Why do some research articles receive more online attention? 
Reasons for online success as measured with altmetrics

Abstract
Recent altmetrics research has started to investigate the meaning of altmetrics and whether altmetrics could reveal something about the attention or impact connected to research. This research continues this line of investigations and studies reasons for why some research has received significant online attention in one or both of two social media services; Twitter or Mendeley. This research investigated Finnish researchers’ opinions about the reasons for why their research had received significant online attention and if the attention received could reflect scientific or societal impact of their research. Based on the findings it can be stated that the level of online attention received is a sum of many factors and that there are also specific differences between the platforms where the attention has been received. For the articles that had received significant attention on Mendeley the reasons for that attention were more often seen as due to an academic audience, while the situation was reverse on Twitter, with the majority of reasons for the attention being linked to a wider audience. Similar trend could be seen when asked about whether the online attention could reflect scientific or societal impact, although a clear consensus about whether online attention could reflect any type of impact at all could not be reached.

Conference Topic
Altmetrics

Introduction
Altmetrics has been defined as “the study and use of scholarly impact measures based on activity in online tools and environments” (Priem, 2014). The research area thus focuses on investigating what mentions of research products (e.g., scientific articles, datasets, code) on the web and particularly in social media can tell about the impact or influence of the research. While the debate about what is meant with impact and whether altmetrics can reflect impact or should we instead be talking about attention or engagement continues, altmetrics research has focused on investigating what the data can reflect and what it can tell us about the research that have received the online attention. Early altmetrics research focused on investigating possible connections between citations and different altmetrics and discovered certain connections between for instance usage statistics on Mendeley (Mohammadi & Thelwall, 2013), Wikipedia references (Evans & Krauthammer, 2011), and tweets mentioning scientific articles (e.g., Shuai et al., 2012; Thelwall et al., 2013), and the numbers of citations those articles later receive. More recent altmetrics research has moved on to investigate the meaning of altmetrics and whether altmetrics could reveal something about the reach, influence, or engagement connected to research. The present research continues this later line of investigations and studies possible reasons for why some research has received significant online attention in one of two social media services, namely Twitter or Mendeley. With the help of a questionnaire we will investigate Finnish researchers’ own opinions about the possible reasons for why their research have received significant online attention and whether the researchers feel that the attention received could reflect either scientific or societal impact of their research.
**Background**

While early altmetrics research focused on investigating relations between citation counts and different altmetrics (e.g., Thelwall et al., 2013), more recent research have focused increasingly on identifying characteristics of the research articles that may influence the level of online attention the articles receive. Haustein, Costas and Larivière (2015) investigated possible connections between document characteristics (discipline, document type, title length, number of pages and references) and five different altmetrics (Twitter, Facebook, blogs, Google+, and mainstream media). Although the coverage of scientific articles was very low on the selected social media platforms (with the possible exception of Twitter), the authors discovered that “both citations and social media metrics increase with the extent of collaboration and the length of the reference list.” The results also showed how editorials and news items were the most popular scientific document types shared on Twitter. Didegah et al. (2016) conducted a similar study investigating a range of factors associating with citation and altmetric counts of Finnish research articles. The factors investigated were individual collaboration (number of authors), international collaboration (number of different countries that the authors came from), institutional impact (Maximum Mean Normalized Citation Score of the different institutions that the authors were affiliated with), Journal Impact Factor (retrieved from the JCR), journal open accessibility, and field type (OECD field of the article). These were then tested for association between citation counts, number of readers on Mendeley, number of tweets on Twitter, and number of posts on Facebook. The main conclusion was the same as in Haustein et al. (2015), that the factors driving citations are very much different from those that drive altmetrics, emphasizing that altmetrics cannot be considered as a replacement for citations, but instead possibly as a complement. In Didegah et al. (2016) most of the tested factors were significantly determining the altmetrics, either associating with an increase or a decrease of the altmetrics. The differences between some of the results in Haustein et al. (2015) and Didegah et al. (2016) also demonstrate the uncertainty present in altmetrics, as factors such as timing of the study and data quality may influence research results. Thus more research and new types of approaches are needed in order to fully understand what different altmetrics may reflect and why some research receive more online attention compared to others.

