruments is pre-requisite for nanotechnology development and novel instruments have high capital value. This plausibly drives invention activity in instruments and creating monopoly through patents. The birth of nanotechnology can itself be traced to the invention of Scanning Tunnelling Microscope (STM) in 1981 (US Patent 4343993) by Gerd K. Binnig and Heinrich Rohrer (Sekhsaria 2013). In 1986, they were awarded the Nobel Prize for this discovery. The STM yields atomic-scale images of metal and semiconductor surfaces which allowed researchers for the first time to probe materials at atomic level. The range of materials that can be imaged with a scanning device increased with the invention of the Atomic Force Microscope (US Patents 4724318 and RE33387) by Gerd K. Binnig in 1986. These two instruments were invented at and with the support of the IBM Corporation, which was interested in scientific advances within the semiconductor industry. Thus industrial research was instrumental for discovery of these two key instruments. The field has progressed with new sophisticated instruments being developed. Also it shows big firms involvement in nanotechnology research. The role of big industry can also be seen in key discovery in this field. This can be seen also in other key discoveries in this field. Carbon nanotubes was discovered by Sumio Tijma in 1991 working at Nippon Electric Company (Shapira, 2012).

Further sub-classification of the technology classes show that substantial inventive activity is observed particularly in the USPTO in “nano-biotechnology or nano-medicine (protein engineering or drug delivery)”. Drug companies are already pushing for nano-enabled interventions for better drug delivery that enhances drug efficacy and has more confined to the affected area. Patenting activity covering quantum dots as markers and nano-optics are also seen. The new imaging technologies and quantum dots enabling new screens as seen in
high value television sets. Thus, patent examination at the level of sub-classes provides insights to the new nano-enabled applications.

Research Trends

Nanotechnology research is getting influenced to a large extent by the downstream activity in the innovation value chain. One of the greatest challenges in nanotechnology commercialization is to produce high quality nano-material, on a large scale at low cost, and in a reproducible manner. Also there is a constant demand for novel nanomaterials. Industry funding and ‘return-to-investment’ demands are directing scientific research towards creating novel nanomaterials that can radically improve the quality of existing products and develop innovative approach in their production process. Also search is for nanomaterials which can transform the next generation technologies.

The exciting possibilities through nanotechnology intervention was initial shown by fullerene, a member of the carbon family. Further research on carbon family led to the discovery of carbon nanotubes and now graphene. Publication trends provide an indication of research activity in the three carbon family nanomaterials (Figure 3). Fullerene was discovered in mid-1980’s after which its publication trend has shown steep growth. Research on fullerene flattened after carbon nanotubes (CNTs) started showing more enhanced properties (Shapira et al., 2012; Izima, 1991). Graphene is now emerging as the most promising nanomaterial because of its unique combination of extraordinary mechanical, electrical, thermal, optical and electronic properties. The steep increase in graphene research is indication of the interest of the research and innovation community. The curve would take a logistic shape in the future because of the possibility of graphene getting more applied as already observed in high-speed electronics and in flexible circuitry.

There was 2473 fold increase in graphene based publications from year 1991-2012; CNTs exhibited 1502 fold increase in publications from 1992-2012; while fullerenes observed only 18 fold increase from 1991-2012. Graphene research is still in nascent stage and evolving very fast. Fullerenes, carbon nanotube, graphene are different forms of nanostructures and changing the form from fullerene to carbon nanotube and graphene has shown the possibility of more promising application. Migration of same research teams from fullerene research to CNT/graphene research is also a major reason behind the changing trend.
Figure 4 highlights countries actively involved in graphene research. Nanotechnology being science–based technologies, research publications (proxy of research activity) is a good indicator of a country’s competency. Figure 4 provides a good indication of how nanotechnology research hot-spots are now dispersed across advanced North as well as emerging South Economies.

**Standardization**

USA, Canada, Japan, UK and China are seen to be actively involved in standard making in nanotechnology. In the ISO Technical committee for nanotechnology standard, these countries have leading roles as working group chairman of committees/sub-committee.

![Figure 5. TC 229 Set Up and Activities](image)

Source: Constructed from Bhattacharya, 2015

Holding chairmanship of a working group is an indication of different countries acceptance of that country providing lead in development of that standard. For example, China created first standard in nanotechnology which was in material specification in 2005. Subsequently it has developed 21 standards. China has played an important role in the adoption of material specification standard in the TC 229 and its role was acknowledged by the ISO-Technical committee by giving her chairmanship of this group. In International Electro-technical Commission and Institute of Electrical and Electronics engineers (IEEE) also these countries have major role. IEEE has tied up with CMC which includes semiconductors and electronic design automation vendors involved in diffusion of next generation technologies. This strategic collaboration is undertaken to develop *anticipatory standards* for creation of next generation of circuit architectures based on carbon nanotubes and molecular based devices (Bhattacharya 2015). This borrows from their successful model that led to the development of IEEE 802 wired and wireless telecommunications networking standards.

European Union as an entity has significant role in defining standard guidelines applicable to countries belonging to the union. The guidelines provide challenge to non-EU countries to enter their market. U.S. leadership in the international standards-setting process allows it to shape the strategic and technical direction of nanotechnology development everywhere. China’s standardisation activity is component of its overarching strategy for future technology assertion in this critical field. Standard consortia in nanotechnology are forming in these countries and EU. Among other emerging economies we observe nanotechnology standardisation activity in Taiwan, and South Korea are making substantial progress.
Discussion and Conclusion

Research publications provide good indication of research competency. Global research in nanotechnology is addressing cutting edge technology areas (such as sensors, catalyst) as well as areas of developmental challenges (water purification, agriculture, drug delivery, etc). Nanomaterial research is a dominant focus with research shifting in areas of promising cutting edge applications namely carbon nanotube and graphene. Interesting evidence is visible from the publication activity in different production techniques of nanomaterials. Research in increasingly now focussing on new techniques specifically used for production of new nanomaterials like graphene. However, dominating areas of research are still the traditional production methods. Patenting trends do not commensurate with research trends i.e. number of patents filed are significantly less as compared to research publications. However, it is promising to observe strong connect with patenting increasingly happening in areas of developmental concerns. Patents are in nanomaterial application for treatment of various diseases like cancer, nerve disorders, drug delivery systems, fuel cells, solar cells, sensors for biomedical application and environment impact assessment, water treatment and coatings. Nanotechnology applications visible in global market are from different areas i.e. from areas of concern like health and water filters to high technology areas like electronics. Technologically advanced countries are making strong presence in standardisation activity like USA, Japan, South Korea, UK and Canada. China is the only visible developing economy making strong claim in nanotechnology standards particularly covering nonmaterial standards. China’s active involvement in standard creation and adoption in nanotechnology is not surprising as it is a component of its overreaching strategy for future technology domination in the subarea nanomaterials.

Bibliometric and innovation indicators cover one important dimension of development of a technology based area. In future, it will be significant to merge the sophisticated methods with the understanding of these indicators to get detailed information of the structure and dynamics of this area. Some of these techniques could be forecasting and foresight analysis, co-citation analysis, co-authorship analysis and other types of social networks. It will also be interesting to implement micro-level studies covering the development of nanotechnology in a specific region or sector.

Abstract
Recently, the United States Patent and Trademark Office (USPTO) has been granting more and more patents with more and more references. This can lead to serious patent citation inflation. This article undertakes an initial exploration into the phenomenon of patent citation inflation, and presents some concepts and measurement methods. On one hand, patent citation inflation rates were measured using a diachronous method, and the results indicate that citation inflation occurred with a serious impact on the patents granted during 1976–1996. On the other hand, cumulative patent citation inflation rates were measured using a synchronous method, indicating cumulative citation inflation has happened during 1976–2015. Furthermore, the short term citation inflation rates were measured using a synchronous method to detect citation inflation to recent patents granted in recent two years by calculating the rate of change in patent impact factor, similar to journal impact factor, reflecting that citations to the new patents have alternately inflated and deflated during 1979–2015. Taken as a whole, the results of this study verify that patent citation inflation has occurred seriously and frequently over the past four decades, and confirm the ability of established indicators to detect and measure patent citation inflation.

Conference Topic
Patent analysis; indicators; methods and techniques; citation and co-citation analysis

Introduction
Half a century ago, Price (1961; 1963) proposed that the number of scientific publications would grow exponentially. Although the law of exponential growth in science has not proven to be completely correct, traditional scientific research publications are increasing and even new fashioned publications are experiencing very rapid growth (Larsen & von Ins, 2010). Likewise, more and more patents have been granted by the USPTO over the past several decades. In 1976, the USPTO granted 74,966 patents, whereas in 2015, 325,467 patents were granted – a more than four-fold increase. Like scientific articles, patents contain references; applicants are required to appropriately describe and cite prior knowledge about the technological background of their inventions (Criscuolo & Verspagen, 2008; Jaffe, Trajtenberg & Fogarty, 2000). Moreover, during a patent’s prosecution, the examiner must search for any related prior patents and publications, called examiner citations, in order to judge the application’s patentability ( Cotropia, Lemley & Sampat, 2013). Cotropia (2009) and Sampat (2010) suggest that providing an abundance of references could be beneficial for applicants, because examiners may be less inclined to evaluate them effectively and instead presume their validity based on the citations offered. In recent decades, particularly, information retrieval systems and web search engines have been used extensively to help patent applicants prepare comprehensive reference information. It seems the more patents that are granted, the greater the number of references that are listed. In fact, both the total and average number of references listed in each patent increased greatly during the period between 1976 and 2015. In 1976, each successful patent application contained an average of six references, whereas by 2015, the average number of references had increased more than eight times to an average of 50. This suggests that patent references have experienced serious inflation in recent decades.
Patent citation analysis have been widely used to reveal technological knowledge diffusion (Chen & Hicks, 2004; Hu & Jaffe, 2003; Park & Suh, 2013; Nelson, 2009), to trace technological trajectories (Epicoco, 2013; Érdi et al., 2013; Martinelli, 2012), to map technical knowledge domains (Wang, Zhang & Xu, 2011; Weng & Daim, 2012), and to evaluate technology and the capacity for innovation (Albert et al., 1991; Lanjouw & Schankeman, 2004; Verspagen, 2000; Wartburg, Teichert & Rost, 2005). However, when using patent citation analysis methods, the continuing increase in the number of patents has rarely been noted. Moreover, a predilection by applicants to provide a greater number of references within their applications would certainly cause an explosion in patent references and would inevitably result in patent citation inflation. Patent citation inflation may have a significant impact on patent evaluations. For instance, evaluating a patent based on the number of citations it has received, without considering citation inflation in different periods, would not be judicious. Other metrics, such as highly-cited patents and the strength of co-citations, should also be applied cautiously. Hence, in this article, we study the phenomenon of patent citation inflation and present several methods to measure it.

Data

We constructed a bespoke database by downloading USPTO patents granted between 1976 and 2015. Only utility patents, which account for over 90% of all patents granted during the period, were analyzed. Michel and Bettels (2001) found that 90% of the references in USPTO patents were to other USPTO patents. A study by Chen (2017) showed that USPTO patents as references accounted for 61% of the total references provided, foreign patents made up 18%, and non-patent references accounted for 21%. Cotropia et al. (2013) found that the three proportions were 64%, 14%, and 22%, respectively. For simplicity, all references to USPTO utility patents that were granted during 1976–2015 were selected as our dataset. Thus, our dataset contained a total of 5,270,483 utility patents with 59,820,251 references. Table 1 shows the citation counts by year.

Methodology

Concepts and formulas

In economics (Abel & Bernanke, 2005; Barro, 1997), inflation means devaluation caused by an increase in the money supply. Inflation leads to a general rise in the price of goods and services and results in a loss of currency value. Patent citation inflation means devaluation in citation counts caused by an increase in the supply of citations. More specifically, it refers to a
rapid increase in the quantity of patent citations, which leads to a rise in the number of citations a patent receives and a subsequent decline in the overall value or impact of those citations. For instance, just because a patent has received significantly more citations than the average for patents issued in other periods does not necessarily mean that the patent is more important or has had more impact, especially if that period is characterized by an unusually high number of citations. A rapid or excessive supply of references – known as patent reference inflation – can result in patent citation inflation which may provide an alternative explanation for the high citation count. Clearly, the year a patent was granted should not play a vital or critical role in whether or not its citation count is considered to be high and, therefore, we have developed several methods to measure patent citation inflation in a given year or period.

Table 2 presents some of basic concepts and computational formulas associated with patent citation and reference inflation. The examples supporting each concept are based on the data in Table 1. Throughout the remainder of the article, in most cases, references refer specifically to a prior USPTO utility patent listed in other USPTO utility patent. The distinction between references and citations is obvious; i.e. a reference is “given to” a patent, whereas a citation is “received by” a patent. In addition, in all the formulas below, \( m \) represents the year under analysis, and \( n \) or \( p \) represents the year of comparison, where \( m \geq p \geq n \geq 1790 \) (the first US patent was granted by President Washington in 1790).

</tr>
<tr>
<td>3</td>
<td>The number of patents granted in year ( m )</td>
<td>( N_m )</td>
<td>( N_{2015} = 299,382 )</td>
</tr>
<tr>
<td>4</td>
<td>The average number of references given to patents granted in year ( n ) by patents granted year ( m )</td>
<td>( AR_{m,n} = R_{m,n}/N_m )</td>
<td>( AR_{2015,1976} = 25,596/299,382 = 0.09 )</td>
</tr>
<tr>
<td>5</td>
<td>The average number of citations received by patents granted in year ( n ) for patents granted in year ( m )</td>
<td>( AC_{m,n} = C_{m,n}/N_n )</td>
<td>( AC_{2015,1976} = 25,596/701,94 = 0.36 ) It is worth noting that ( AC_{m,n} ) is usually greater than ( AR_{m,n} ) since the number of granted patents per year has increased over this forty year period.</td>
</tr>
<tr>
<td>6</td>
<td>The total number of references given to patents issued since year ( n ) by patents granted in year ( m )</td>
<td>( SR_{m,n} = \sum^n R_{m,i} )</td>
<td>( SR_{2015,1976} = 5,406,315 )</td>
</tr>
<tr>
<td>7</td>
<td>The total citations received by patents granted in year ( n ) as of the end of year ( m )</td>
<td>( SC_{m,n} = \sum^n C_{m,i} )</td>
<td>( SC_{2015,1976} = 808,420 )</td>
</tr>
<tr>
<td>8</td>
<td>The average reference rate: the average number of references given to patents granted since year</td>
<td>( ASR_{m,n} = SR_{m,n}/N_m )</td>
<td>( ASR_{2015,1976} = 5,406,315/299,382 )</td>
</tr>
</tbody>
</table>
Equations (6)–(9) show that the cumulative total and cumulative average number of references are not usually equal to the corresponding cumulative citation counts. However, if \( p = n \), they are equal; i.e., \( CSR_{m,n,n} = CSC_{m,n} \) and \( CAR_{m,n,n} = CAC_{m,n} \). For instance, \( CSR_{2015,1976,1976} = 59,820,251 \), and \( CAR_{1977,1976,1976} = 0.11 \).

### Indicators for detecting patent citation inflation

For the purposes of this study, we consider two kinds of inflation: patent reference inflation and patent citation inflation. Patent reference inflation means that the patents issued in a particular period have a higher average reference rate than the patents granted in other periods. The average reference rate is used to determine whether patent reference inflation exists – i.e., if the average number of references listed in the patents that were granted in a year is significantly higher than other years, patent reference inflation is present. For example, in a period from year \( p \) to year \( m \), patent reference inflation can be measured by the rate of change in the average number of references to patents granted since year \( n \) in each patent issued in year \( m \) versus year \( p \). This ratio is calculated by

\[
R_I_{m,p,n} = \frac{ASR_{m,n} - ASR_{p,n}}{ASR_{p,n}} = \frac{\sum_{m}^{p-1} \sum_{i=1}^{n} R_{i,m} - \sum_{i=1}^{p} \sum_{i=1}^{n} R_{i,p}}{\sum_{i=1}^{n} N_{i}}
\]

where \( R_I \) denotes the rate of change of average reference rate. The higher rate of change, the more serious the patent reference inflation. For instance, \( R_I_{2015,2014,1976} = (SR_{2015,1976}/N_{2015})(SR_{2014,1976}/N_{2014}) - 1 = -0.034 \) means that, in 2015, the patent reference inflation rate was \(-3.4\%\) (deflation), caused by the average reference rate declining.

Patent citation inflation means that the patents issued in a particular period were cited more, on average, than patents issued in other periods. Similarly, the average citation rate is the
indicator for patent citation inflation. If the average number of citations received by the patents issued in a given year is significantly higher than other years, patent citation inflation is present. Patent citation inflation for the patents granted in a given year \( m \) can be measured by the rate of change in the average number of citations for each patent issued in year \( n \) and for those in year \( p \) using the following calculation:

\[
CI_{m,p,n} = \frac{ASC_{m,p} - ASC_{m,n}}{ASC_{m,n}} = \frac{\sum_{n}^{m} c_{i,p} - \sum_{n}^{m} c_{i,n}}{\sum_{n}^{m} c_{i,n}}.
\]  

(11)

For instance, \( CI_{2015,1977,1976} = (SC_{2015,1977}/N_{1977})( SC_{2015,1976}/N_{1976}) -1 = 0.043 \) means that, by 2015, the citation inflation rate of patents issued in 1976 compared to those issued in 1977 was 4.3%. In other words, as of 2015, the average citation rate of the patents issued in 1977 was 12.01, whereas that in 1976 was 11.52 – an increase of 4.3%, caused by the average citation rate increasing. Alternatively, we can limit the receiving time of the patents analyzed within a 20-year period after granted in order to avoid bias toward old patents, which have had more time than new patents to garner citations, using the following calculation:

\[
CI_{m,p,20} = \frac{ASC_{m+20,m} - ASC_{p+20,p}}{ASC_{p+20,p}} = \frac{\sum_{m}^{m+20} c_{i,m} - \sum_{n}^{m+20} c_{i,p}}{\sum_{n}^{m+20} c_{i,p}}.
\]  

(12)

For instance, \( CI_{1995,1994,20} = (SC_{1995,1994}/N_{1994})( SC_{1994,1994}/N_{1994}) -1 = 0.083 \), which means the patent citation inflation rate between the patents issued in 1995 and in 1994 is 8.3%; that is, during the period of 20 years after issued, averagely each patent issued in 1995 received 21.89 citations, whereas patent issued in 1994 received 20.21, patent citation inflating 8.3%. The cumulative average of citations/references is another way to explore patent citation/reference inflation. Cumulative patent citations inflation can be measured by the rate of change in the cumulative average of the citations to patents granted since year \( n \) received for each patent issued before the end of year \( m \) and that of year \( p \) with the calculation:

\[
CCI_{m,p,n} = \frac{C_{AC_{m,n}} - C_{AC_{p,n}}}{C_{AC_{p,n}}} = \frac{CAR_{m,n,n} - CAR_{p,n,n}}{CAR_{p,n,n}} = CRI_{m,p,n}.
\]  

(13)

Again, the citations analyzed can be limited to patents that were granted within a 20-year period prior to year \( m \) and \( p \) with the calculation

\[
CCI_{m,p,20} = \frac{C_{AC_{m,n,20}} - C_{AC_{p,20}}}{C_{AC_{p,20}}} = \frac{CAR_{m,m-20,n,20} - CAR_{p,m-20,n,20}}{CAR_{p,m-20,n,20}} = CRI_{m,p,20}
\]  

(14)

The patent cumulative references inflation rate (\( CRI \)) is different from the patent reference inflation rate (\( RI \)). \( RI \) is measured from the view of one year – the year the patents were issued – whereas \( CRI \) is measured over a period, usually many years.