While most of previous altmetrics research has utilized mainly quantitative research methods, qualitative approaches have been almost non-existent. Qualitative content analysis, for instance, could bring new viewpoints into altmetrics research. Qualitative content analysis can be used as a separate research method as well as a theoretical context provider that can be subjected to several different forms of analysis (Tuomi & Sarajärvi, 2009, 91). Qualitative content analysis can be described as a subjective method of research that enables the interpretation of data through a series of classifications and through the underlying themes of content (Hsieh & Shannon, 2005; Zhang & Wildemuth, 2009). The purpose of qualitative research is not to produce quantifiable information or to provide statistical significance for the data. Instead, it can be used to help us understand the surrounding reality and to enable us to classify it into different codes of conduct, appearing themes and emerging categories (Zhang & Wildemuth, 2009). The present research will take a more qualitative approach to investigate the possible reasons why some research receives significant online attention on Twitter and on Mendeley. Whereas Mendeley is a social reference manager owned by Elsevier, Twitter is a microblog service with over 300 million active monthly users. Mendeley is mostly used by academics in their work (Mohammadi, Thelwall, Haustein, & Larivère, 2015), while Twitter is used for much wider variety of reasons and purposes (e.g., Ke, Ahn, & Sugimoto, 2016; Mislove, Lehmann, Ahn, Onnela, & Rosenquist, 2011; Semertzidis, Pitoura, & Tsaparas, 2013; Uddin, Imran, & Sajjad, 2014). Both of the selected altmetrics data sources, Twitter and Mendeley, are clearly different in both their purpose and user base,
which will give this research an interesting starting point to examine differences in the possible reasons for the accumulated attention.

**Data and methods**

The goal of this research was to investigate what authors of scientific articles that had received significant attention on either Twitter or Mendeley thought had contributed to the received attention and what they felt that attention could tell, if anything, about the impact of that research.

The overall research design was to create a questionnaire that would demonstrate how the participants view the success of their research articles in two data sources of altmetrics; Twitter and Mendeley. Researchers who during 2012 to 2014 had an affiliation to a Finnish research institute or a university and whose article or articles scored in the top one percent of the most shared articles on Twitter or most saved articles on Mendeley were chosen to participate in the survey. All scientific articles with at least one author with a Finnish affiliation were retrieved from the national VIRTAA research publication database. Using DOIs the articles were matched with altmetrics data aggregated and provided for this research by Altmetric LLP (https://www.altmetric.com/). The articles were then sorted in descending order based on how many times they were tweeted or how often they had been saved on Mendeley. Of these only the articles that made the top 1% percent on either platform were chosen for this study. This resulted in a total of 109 articles that were frequently tweeted and 102 articles that were often saved on Mendeley. These articles had a total of 465 authors with a Finnish affiliation, which made the set of participants that were contacted. Of these 170 researchers (36.6 percent of all researchers included in the data) answered the questionnaire. Due to missing or closed email addresses, 69 researchers (14.8 percent) could not be reached at all. In some cases, the researcher had published an article that faired in more than one online service. If this happened, their answer was registered to the data multiple times: the same answer for both individual online services. However, in the study, each participant was only observed once, i.e. each participant was counted as a single observation.

The questionnaire was conducted as an email survey and the content of it was both in English and in Finnish. Of all the participants, 10 percent (20 people) replied in English. The participants were introduced to two questions regarding the online attention their article received, questions that also function as the overall research questions of this research:

1. **Which factors do you think have influenced the attention this paper has received on the above-mentioned platforms?**
2. **What do you think this online attention tells about your paper and its societal or scientific impact?**

Unlike in altmetrics research in general, the aim of this study was to utilize mainly qualitative methods in assessing the research questions. The data analysis based on the answers received first started with a thorough read-through of the answers. After forming a cohesive view on the data, the text was then submitted to a further, more specific inspection. The data were scanned for words, expressions or sentences that seemed to appear regularly from one answer to another. As instructed by Hsieh and Shannon (2005), the impressions the data left for the researcher were also committed to paper and used in the coding of the answers. Finally, the whole data were coded to different word or phrase categories. The process of coding was performed by using inductive analysis, where the coding takes place by creating new categories when necessary whilst reading through the data instead of submitting the data to a set of fixed categories. By using the means of inductive content analysis, we were able to
perceive the forming of different categories based on the material (Zhang & Wildemuth, 2009; Tuomi & Sarajärvi, 2009, 96).