If limiting the citations analyzed to patents that were granted within a 2-year period prior to year \( m \) and \( p \), we can get an indicator to measure short term citation inflation rate, with the calculation

\[
IFI_{m,p} = \frac{(c_{m,m-2} + c_{m,m-2})(N_{p-1} + N_{p-2})}{(c_{p,p-2} + c_{p,p-2})(N_{m-1} + N_{m-2})} - 1.
\]  

(15)

The indicator of short term citation inflation rate (\( IFI \)) actually denotes the rate of change between the patent impact factor, which is similar to journal impact factor, in year \( m \) and in year \( p \), reflecting citation inflation to new patents granted within recent two years.

**Results**

*The explosion of patent citations*

Figure 1 shows the distribution of the total references in patents grouped by the year of issue and the cumulative number of patents granted during 1976–2015, represented as exponents. Figure 1a shows that since 2011 the total number of references (\( SR \)) has increased faster than the cumulative number of patents (\( SN; SR_{p,1976} > SN_{p,1976} \), where \( p \geq 2011 \)). This means that
each patent granted since 1976 averagely has been cited more than once per year since 2011 (see Figure 1b). The USPTO granted 5.27 million patents during the years 1976–2015, and these patents were referenced 5.4 million times in 2015 alone. In recent years, the number of references to patents has increased much faster than the number of patents granted, revealing an explosion in patent citations. Figure 1c shows the distribution of the average reference rate \((ASR)\). Until 2011, the average reference rate had been increasing, but in recent years the rate has remained steady at around 18 \((ASR_{2015,1976} = 18.06)\).

![Figure 1. (a) The distributions of the number of references \((SR_{m,1976})\) and the accumulative number of patents \((SN_{m,1976})\), (b) their ratio, and (c) the average reference rate \((ASR_{m,1976})\), grouped by the year of issue](image)

Figure 2a shows the total number of citations received by the patents granted in year \(n\) \((SC_{2015,n})\). The patents granted in 1976 were cited a total of 808,420 times during 1976–2015. The patents granted in 1998 received the most citations, reaching over 3.35 million. Figure 2b shows the curve representing the average citation rate \((ASC)\). As of 2015, the average citation rate of the patents granted in 1976 is 12; for the patents granted in 1998, it increases to the maximum 23, which is – double that of 1976; for the patents granted in 2015 the rate decreases to nearly zero \((ASC_{2015,2015} =0.04)\), since the patents were rarely cited in the same year.

![Figure 2. (a) The distributions of the sum of citation counts \((SC_{2015,n})\) and (b) the average citation rate \((ASC_{2015,n})\), grouped by the year of issue](image)

If the patents have received significantly more citations, on average, than earlier patents, patent citation inflation is certainly present, especially for the period 1976–1996 in Figure 2b. If patent citation inflation is not present, the patents issued more recently should have received fewer citations, on average, than prior patents, since they have had more time to be cited. The phenomenon that the older patents received fewer citations can be used as an indication of patent citation inflation. Generally, old patents have a higher number of citations than new ones simply because they have had more time to be cited. Hence, an average citation rate curve should decline from left to right. Yet, the curve in Figure 2b is an inverted V-shape. This is a very strange phenomenon, which could be interpreted as patent citation inflation. When a period is characterized by an enormous number of references to other patents, patent citations inevitably increase, and this leads to patent citation inflation. However, according to the
theory of obsolescence in scientific literature (Burton, & Kebler, 1960; Gosnell, 1944; Marton, 1985; Price, 1965), more recent patents have a higher probability of being cited than old patents. Therefore, when patent reference inflation is present, more recent patents should logically have an even higher probability of being cited, but this is not the case. Figure 2b shows that the gap between the peak year (1998) of average citation rate and the latest year (2015) is 17 years.

Figure 3 shows that the curve of cumulative average citation rate (CAC) inclines from left to right over the period 1976–2015, following the average references rate (ASR). In 2015, the average reference rate (ASR<sub>2015, 1976</sub>) reached to 18.06, meaning that each patent granted in 2015 on average supplied 18 references to patent granted since 1976; consequently, by the end of 2015 the cumulative average citation rate had increased to 11.35, meaning that each patent granted since 1976 had received 11 citations averagely. This indicates that the number of references included in patents has been increasing by a significant amount each year. As a result, each patent granted since 1976 has, on average, received an increasing number of citations leading to serious patent citation inflation over the past four decades.

*Figure 3. The distributions of the cumulative average citation rate (CAC<sub>m, 1976</sub>) and the average reference rate (ASR<sub>m, 1976</sub>)*

*Measuring patent citation inflation*

Figure 4 shows the annual patent reference inflation rate (RI<sub>m,m−1, 1976</sub>) during the 20-year period from 1996 to 2015. With the exception of 2012 and 2015, patent reference inflation rates for the period are positive. In 2005, the patent reference inflation rate reached to the maximum 11.52%, i.e., the average reference rate in 2015 was 11.52% higher than in 2004. During the 20-year period from 1996 to 2015, the patent reference had inflated 137.24% (RI<sub>2015, 1996, 1976</sub> = 1.3724; the average reference rate in 1996 was 7.61, whereas that in 2015 reached 18.06 – a more than two-fold increase). This indicates that within the 20-year period patent reference inflation had occurred frequently and seriously – twelve out of the twenty years with inflating more than 5%.

*Figure 4. The distributions of annual patent reference inflation rates RI<sub>m,m−1, 1976</sub> (1996 ≤ m ≤ 2015)*

The patent citation inflation rate CI represents the rate of change in the number of citations over the patents issued in different year. Figure 5a shows the patent citation inflation rates between 1976 and 2015 (CI<sub>m,m−1, 1976</sub>; 1976 < m < 2015). Until 1996, all patent citation inflation rates were positive, whereas the period between 1999 and 2015 shows a decline.
While the citation inflation is clearly indicated between 1976 and 1996, the negative values between 1999 and 2015 do not necessarily indicate citation deflation, because these more recent patents have not had as much time to build their citation count. Figure 5b highlights the period 1976 to 1996 \((CI_{p,p−1,1976};\ 1976 < p < 1996)\), all rates with positive values. Figure 5c shows the patent citation inflation rate \((CI_{p,p−1,20};\ 1976 < p < 1996)\), citations received during 20 years period after issued, all rates with positive values, too. Further, the earlier the patents were granted within the period 1976 to 1996, the less citations on average they have received (see Figures 2, 5b and 5c). It indicates that citations to the patents granted during this 20-year period suffered serious inflation. The curve for \(CI_{p,p−1,1976}\) in Figures 5b is similar to \(CI_{p,p−1,20}\) in 5c. For the indicator \(CI_{p,p−1,20}\), the receiving time of the patents analyzed are limited within a 20-year period after granted in order to avoid bias toward old patents having had more time to garner citations, is more reasonable than the indicator \(CI_{p,p−1,n}\).

Figure 5. The distributions of the patent citation inflation rates \((a)\ CI_{m,m−1,1976};\ (b)\ CI_{p,p−1,1976};\ and\ (c)\ CI_{p,p−1,20}\ (1976 ≤ m ≤ 2015, 1976 < p < 1996)\)

Figure 6a shows the annual cumulative patent citation inflation rate from 1976 to 2015 \((CCI_{m,m−1,1976};\ 1976 ≤ m ≤ 2015)\). All rates are positive, and the curve declines from the left in the early period to the right in the later period. In 2015, the patent cumulative citation inflation rate was 3.7% over 2014. This means that the cumulative average number of citations received by each patent issued since 1976 was 3.7% higher than in 2014. Figure 6b separates the period between 1997 and 2005 \((CCI_{p,p−1,1976};\ 1997 ≤ p ≤ 2005)\), and Figure 6c shows the citations received during the period of 20 years after the patents were granted \((CCI_{p,p−1,20};\ 1997 ≤ p ≤ 2005)\). During 1976–2015, all of the annual patent cumulative citation inflation rates are positive (see Figures 6a), which means that, all patents granted since 1997 have, on average, received an increasing number of citations (see Figure 3).

Figure 6. (a) The distributions of the annual cumulative patent citation inflation rate \(CCI_{m,m−1,1976};\ (b)\ CCI_{p,p−1,1976}\ and\ (c)\ CCI_{p,p−1,20}\ (1976 ≤ m ≤ 2015, 1997 ≤ p ≤ 2005)\)

---

1 Comparing 1976 to 1995 as example, i.e., \(CI_{1995,1976,20} = 2.797\), each patent issued in 1995 averagely received 21.89 citations during the 1995–2015 period of 20 years after issued, whereas that in 1976 received 5.76 during the 1976–1996 period of 20 years after issued, patent citation inflating 279.7% for the two groups of patents, whose issue years with a difference of 20 years. Using Another indicator, \(CI_{2015,1995,1976} = 0.901\), as of 2015, the average citation rate of patents issued in 1976 was 11.52 citations, but that of patents issued in 1995 reached 21.89 – an inflation rate of 90.1%, caused by the average citation rate increasing greatly. Avoiding bias toward old patents having had more time to garner citations, each patent issued in 1976 on average received 5.76 during the 1976–1996 period of 20 years after issued, and \(CI_{1995,1976,20} = 2.797\), means patent citation inflating 279.7%; otherwise, each patent issued in 1976 on average received 11.52 citations during the 1976–2015 period, and \(CI_{2015,1995,1976} = 0.901\), means patent citation inflating 90.1%.
Figure 7 shows the distributions of the annual patent impact factor (PIF) and the annual short term citation inflation rate (IFI), indicating the rate of change in patent impact factor, and reflecting citation inflation to new patents granted within recent two years. The two curves in Figure 7 are similar to each other, and PIF follows and varies with IFI. But IFI varies greatly and are more sensitive than PIF. Distinctly, the change of PIF can indicate the citation inflation to the new patents granted within 2-year period. In 2010, the short term citation inflation rate (IFI) reached 0.268, meaning that the PIF increased from 0.54 in 2009 to 0.68 in 2010 – an increase of 26.8% or inflating 26.8% – for citations to the new patents granted in 2008–2009. In 2011, citations to the new patents granted in 2009–2010 deflated 14.1%. Figure 7 shows that citations to the new patents alternately inflated or deflated, and sometime seriously. But in a long run inflation and deflation counteract each other, so that the citations to new patent have not accumulated to greatly severe inflation during the several decades. In other words, the average number of citations to new patents varies from 0.39 to 0.68, is not suffered serious patent reference inflation in recent decades. It indicates that patent impact factor is a stable indicator in the view of long term in that it can avoid the suffering of patent reference inflation.

Figure 7. The distributions of the annual patent impact factor and the annual short term citation inflation rate $IFI_{m,m-1}$ (1979 ≤ $m$ ≤ 2015)

Interpretation of the Results and the Methods

This article explores the phenomenon of patent reference and citation inflation using a synchronous method and a diachronous method. Patent reference inflation rates (RI), representing the rate of change in the average reference rate, were measured using a synchronous method. The results show that during the period from 1996 to 2015 most patent reference inflation rates reached more than 5%; up until 2011, followed by a sharp decline from 2012 to 2015 in the range of 2.3% to −3.4%. Cumulative patent citation inflation rates (CCI), denoting the rate of change in the cumulative average reference rate, were measured using a synchronous method, indicating cumulative citation inflation has happened during 1976–2015. Cumulative average citation inflation rate is an appropriate, but rough, indicator of the cumulative citation inflation of patents issued over a long period instead of one year. Short term citation inflation rates (IFI) were measured using a synchronous method to detect citation inflation to new patents granted in recent two years by calculating the rate of change in patent impact factor, similar to journal impact factor, reflecting that citations to the new patents have alternately inflated and deflated but in a long run have not accumulated to greatly severe inflation during 1979–2015. This indicates that patent impact factor is a stable indicator in the view of long term in that it can avoid the suffering of patent reference inflation.

Patent citation inflation rates, representing the rate of change in the average citation rate, were measured using a diachronous method. Citation inflation occurred with a serious impact on the patents granted during 1976–1996. All patent citation rates for this period are positive, indicating a year on year increase in the average number of patent citations. However, between 1997 and 2015, all patent citation inflation rates are negative except for 1998. This
means that, year on year, each patent received fewer citations, on average, but this by no means indicates that patent citations suffered deflation. This is a normal, common-sense phenomenon: patents granted more recently have had less time to receive citations and would therefore have fewer average citations.

Unlike synchronous method, diachronous method can only be used to measure citation inflation in patents that have had enough time to accumulate citations. The features and characteristics that accompany obsolescence in scientific literature (Burton, & Kebler, 1960; Gosnell, 1944; Marton, 1985; Price, 1965) mean that a diachronous method does not provide a complete measure of citation inflation rates (CI). When using the diachronous method, a positive patent citation inflation rate (CI) indicates that patent citation inflation is present; otherwise, it cannot indicate that patent citation deflation happens. Factually, patent references suffered serious inflation in the 1997−2011 period, which may lead to more citations for the patents issued during the same period and, consequently, resulting in patent citation inflation. It means that citation inflation rate (CI) is an incomplete indicator with some limitations, which cannot entirely and precisely detect and measure the citation inflation to the new patents granted in recent years especially since patents need time to collect citations when using the diachronous method. However the short term citation inflation rate (IFI), which is synchronous measure, can be used to detect citation inflation to new patents granted within recent two years by calculating the rate of change in patent impact factor.

In addition, according to the theory of obsolescence in scientific literature proposed by many early scholars (Brookes, 1970; Burton, & Kebler, 1960; Gosnell, 1944; Griffith, Servi, Anker & Drott, 1979; Marton, 1985; Price, 1965), scientific literature typically receives many more citations in the first few years of being published. A citation peak is reached several years later, after which gradually fewer and fewer citations are received due to obsolescence. We assert the interaction between patent obsolescence and patent reference inflation is the cause of the strange inverted-V shape in the average citation rate (see Figure 2). When patent references are undergoing inflation, new patents hold the lowest average citation rates because they have not had sufficient time to receive citations. Yet, old patents, that have had enough time to accumulate many citations, see the highest average citation rates, and this is further reinforced by serious patent reference inflation during 1976−1996: the earlier the patents were issued, the less the average citations they received. Patent reference inflation rates, representing the rate of change in the average reference rate, were measured using a synchronous method, with the results showing high patent reference inflation during 1976−2011: until 2011, references to other patents increased greatly each year. Cumulative patent citation inflation rates, denoting the rate of change in the cumulative average reference rate, were also measured using a synchronous method, indicating cumulative citation inflation.

**Conclusions and Discussion**

Over the last forty years, the USPTO has granted an increasing number of patents each year, some of which include a large number of references to other patents. Such an increase in the number of references has led to serious patent citation inflation in this period. This article explores the phenomenon of patent citation and reference inflation using a synchronous method and a diachronous method.

Patent citation inflation rates, representing the rate of change in the average citation rate, were measured using a diachronous method, and the results indicate that citation inflation occurred with a serious impact on the patents granted during 1976−1996: the earlier the patents were issued, the less the average citations they received. Patent reference inflation rates, representing the rate of change in the average reference rate, were measured using a synchronous method, with the results showing high patent reference inflation during 1976−2011: until 2011, references to other patents increased greatly each year. Cumulative patent citation inflation rates, denoting the rate of change in the cumulative average reference rate, were also measured using a synchronous method, indicating cumulative citation inflation.
has happened during 1976–2015. Furthermore, the short term citation inflation rates, denoting the rate of change in the patent impact factor, were measured using a synchronous method to detect citation inflation to new patents granted in recent two years, reflecting that citations to the new patents have alternately inflated and deflated during 1979–2015. Taken as a whole, the results of this study verify that patent citation inflation has occurred seriously and frequently over the past four decades, and confirm the ability of established indicators to detect and measure patent citation inflation.

This article presents some measurement methods to explore into the phenomenon of patent citation inflation. Patent citation inflation rate (diachronous measure), is an incomplete indication of a phenomenon of citation inflation and it can only be used to measure citation inflation to old patents that were issued many years ago because patents need time to accumulate citations. Whereas the short term citation inflation rate, which is synchronous measure, can be used to detect citation inflation to new patents granted within recent two years by calculating the rate of change in patent impact factor. Cumulative patent citation inflation rate (synchronous measure), is an appropriate, but rough, indicator of the cumulative citation inflation of patents issued over a long period instead of one year.

The methods used to measure patent reference and citation inflation in this study are only able to provide a rough indication of patent citation inflation, not a complete and precise picture of the landscape. In future research, we intend to improve our measurements methods to provide a deeper analysis of the causes and effects of patent citation inflation, along with some theoretical methods to eliminate some patent citation inflation’s negative effects.

Abstract
This proposed dissertation research submitted to the Doctoral Forum aims to expand the scope and depth of altmetrics research. On the one hand, the context of web-based digital traces around scholarly works will be explored. On the other hand, this study will expand single platform examinations to show a more holistic picture across multiple platforms and environments. In addition, instead of directly taking counts of occurrences as a proxy for impact, this study will investigate and discuss how the scholarly works have impacted the scholars’ research, teaching, and creative activities in the interpretation of the traces as impact indicators. By incorporating qualitative approaches into metrics research, the pursuit will hopefully contribute to more discussions about the validity and utility of metrics.

Introduction
Researchers leave traces of their behavior during many stages of their research process. Parts of this process were formerly invisible. Now with scholarship moving online, we can access various types of altmetrics digital traces. Although the term “altmetrics” (Priem, 2010; Priem et al., 2010) is sometimes considered a misnomer (Haustein, Bowman & Costas, 2015) because they are considered complements and not alternatives to citation-based metrics, many theoretical discussion and empirical studies have been conducted in recent years around this concept. Years before the term “altmetrics” was coined, the idea of measuring broader scientific impact on the web had been discussed. The idea of “polymorphous mentioning” in “listservs, electronic discussion fora” and “reading lists or electronic syllabi” is believed to be a critical feature of web-based scholarly communication (Cronin et al., 1998). In addition to scholars being informally cited, Cronin (2005) predicts that “web-based digital objects and usage statistics” will be used to “model scholars’ communication behaviors” and “track their scholarly influence and impact”. In this proposed research, the meaning of the various indicators grouped under the term altmetrics will be discussed from the fundamental concept of digital traces, i.e., the footprints of the scholarly activities.

By investigating footprints of scholarly acts such as of reading, organizing, sharing and discussing scientific works, this study aims to develop a richer picture of scholars and their work. Specifically, I hope to contribute to three main challenges in interpreting the digital traces: 1) to expand current altmetrics beyond simple capture of occurrences of events to include the context in which they occurred, 2) to explore cross-platform behaviors to have a more comprehensive understanding of the research process, and 3) to understand the limitations of the traces as evidence of impact and value.
Related Work

Scholarly Acts
The concept of altmetrics includes a group of metrics based on usage data and social media events related to scientific works. Impactstory aggregates various metrics on the individual researcher level. Their framework of altmetrics (ImpactStory, 2012) includes view, save, discussion, and recommendation. Another similar classification is proposed by Lin & Fenner (2013) for Public Library of Science (PLoS). Haustein, Bowman & Costas (2015) present a framework of “acts” grouped into three categories: accessing, appraising, and applying, with an increasing level of engagement. In this proposed research, the term of “act” is adopted to describe scholarly activities occurring in the context of diverse scholarly communication tools, publishers, online repositories, and general social media. Some of these acts overlap with or influence other acts. For instance, Mohammadi, Thelwall & Kousha (2016) found that 85% of their survey respondents bookmarked articles in Mendeley to cite them in their publications. In a preliminary attempt to enrich the framework of digital traces these acts create, nine groups of 40 acts were defined by Xu & Hemminger (work in progress). Researchers at University of North Carolina at Chapel Hill were invited to rank the cards of scholarly acts in terms of how much they think the acts indicate the scholarly product involved is of value to them. Although the results are yet to be analyzed, this study will inform the further refining of the scholarly acts framework.