Defining the unit of coding is one of the most important things to take into consideration (Weber, 1990). In qualitative research, the definition of the coded unit is often times more abstract than just an individual word, a sentence or a paragraph (Zhang & Wildemuth, 2009). Therefore in our material, the categories were formed mainly based on individual words, but with the context of the word taken into consideration as well. Depending on the context and the way the respondents answered the proposed question, some of the answers could have been coded into several different categories (Tesch, 1990), as was done with our data. There were some overlapping categories, as the inductive content analysis and the possibility of coding answers into several different categories allowed for this to happen. However, some of these overlapping categories were later merged together wherever possible and their possible negative effects on analysis have been identified during the stages of analysis and discussed by the authors. Towards the end of the process of analysis we strove towards discovering a larger context for the categories identified – main themes that might serve best in describing the opinions of researchers about the success of their research in the analysed online services (Hsieh & Shannon, 2005).

Of the answers from the 170 respondents, 109 answers concerned an article or articles that were among the top one percent of most tweeted research articles on Twitter and 95 concerned an article or articles that were among the top one percent of the most saved references on Mendeley. As some articles appeared in the top one percent on both Twitter and on Mendeley and these answers were inserted to both platforms, the total number of answers ended up being higher than 170.

In terms of responses by online service, for the articles that were among the top one percent of articles that were most frequently saved on Mendeley researchers from the Natural Sciences answered the questionnaire most frequently – 50.5 percent (48 persons) in total. Researchers from Engineering and technology answered the questionnaire with an 34.7 percent share (33 persons), while the share of Medical and Health Science researchers that responded to the questionnaire regarding success in Mendeley, was only 10.5 percent (10 persons) responding and with Social Sciences researchers amounting to about 4.2 percent (4 persons). With 49.5 percent (54 persons) of the answers to Twitter Medical and Health Sciences researchers provided the most answers. Researchers from Engineering and Technology answered the questionnaire with a share of 28.4 percent (31 persons), while the share of answers from Natural Sciences researchers was only 20 respondents (18.3 percent) of the possible 109 people responded to the questionnaire regarding success on Twitter. Respondents from Social Sciences amounted to about 3.7 percent (4 persons).

Results

As there was no prevailing theoretical frame of reference that would have provided us with hypotheses over the answers, we settled on utilizing the previously introduced method of inductive content analysis by Hsieh and Shannon (2005) to analyse the answers to the questionnaire. With inductive content analysis we were able to identify several reoccurring factors that were mentioned to be behind the online success (question 1) or that were thought to reflect social and scientific impact (question 2) of the paper in question. The overarching themes that were built by further grouping the categories in question 1 were constructed based on what sort of audience the researchers might have envisioned when they described the reasons for the success of their article. After the first stage of analysis we were able to interpret the data and identify two dominant overarching themes – attention from an academic audience and attention from a wider audience beyond academia. The chosen themes, academic and wider audience, were created based on what type of audience the
response could be thought to intend. In other words, in the creation of themes the audience was taken into account. For instance, when considering the reasons stated for the popularity or gained attention the category for “respected publication channel” was coded to be more important for an academic audience, rather than for a wider audience beyond academia. The category “timeliness” on the other hand was coded to be mainly appealing for a wider audience. There were some overlapping between the categories (e.g., timeliness – novelty), but these were not merged together because of the subtle nuances in the meaning and intention of the responses. Behind this decision were the perceived motivations to share the article on Twitter or to save it on Mendeley. It was presumed that an academic audience has differing motivations to share or save the article than a wider, mainly non-academic audience would have.