Evaluation of Altmetrics
Sud & Thelwall (2014) conclude six methods to evaluate altmetrics: correlation with peer review and other metrics, the sign test, creator motivation interviews or questionnaires, user motivation interviews or questionnaires, source content analysis, and pragmatic evaluations. These methods are a combination of quantitative and qualitative approaches. In terms of the relationship between altmetrics scores and citation measures, positive results have been reported between citations and Wikipedia mentions (Evans & Krauthammer, 2011), Tweets (Eysenbach, 2011; Shuai, Pepe & Bollen, 2012), Mendeley bookmarks (Bar-Ilan et al., 2012; Mohammadi & Thelwall, 2013), as well as other social media including Facebook wall posts, blogs, mainstream media and forums (Thelwall et al., 2013). Most of these studies point out that no matter the correlation coefficients being low or high, the scholarly impact that these two systems of metrics capture are different. As a result, it is necessary to follow up with qualitative approaches to better interpret the impact reflected. Qualitative approaches provide a deeper understanding of not only the scholarly acts but also the confidence of the metrics. For instance, Mohammadi, Thelwall & Kousha (2016) conducted a survey of 860 Mendeley users and found that most (55%) users had read or intended to read at least half of their bookmarked publications, thus concluding that it is reasonable to use Mendeley bookmarking counts as an indication of readership.

Potentially Relevant Theories
In Haustein, Bowman & Costas’s chapter (2015) in a book on theories of informetrics and scholarly communication edited by Sugimoto (2016), they relate the acts to both citation theories and social theories. Citation theories they analyze include normative theory (Kaplan, 1965), social constructivist theories (Gilbert, 1977; White, 2004; Murugesan & Moravcsik, 1978), and concept symbols theory (Small, 1978). Social theories they discuss include social capital theory (Bourdieu, 1985), attention economics theory (Davenport& Beck, 2001), and impression management theory (Goffman, 1959). These theories are potential theories that can be extended using digital traces and metrics to understand value in the scholarly process.
Research Questions

*RQ1: How to interpret the digital traces?*
1. How do technical affordances of platforms and user features affect the interpretation of digital traces?
2. What are the motivations behind the traces?
3. What about other traces that cannot be easily collected (e.g. organizing into personal folders, sharing in e-mails, discussing with a colleague, etc.)?

*RQ2: What does the impact flow look like?*
1. What are the common orders of the acts?
2. Does one act (e.g., tweeting) predict the following act (e.g., citing)? How does one act affect the following act(s)?
3. What is the relationship between the acts and the perceived impact?

Methodology

*Data Collection*
1. Existing documents and artifacts
   a. Altmetric.com data
   b. Twitter data
   c. Mendeley data
2. Online Survey
   a. Targeted audience: The focus of this research will be on some of the most popular acts in terms of the number of captured online events. Considering that Mendeley reader counts (accounting for two-thirds of recent journal articles) and tweets (accounting for one-fifth of recent journal articles) have been shown to be the most prevalent online events captured for scientific papers (Haustein, Bowman & Costas, 2015), this study aims to target the creators of these traces as the target audience of investigation. I plan to firstly retrieve Twitter users who have tweeted at least three scientific articles. Then, those who provide real-world information (name, position, affiliation) in their profile descriptions will be identified and searched to see if they are Mendeley users. At last, I will collect their e-mail addresses on their public home pages, if any. Users who satisfy these three criteria will be put into the pool of targeted survey audience. At last, I hope to get a pool of 5000 randomly sampled users.
   b. Survey logistics: The Qualtrics-based survey will be tested, evaluated and refined through a series of pilot studies. E-mail survey invitations will be sent out to the 5000 potential participants, with a reminder to nonresponding persons in another 2 weeks.
   c. Survey content: The survey will be designed around the following aspects:
      i. Twitter and Mendeley-specific questions. For instance, how many percentages of the saved/tweeted articles are read/cited, do they prefer to send original tweets or retweet, do they usually save articles to organized folders in Mendeley, and so on.
ii. In addition to Mendeley and Twitter, ask them what other commonly (monthly or more frequently) used tools they use in their research, teaching, and creative activities.

iii. Based on their selection of tools, identify their acts and ask them to rank the order of the acts.

iv. Inquire if they are certain of the rationale of their saving/tweeting/blogging/citing scientific articles, to test out if social media based metrics are based on more cursory and perfunctory acts compared to citations.

v. For the types of acts that they can clearly explain the motivations, ask them their common motivations.

d. Semi-structured Interview

e. Interview logistics: At the end of the survey mentioned above, I will ask the participants if they are willing to participate in an additional (compensated) interview and their contact information. The interview will be coordinated via e-mail but conducted via phone. For these interview participants, I will identify and send their tweets of scientific articles and ask them to have their Mendeley library open before the interview. During the interview, I will ask questions based on the tweets and articles saved in their Mendeley.

f. Interview content: The aim of the interview is to gain a more in-depth understanding of the following aspects:

   i. To collect their opinion about these tweeted articles. In other words, have these articles in fact contributed to their research, teaching, and creative activities? If yes, how?

   ii. To gather information about if other types of acts have been conducted to those tweeted articles. For instance, is the tweeted article also saved into personal folders/blogged/discussed in class/shared on e-mail listservs/discussed in a research group meeting/cited?

   iii. To know more about their motivations of all the acts.

Data Analysis

1. Statistical analysis of survey data
2. Markov Model analysis and/or Optimal Matching, and visualization of the sequence
3. Qualitative analysis of interview data

Implications

Theoretical Contribution

This study will explore the story behind the metrics. The impact flow in the research process will be depicted to better explore researchers’ information behavior and motivation. These practices will not only contribute to the development of web-based indicator theory, which is strongly in need, but also inform the revisit of citation theory in this digital era.

Methodological Contribution

This study combines qualitative and quantitative research methods. On the one hand, instead of directly taking counts of traces as a proxy for impact, this study will use survey and interview to collect more information about the traces. How these articles have in fact contributed to their research, teaching, and creative activities will be incorporated in the interpretation of the traces.
as impact indicators. On the other hand, this study will view the traces via a metrics-based lens and extend the work previously conducted on the information behavior of scientists.

**Practical Contribution**

The “altmetrics” data of scientific activities are now being provided in diverse scholarly communication tools, aggregated data providers, as well as publishers and online repositories. Although the data are still far from being well understood, they are being used by individuals, publishers, universities and scientific institutes all around the world in various ways. This study will draw firmer conclusions about the meaning of the metrics, thus providing better guidance on how to use them.

**Doctoral Forum Feedback**

I see four fundamental issues that I would like to discuss at the Doctoral Forum:

- I would like to get any types of suggestions to improve this study.
- I would like to discuss methodological issues of the filtering of survey participants (sampling strategy, technical assistance, and feasibility).
- I would like to get feedback particularly on the design of the survey and interview.
- I would like to brainstorm possible ways to evaluate this study and discuss implications and future directions of this study.

**Statement of Intent**

My name is Shenmeng Xu and I am a doctoral student at the School of Information and Library Science at University of North Carolina at Chapel Hill. My research interests lie in the field of scholarly communication, scientometrics, and altmetrics.

At ISSI 2017, I hope to share my work incorporating qualitative approaches into metrics-related studies, and hopefully contribute to more discussions about the validity and utility of metrics. Although this is not exactly a new perspective, I believe this is an important issue that can never be overemphasized. I hope to bring my expertise in the intersection of scientometrics and scholarly communication to other participants as they work with metrics-related topics in their dissertations.

I would like to attend the doctoral forum because it provides a unique platform to get feedback on my reconceptualization of and approach to understanding the “altmetrics” digital traces. The ISSI community has a rich history of encouraging research that involves studies of scholarly communication and metrics. I believe that the collective of researchers and fellow students in both fields will give me necessary, dual-view insights into the problems I’m grappling with in my work. I plan to write my dissertation proposal this summer and defend it in the Fall semester. An opportunity to attend this doctoral forum will help me strengthen my proposal, and better understand how the ISSI community perceives my research goals.

**Acknowledgement**

I would like to thank my advisor Dr. Bradley M Hemminger for his support and great suggestion on improving this work. I would also like to thank Altmetric.com and its founder Euan Adie for supplying the data and its descriptions.

Abstract
Scientific knowledge, conveyed through the content of scientific literature, is constantly changing as new discoveries and advances are made. These changes could be evolutionary as well as revolutionary changes. Although many population dynamics models and scholarly metrics were successfully applied to characterize the changes of scientific knowledge, accessing scientific knowledge to meet our needs for assessing the state of the art of a research area and making various decisions remains to be a major challenge. In this proposed research, we aim to characterize the scientific dynamics at multiple levels of granularity by analyzing metadata as well as full-text content of scientific literature with various state-of-the-art techniques of graph mining, text mining, and visual analytics.

Introduction
Scientific dynamics conveyed by vast volume of scientific literature is essential for conducting scientific research, making science policies and public understanding of science. The scientific dynamics could be observed at multiple levels of granularity which meet our different needs for scientific knowledge. For example, a scientist and a scientific policy maker may need different information about scientific dynamics for their specific tasks; a researcher who is seeking for research opportunities and a researcher who is conducting a specific research may have different information needs about scientific dynamics.

Today, we still have to build our understanding of scientific dynamics based on scientific literature through painstakingly time-consuming and cognitively demanding processes. The knowledge acquisition process from the vast volume of scientific literature remains to be the most challenging bottleneck not only for scientists and researchers but for everyone who needs to obtain an accurate picture of the state of the art meeting their needs.

The proposed research aims to establish characterize the scientific dynamics at multiple levels of granularity by analyzing metadata as well as full-text content of scientific literature with various state-of-the-art techniques of graph mining, text mining, and visual analytics. The central idea of this research is that structural dynamics of science can be captured by detecting the structure of network constructed by links among scientific literature and that detailed levels (topic, assertion and publication levels) analysis along with their status of uncertainty and novelty in the context of structural dynamics.

Research Objectives
The major objectives of this proposed research are stated as follows:
Constructing evolution model of a domain based on dynamic bibliometric network.

Bibliometric networks, including bibliographic coupling and co-citation networks are widely used approaches to identifying research fronts (Boyack & Klavans, 2010; Shibata, Kajikawa, Takeda, & Matsushima, 2009). For this objective, we construct bibliometric network for each time period and detect communities for each network. To model scientific dynamics over time, we align communities over time. We also extract keywords to characterize detected evolving patterns.

Identifying research concepts and assertions from unstructured text.

The input of this task is a collection of scientific articles in full text. The output is research concepts which constitutes a domain taxonomy and assertions. Assertions in the context of this proposal refer to propositions expressed in the generic form of (Subject)-(Predicate)-(Object), for example, as in (West Nile Virus)-(Causes)-(Persistent Infection). The negation of an assertion is also an assertion. Identified research concepts and assertions will be used to identified detailed level dynamics.

Measuring novelty dynamics of research concepts and uncertainty dynamics of assertions.

Both novelty and uncertainty are early signs and essential features of emerging trends (Rotolo, Hicks, & Martin, 2015). Representing novelty dynamics of research concepts and uncertainty dynamics of assertions fruitfully extends our analytics on science dynamics to a new level of granularity and assist us to keep abreast with the advances of science. Thanks to advances of recurrent neural networks and availability of full-text content, we have chances to represent novelty and uncertainty and measure their dynamics quantitatively.

Integrating analytics techniques for the study of scientific dynamics at multiple level of granularity.

The last objective of my proposed research is to integrate various analytics techniques and display identified information in an explorable interface, which allows users to explore information among multiple levels of granularity according to their needs.

Current Status

In this section, I briefly present three studies which are essential components for my proposed study. The first study presents a visualization for scientific evolution which provide a picture of structural dynamics of science and give a broad context for us to learn detailed level dynamics of science; The second study (work-in-progress) introduces a method to measure novelty dynamics of a research concept; The last study (work-in-progress) introduces a method to represent citation as a vector based on embedding learning.

CiteFlow: Identifying and Visualizing Evolving Patterns in Scientific Literature

CiteFlow is designed to help users track and understand how and why intellectual structure develop and change over time through bibliographic networks of scientific literature. To address this goal, we focus on enabling users to interactively analyse overall network evolution trend, critical events and articles, and text information. Based on these requirements, we designed CiteFlow which consist of four components: a network constructor, a network analyser and an information extractor, and a visualizer.

Figure 1 provides an overview of CiteFlow system. The network constructor is tasked to extract references, abstract, various metadata of research articles, and construct networks. The metadata includes author(s), keywords, publication time and title for each article. The networks include co-citation and co-word networks. The output of the network constructor is dynamic networks with associated metadata and text data. The output is sent to the network analyser.
which extracts a set of communities for network at each time as well as temporal relations of communities (Palla, Barabási, & Vicsek, 2007). Then information extractor extracts the keywords for each detected community and labels them based on abstracts of related articles. Lastly, the visualizer transforms the results from network analyser and information extractor into a comprehensible visualization.

Figure 1. CiteFlow Overview.

Figure 2 shows a visualization case created by CiteFlow. The analysed collection contains articles published from 1966 to 2016 which cited three historical models of science. From this visualization, we can see an evolving patterns of science models. For example, studies on ‘citation network’ emerged in 1980s and got bursty in early 2000s.

Figure 2. Evolution in collection of articles citing three historical models of science (1966-2016): Lotkas law, Goffmans epidemic model, and Prices network model.
Detecting novelty and predict emerging trends in science by word embeddings.

Representing scientific knowledge is a key component of the goal of our proposed research. Notable recent advances of word embedding techniques such as word2vec (Mikolov, Sutskever, Chen, Corrado, & Dean, 2013) and GloVE (Pennington, Socher, & Manning, 2014) have been shown great performance of representing semantics of words. The word embedding techniques are naturally promising to improve our ability to represent scientific knowledge. However, these methods statically represent semantics of each word over all time, making them incapable for interpreting semantic evolution, i.e. scientific knowledge dynamics in our research context. The main challenge of computing temporal word embedding is to represent word semantics derived from different text corporuses across time in a same vector space, which enable us to compare semantic change of research concepts. To resolve this issue, we first constructed embeddings by word2vec in each year and then aligned them by using orthogonal Procrustes over time.

In the next steps, we will measure semantic change (i.e. novelty) of research concepts and evaluate predictive effects of measured novelty on emerging trends. In the future, we may extend word2vec to represent uncertainty between two research concepts and the change of uncertainty over time.

Citation2Vec: Measuring citation similarity based on citation context with embedding learning.

Full-text content of scientific articles leaves us with opportunities to analyse citation context and citation proximity. Citation context is the surrounding text of a citation which describe the author’s interpretation of the cited work; citation proximity is the distance between two citations within the full text of an article which may describe the relatedness of two cited papers. Both of the text information based on citation context and sequential information based citation proximity may be used to describe the cited papers. Inspired by distributed representations of words in natural language processing, we propose a novel approach to represent cited papers by learning from citation context and proximity.

Unlike existed study on distributed representations of scientific articles learning from citation graph or/and text information, our method learns citation representations with citation context and citation proximity. We proposed three methods of learning citation representations from citation context and citation proximity. The ideas of unsupervised learning of citation representations are extensions to word2vec where language model is Skip-Gram model and Negative Sampling is incorporated to optimize loss functions.

The first method is only based on citation context, where embedding vectors for learning are vectors of words surrounding centre citations; The second method is only based on citation proximity, where embedding vectors for learning are vectors of citation vectors surrounding centre citations; The last method is combined first method with second one, where embedding vectors for learning are vectors of words as well as citation surrounding centre citations.

We will compare these three methods based on CITREC (Gipp & Meuschke, 2015), an open evaluation framework for citation-based similarity measurement. CITREC prepares the data of two formerly separate collections for a citation-based analysis and provides the tools necessary for performing evaluations of similarity measures.

Acknowledgments

I acknowledge my doctoral candidacy committee members: Chaomei Chen (Chair, Drexel University, USA), Pak C. Wong (Pacific Northwest National Laboratory, USA), Erjia Yan (Drexel University, USA), and Christopher Yang (Drexel University, USA).

On normalization by division and comparing citation counts

Lawrence Smolinsky*

Department of Mathematics, Louisiana State University, Baton Rouge, LA (USA)

Introduction

Bibliometric measures based on citation counts are often used as an objective measure of research productivity. Finding a method of comparison is extremely challenging given the diversity of scholarly publications particularly by field and age. These are some aspects that effect the way publications accumulate citations. Developing measures using citations depends on understanding the distributions of citations of publications. Methods for normalizing the count across fields for comparison is in constant development.

Division

One heuristically attractive idea is to divide by a version of the expected number of citations to the paper. It may be done for individual papers, institutions, states, etc. Some of the reasons division is attractive is that it is simple to do and transparent in that percentage above or below average may be used in daily life. Some indicators that rely on division are the mean normalized citation score (MNCS) or InCites’s mean category normalized citation impact or normalized citation impact.

Whether division by a mean, median, or other parameter can make citation counts between different areas comparable is dependent upon the distributions being normalized. Each field may be thought to have its own distribution of the number of papers having a given number of citations. These distributions can be interpreted as probability distributions by dividing by the number of papers. For the purpose of cross field comparisons, they should ideally be adjusted so they have the identical distributions for each field. Normalizing by dividing by the mean may give the various distributions the same mean, but otherwise they may be quite different. However, there are families of distributions which become identical with a division adjustment by the mean. In other words, there are well-known families of distributions for which two random variables X and Y in the family with respective distinct means \( m_x \) and \( m_y \) have \( x \sim m_x \) and \( y \sim m_y \) identically distributed. The mean is then a scale parameter. These distributions include the exponential, \( \text{Exp}(\lambda) \), the gamma distribution with fixed \( n \), \( \Gamma(n, \lambda) \), and, a standard candidate in bibliometrics, the lognormal with a fixed \( \sigma \), \( \text{Lognormal}(\mu, \sigma^2) \). Discrete distributions are problematic for scaling since the domain may change. The lognormal scaling was essentially examined in Radicchi, Fortunato, and Castellano (2008) for data in sample areas for the year 1999. They examined the distribution of articles published in a single year in a specific area and approximated it by a lognormal and then compared the various distributions by scaling. The model has its flaws. For example, the lognormal is zero at zero while the number of articles with zero citations is significant. Furthermore, while Radicchi, Fortunato, and Castellano only give an exponential scale graph including multiple areas (2008 Fig. 2 p. 17269), one can visually see some fields below the normalized graph in the tail, e.g., anesthesiology and mathematics. However, suppose one accepts the lognormal with a fixed parameter \( \sigma \) for as the model for the distribution of citations in all fields, i.e., only the parameter \( \mu \) changes from field to field. Then division by the mean for each field normalizes the citation distribution to the common distribution \( \text{Lognormal}(\mu, \sigma^2, \sigma) \) for each field. An indicator like the MNCS, which is a sum of \( n \) normalized random variables (for a fixed \( n \)), will have a common distribution across fields. Even though the distribution may be complicated, it will the same across fields. Furthermore, although the lognormal is sometimes called a thick-tailed distribution, all of the moments of the lognormal exist and the central limit theorem applies to it. Again, assuming that only the parameter \( \mu \) changes from field to field, one can normalize by the median rather than the mean. One has then normalized the citation distribution to the common distribution \( \text{Lognormal}(0, \sigma) \) for each field. We also note that Leydesdorff and Opthof (2011) commented that “.... the ‘mean’ is not a proper statistic for measuring differences among skewed distributions” and suggested using the median. In the lognormal model with a fixed \( \sigma \), both the median and mean are scale parameters.

The discrete lognormal may be a candidate for citations to articles to a single subject and year (Evans, Hopkins, & Kaube 2012; Radicchi, Fortunato, & Castellano, 2008; Thelwall & Wilson, 2014), but it is not clear that \( \sigma \) is fixed across fields. The hooked power is another candidate (Thelwall & Wilson, 2014). But power laws are also candidates (Katz 2016; Yao et al. 2014) and it may depend on the time period. With such variation of opinion and variation of citation distributions, following
principle six of the Leiden Manifesto (Hicks et al. 2015), “Account for variation by field in publication and citation practices” seems a challenge for normalization by division or other formulas.

Percentiles
Knowing the full information of percentiles for two continuous distributions, allows one to transform them into a common distribution. Discrete distributions may pose problems. Eugene Garfield concluded his book (1979 p. 249) commenting on the power of percentile comparisons:

Evaluation studies using citation data must be very sensitive to all divisions, both subtle and gross, between areas of research; and when they are found, the study must properly compensate for disparities in citation potential. This can be done very simply. Instead of directly comparing the citation count of, say, a mathematician against that of a biochemist, both should be ranked with their peers, and the comparison should be made between rankings. Using this method, a mathematician who ranked in the 70 percentile group of mathematicians would have an edge over a biochemist who ranked in the 40 percentile group of biochemists, even if the biochemist’s citation count was higher.

In other words, the proper way to make comparisons would be by percentiles. But this method has its challenges too. It still requires an understanding and integrity of the field distributions. As Garfield (1979 p. 249) continued, “We still know very little about how sociological factors affect citation rates. There is still much uncertainty about all the possible reasons for low citation rates. And there is still much to learn about the variations in citation patterns from field to field.” It is still true today and poses a serious issue if citation analysis is to respect the first principle of the Leiden Manifesto (Hicks et al. 2015), “Quantitative evaluation should support qualitative, expert assessment.” We take the example of one field in which to perform citation analysis and normalization.

Mathematics
Details by subfield classification in mathematics was examined by Smolinsky and Lercher (2012). Even in a single Journal Citation Report field, the distribution of citations in subfields may be very different and at odds with expert assessment. They examined young researchers who were the highest respected by expert assessment, i.e. Sloan fellows. They classified Sloan fellows using a classification by the joint committee of the mathematics, applied mathematics, and statistics societies. The researchers fell into 9 fields (the field of statistics was not included).

In terms of the expert assessment, Algebra seemed to be the highest assessed. It had by far the most Sloan fellows (32 of 99). Hiring of new PhD’s at the top 48 “Group I” mathematics departments was also greatest in algebra. However, this was in contrast to the bibliometric data. The algebra Sloan fellows were 7th out of 9 in the number of publications per fellow and 6th out of 9 for citations per paper.

Putting aside the contradiction between the two assessments, the variation in a single field among subfields is well known. Glänzel and Schubert (2003 p. 357) sum it up: “The classification of scientific literature into appropriate subject fields is...one of the basic preconditions of valid scientometric analyses. Publication activity and citation habits considerably differ among subfields.”

Acknowledgments
The author is grateful to George Cochran for a discussion on scale parameters in probability distributions.

Indicators for the Evaluation of Technological Activity

Alexandre Lucas¹, Birger Larsen², Elías Sanz Casado³ & Angel Freddy Godoy Viera⁴

Introduction

The use of indicators for the evaluation of scientific and technological activities has been widely adopted to characterize and measure its volume and to identify its main actors and investments. One type of approach is to study scientific production which also may also include patents metrics. Another is statistics of governments and international organisation like the OECD that gather information and produce global indicators in their regular reports (González Guitián & Molina Piñeiro, 2008). Despite the large volume of information available, there is a perceived lack of applicability of these data for real time decision making. In this paper, we outline our initial work in establishing dynamic Indicators for the Evaluation of Technological Activity (IETAs) and their potential use in real-time decision making wiht purpose of presenting the idea to ISSI’2017 participants for feedback and exchange of ideas.

Importance

Relying on patent metrics and government data is not sufficient to make real-time decisions about technology investments. The main challenges are:

- Difficulty in obtaining relevant indicators
- Problems with patent-based indicators
- Velocity of technological innovation and the creation of technological companies and products
- The growth of unstructured data
- How to know if some data or information is about technology?
- Open Science and its influence on the future of scientific indicators of economic activities
- Specific issues for the indicators regarding each country - in our particular case for the countries Brazil, Spain and Denmark

Institutes of Science, Technology and Innovation

For our study of IETAs we choose as our case Institutes of Science, Technology and Innovation (ISTIs). ISTIs are important actors within the world of technological development and the innovation ecosystem of each country or even the world. To understand the roles of the involved actors in the phases of development of the technology we use the Technology Readiness Level scale (TRL), initially developed by NASA, but adopted widely by various sectors and organizations including the Horizon 2020 EU program (Mankins, 2009). Fig. 1 shows the TRL scale and our analysis of the types of Research, Development and Innovation (R&D&I) activities and relate the relevant actors across phases. Without discussing the limits of each actor’s position, with the infographic we want to show that the ISTIs are in the middle of the path of technological development. This interval between the TRL 3 and TRL 7 is also known as the “valley of death of innovation” because it is the region with the greatest risks and requirements of investments (Markham et al. 2010).

Fig. 1: Technology Readiness Level and type of R&D and Innovation and related actors in across phases.

About IETA Research

Our research into IETAs started in June 2017 and is planned to be implemented in 4 main steps: 1. Characterization and conceptualization (defining the concept of ‘technology’) and state-of-the-art. 2. Study of Information Retrieval and Text Mining approaches that can support the creation of IETAs. 3. Proposal of principal IETA indicators. 4. Application and test of proposed indicators. In relation to Step 1, we have begun outlining a range of aspects or elements involved in technological activities as shown in Fig. 2. In the present paper the research focus is on information related to technological activity and its flow.
Real-time Indicators

The need for rapid and informed decision-making is increasing fast, and with the current hype around Big Data expectations are building for approaches that can support decision-making in real-time. Fig. 3 shows the lifecycle steps of technology development and the perception of development and impact. As can be seen, it may take long while from an incoming grant or investment until production of the first formal results and end reports.

Expected Results

As indicated in Figs. 2 and 3, we consider a wide range of elements and stages of technological activity. In this paper, we will focus on two examples that involve bibliometric and altmetric data. The first approach is concerned with identifying signs of interest in certain technologies, and we reflect on the possibilities offered in the data related to the Web of Science (WoS). Given a target technology (clearly recognised), expressed as a set of terms as phrases, we may of course search the WoS and analyse publication trends. In addition, the search log of WoS, if made available, can tell us about searcher interest in the target technology (through volume of search terms) as well as which papers are downloaded, e.g. a temporal analysis over the last 5 months. These data may be compared to published papers - allowing indicators and monitoring of early interest to be constructed.

The second approach is concerned with identifying the terms and phrases that characterise of given technology. Initial keyword searches can be conducted in WoS, and fields like Title, Abstract, Keywords, Subject Categories, Journal Names, Project/Grant identifications and Authors and Affiliations can be analysed, e.g. using clustering and visualisation, to extract additional prominent terms to give an overview of the technology aspects and the research fields in which they are relevant as well as provide new search terms for further analysis. In addition, the full text links in WoS to local library content may be utilised to download samples of available full text papers and do in-depth analysis of these using e.g. text mining and clustering. From this, we also hope to provide principal insights into procedures for identifying and characterising technologies - making it easier to so automatically in the future.

Future work and conclusion

Our next step is to carry out the two approaches as outlined in the proceeding section. We also plan to apply information retrieval and text mining techniques to unstructured data from technology and other types of relevant reports. Our aim with presenting these initial project ideas to ISSI’2017 participants is to prompt feedback and to exchange further ideas with the conference participants on how best to proceed.

Applying the method of reflections to scientific production in the EU

Wout S. Lamers

Centre for Science and Technology Studies (CWTS), Leiden University, Leiden (The Netherlands)

Introduction
In this paper, we present an initial exploration of the Hidalgo & Hausmann (2009) ‘method of reflections’ applied to scientific production, in particular to European NUTS regions’ scientific production portfolios. This analysis leverages the internal CWTS enhanced Web of Science database to assign publications to geographical areas and classify them into fine-grained scientific topics.

Background
Scientific knowledge production is distributed throughout the world in a highly non-uniform manner. On the whole, the global production of scientific knowledge is concentrated in a relatively limited number of organisations. Similarly, large numbers of journal publications originate from a smaller number of countries, regions or cities. Much like the production of goods, scientific production is highly localized and concentrated, regardless of whether one looks at its geographical or organisational distribution. This suggests that, if we assume that inputs for knowledge production are not distributed nearly as lopsided as its outputs, different organisations, or different regions, must have different capabilities for generating new knowledge.

Method
Hidalgo & Hausmann (2009) show that in economics, product-producer bipartite networks can be analysed to estimate the capabilities of the producers. This so-called ‘method of reflections’ iteratively calculates an average value of the neighbours of a network component. First, diversity of producers’ portfolios and the ubiquity of the produced products are established by counting the edges for each producer and product, respectively. Each reflection subsequently averages the value of a node’s neighbors an increasing number of edges removed from the starting position, resulting in adjusted diversity and ubiquity values.

In this case, we consider European Union NUTS2 regions as producers, and a fine-grained classification of about 4000 scientific topics (see Waltman & Van Eck 2012) as product categories for publications published 2000-2014. Each region is considered to be active in a certain scientific topic if it outputs more publications in this topic than would be expected given its total publication output and the average distribution of publications over the topics. The total number of active topics in a region, and regions in which a topic is active, then constitute the diversity scores for the regions and ubiquity scores for the fields. In this initial exploration, we limit ourselves to the diversity of regions’ scientific production.

Each subsequent ‘reflection’ computes new values – the first step for the regions is the average ubiquity of the regions’ science topics, the second step the average diversity of the regions that share its topics, and so on. This allows us to distinguish between regions with similar sized portfolio of scientific activity; if one region is active in topics that predominantly feature in less diverse regions, and another is active in topics that predominantly feature in diversified regions, the diversity scores in subsequent reflections for the latter region will be higher than those for the former region.

Preliminary results
Figure 1 contains the distribution of the diversity of all 271 regions. London is the most diverse region, followed by Paris. It is clear that a small number of more diverse regions are followed by a continuum of diversity, and the down-sloping tail represents regions with more marginal publication outputs.

A map depicting the regions and the diversity of their scientific production can be found in figure 2. It is clear that the most scientifically active regions are those that contain major centres of population (and, as a result, scientifically active institutions). Beyond this pattern, it seems that the more scientifically active regions are spread across Europe. Most capital regions of Europe show high activity.
Figure 2: diversity rank of EU28 NUTS2 regions

Figure 3 shows the result of the method of reflections, after eight steps through the bi-partite network. This corresponds to a generalized measure of diversification, taking into account the region’s local bipartite neighbours up to 8 steps removed. High values here can be attributed to regions being well-connected to other high-diversity regions and to low-ubiquity topics. It is clear that north-western Europe eclipses south-eastern Europe, and that countries are surprisingly uniform in the ranking of their regions. This may be explained by geographically bound research topics shared by the country’s regions. These outcomes suggest that country-specific capabilities exist, that tie the regions of countries together in the bipartite network.

Figure 3: inferred capability rank of EU28 NUTS2 regions, based on 8th order reflection

Whether these inferred diversity scores of regions correspond to their capabilities may be explored by comparing them to other regional statistics. We check if regions’ diversity, and diversity-related reflection outcomes, correlate to regional GDP per inhabitant, and to regional purchasing power. See table 1 for the outcomes.

Table 1: correlation between measures of diversity and regional purchasing power and GDP per head of population

Table 1 shows increasing correlation, to a point, for both regional GDP per inhabitant and purchasing power, as the method of reflections progresses. While this is of course not a definitive confirmation of our capability-related view on regional knowledge production, it does suggest that knowledge production networks can be mined for additional information on the knowledge producers and how their portfolio’s relate to one another. While regions make an attractive visual case for demonstration purposes, universities and other research organisations might be better suited for this kind of analysis as their ‘capabilities’ might be easier to quantify and more readily influenced by institution (hiring and funding allocation) policy.

Introduction
Co-word analysis has been widely used to reveal knowledge structures of a research field (Callon et al., 1983). Semantic items used in the co-word analysis are assumed to represent the content of articles, such as terms from titles (Bhattacharya & Basu, 1998) and abstracts, or subject terms assigned by professional indexers (Ocholla et al., 2010). Author keywords have also been selected as one crucial data source for establishing co-occurrence relationships between keywords in many co-word analysis studies (Cho, 2014). The number of author keywords influences the results of co-word analysis. In the co-word analysis, not all author keywords are used to form co-occurrence relations. Only the keywords from papers that have two or more keywords are used. Therefore, investigating on the number of author keywords in research articles will help know the coverage of papers by the co-word network using author keywords. Author keywords are often requested or encouraged by many journals to highlight the content of articles in their publication policies. Some journals even specify the number of keywords author should assign. However, in a research field, what is the distribution of author keywords in papers? Further, to our best knowledge, there are no studies that compare author keywords distributions in multiple disciplines. In this study, we will investigate on how many author keywords are assigned to articles in multiple disciplines with the aim of revealing the underlying quantitative patterns.

Data and methods
Six research fields from soft science to hard science were analysed, including Ethnology, Sociology, Library and Information Science (LIS), Economics, Physics, Fluids & Plasma (Physics), and Acoustics. Articles from top journals in these six fields were retrieved from the Web of Science database. Bibliographic records of articles with the types of article were downloaded. Author keywords in the papers were parsed and stored into MySQL databases. The number of keywords for each article in the six fields was counted. Normal distribution, Poisson distribution, and Weibull distribution were fitted for the number of keywords per paper by applying Maximum Likelihood Estimation. Chi-Square(χ²) tests and Kolmogorov-Smirnov(KS) tests were applied to evaluating the goodness of fit.

Results and discussion
The six disciplines have different magnitudes of selected research articles (Table 1). Table 1 shows that a significant proportion of papers across all these fields do not have any author keywords. Sociology has the lowest rate of keyword absence with 22.56% and Acoustics has the highest rate with 73.84%. In addition, very few papers in these fields have only one keyword. Generally speaking, research fields in hard science (e.g., Physics and Acoustics) tend to have more papers without author keywords than those of soft science (e.g., Ethnology and Sociology).

The significant portion of papers without any keywords or with one keyword in the six fields indicates that only using author keywords in co-word

analysis could suffer from the short of paper coverage in the fields. One major reason for the absence of keywords could be the publication rules of the journals. Many journals do not allow authors to assign any keywords to articles, such as *Acta Acustica united with Acustica* in Acoustics and *The World Economy* in Economics. Some journals did not allow keywords in earlier years but started to require author keywords more recently. For example, *Applied Acoustics* did not ask for author keywords before 1995, but later did. Another factor comes from the authors. Even some journals require author keywords, some papers still have no keywords. For example, 14 of 40 papers published in *Youth & Society* in 2014 have no keywords.

Figure 1 presents the author keyword distributions in the six fields. The number of papers is logarithmized.

Conclusions

Author keywords in six fields were analysed quantitatively. Results show that a large portion of papers have no keyword or only one keyword. The six fields share similar author keyword distributions with Weibull distributions best fitted although not strictly. The quantitative patterns of author keywords provide practical implications to keyword selection in co-word analysis and reveal the underlying mechanisms in scientific communication. In future, journal rules on author keywords will be further analysed to interpret the patterns. In addition, we will explore whether and how co-word analysis is influenced by the patterns of author keywords.

Investment and results in R&D in the temporal context of the economic crisis: a metric approach

Introduction
With the beginning of the global economic downturn in 2008 many countries have reduced their investment in R&D. The tendency of nations’ scientific spending has traditionally been procyclical, being positively related to the level of economic activity (OECD, 2016). Although the causal relationship is not guaranteed (Leydesdorff & Wagner, 2009), there is a lot of scientific literature that positions R&D investment as a driver of productivity and long-term economic growth in the industrially advanced nations (García-Porras et al., 2015). Although higher investment does not always guarantee better results (King, 2004), because scientific policy plays a key role, insufficient funding can lead to research deficiencies (Reed et al., 2007).

The objective of the present work is to explore the effect that cuts in the R&D investment may be having on the results of scientific production and its performance at the international level.

Methods
An exploratory analysis is carried out on inputs-outputs. The countries studied have been selected according to their level of expenditure in R&D: Japan, Finland and Sweden (high R&D effort); Slovenia and Czech Republic (increasing effort); Spain, Italy and Poland (low effort); France, Netherlands and United Kingdom (average effort). The period of analysis covers the pre-crisis stage (2000-2007) and the post-crisis stage (2008-2015). As a measure of the variables, the Average Annual Growth Rate (AAGR) is used by time series. For the input, the study variable is the expenditure on R&D (% of GDP), with data extracted from the OECD. For the output, some bibliometric indicators that quantify the performance of scientific production: Normalized Impact Index (NI), percentage of Leadership (L), percentage of Excellence (Exc.) and percentage of Excellence with Leadership (EwL), all extracted from Scopus, through the access support of SCImago Institutions Rankings (SIR).

Results

Inputs (R&D expenditures)
Finland, United Kingdom, Spain and Japan performed, on average, a greater economic effort in the years before the crisis and reduced it in the later years (Figure 1). United Kingdom highlights, with a negative growth in both periods. Italy is the only nation whose AAGR has been similar before and after the crisis. The remaining countries (Sweden, France, Netherlands, Czech Republic, Poland and Slovenia) have intensified their investment in the years of economic recession compared to the previous period, some significantly (the last three).

Figure 1. AAGR of GERD as percentage of GDP in the pre-crisis and the post-crisis period

The analysis by time series (Figure 2) shows that Finland, Japan, Poland, Spain and United Kingdom made an increasing R&D effort during the first years of the decade, but from 2009 there was a coincidental decrease with the years of economic instability. In Slovenia the same has happened but from 2012. Czech Republic and France have had...
similar behavior, reducing the growth rate of their investment from 2009 after a few years of increase. Sweden and Italy have been changing, with some periods of increase and others of decrease in their growth; while in the Netherlands spending was negative before the crisis, but positive from 2009.

Figure 2. AAGR of GERD as percentage of GDP by time series

Outputs (R&D results)

Analysis of scientific results by time series shows that R&D cuts, caused by the economic downturn, may be negatively affecting the growth of leadership (Figure 3) and excellence with leadership indicators (Figure 4). In all the countries analyzed, percentage of leadership has decreased over time; although it is true that this has been more pronounced since 2009 in almost all countries (Finland, Sweden, Czech Republic, Slovenia, Poland, Spain, France, the Netherlands and United Kingdom). This has affected the rate of excellence with leadership, which has also decreased especially during the crisis in Finland, Japan, Sweden, Spain, France, Netherlands and United Kingdom, so some countries are losing scientific autonomy and rely on others to produce high-quality research.

Figure 3. AAGR of Normalized Impact and % Leadership by time series

The growth trend of excellence (Figure 4) has been predominantly positive in some countries (Czech Republic, Slovenia, Italy and Poland) and even increasing in the years following the recession. Japan and United Kingdom went from a negative growth trend to a positive trend in the latest time series. However, in other countries the growth rhythm has slowed since 2009 (Spain and Italy), even becoming negative from 2012 (Sweden, France and Netherlands).

Figure 4. AAGR of % Excellence and % Excellence with Leadership by time series

The indicator whose growth has been least affected by cuts in R&D is the normalized impact index (Figure 3). In some countries it has remained more or less stable with positive rates (Japan, Sweden, Italy, Spain and United Kingdom) and in others it has grown more in the crisis years than in the previous years (Finland, Czech Republic, Slovenia and Poland). France and Netherlands are the only ones with a tendency to decrease in their impact from 2009. Further research should be done to better understand the potential effects on funding and research performance in order to foster the best political and academic strategies that might help for building the research agendas of nations.