Table 1 shows the identified themes from the responses to the first question grouped according to the overarching themes (academic audience – wider audience). The table is sorted descending according to Mendeley categories. Certain categories were clearly more popular for articles that had received significant attention in both Twitter and Mendeley, such as timeliness (Twitter 20 mentions, Mendeley 19 mentions), respected publication channel (T 20, M 23), popularizable topic (T 16, M 12), activity of the authors in disseminating information about the article (T 8, M 8), and review/meta-analysis article (T 7, M 13). As can be seen in Table 1, responses connected to articles that had received significant attention on Twitter emphasized more personal attributes and the role of communication, while responses connected to articles saved on Mendeley reflected a more academic and analytical approach to the factors leading to the received online attention. Where almost 68 percent of the responses for Mendeley were classified as reasons related to an academic audience, for Twitter about 60 percent of the responses were classified as attributes appreciated by a wider audience. For responses connected to Twitter five topics were clearly emphasized as reasons for the received attention; emotionally engaging topic (30 mentions on Twitter, 0 mentions on Mendeley), respected publication channel (T 20, M 23), timeliness of the topic (T 20, M 19), novelty of the topic (T 17, M 6), and popularizable topic (T 16, M 12). For Mendeley the responses were more evenly spread over more topics. There were a total of eight categories that received over ten mentions in the responses; significant research results (40 mentions on Mendeley, 8 mentions on Twitter), respected publication forum (M 23, T 20), timeliness (M 19, T 20), new research method (M 18, T 2), review/meta-analysis article (M 13, T 7), popularizable topic (M 12, T 16), top researchers as authors (M 12, T 2), and interesting topic (M 12, T 0).

In the responses to the second question there were again some identified topics common to both platforms. The responses were again grouped into overarching themes based on what the online attention was thought to reflect or indicate and some clear differences between the platforms in regard to the second question emerged. Figure 1 shows that online attention was in many cases thought to reflect scientific impact of the article, especially on Mendeley (Twitter 12 mentions, Mendeley 45 mentions). Authors of the articles that had received significant attention on Twitter emphasized their opinion that the online attention was a reflection of some type of impact other than scientific impact (33 respondents), but almost as many respondents (24) stated that they did not believe that attention on Twitter reflected any type of impact. Thus, no clear consensus about the impact could be reached among the authors of the articles that had received significant attention on Twitter. Same, although to a lesser degree could be seen for Mendeley, with 45 responses stating that the online attention is a reflection of scientific impact, 14 responses claiming it to be a reflection of societal impact, and 12 respondents claiming that online attention does not reflect any type of impact. On the other hand, some authors of articles that had received significant attention on Mendeley stated that the online attention correlated with the number of citations their research had received and that it reflected how the scientific community was interested in the research. In addition, other aspects of the research or of its authors (Twitter 22 mentions, Mendeley 39 mentions) and quality of the research (T 18, M 28) were also quite often mentioned as being reflected in the online attention received.

![Figure 1. Respondents’ opinions about what online attention on Twitter and Mendeley tells about the article’s impact, about the research or of other attributes of the article or its authors](image)

**Discussion**

The overall aim of this study was to investigate Finnish researchers’ opinions about the reasons why their research had received significant attention online on either Twitter or Mendeley or on both. Some shared attributes of the research or the publication appeared repeatedly for both Twitter and Mendeley. Especially high quality of the publication channel, timeliness of the publication, and personal connection to the research topic were seen as attributes that influenced the online attention on both platforms. In addition, depending on the
platform, top researchers as authors, emotionally appealing subject, and the novelty of the research topic were also often mentioned as reasons for the received attention. Based on the findings it can be stated that the level of online attention received is a sum of many factors and that there are specific differences between the platforms where the attention has been received. The categories were grouped according to whether the researchers thought that the online attention was due to attention received from an academic audience or from a wider more general audience. From this grouping it was apparent that for the articles that had received significant attention on Mendeley the reasons for the attention were more often due to an academic audience, while the situation was reverse on Twitter, with the majority of reasons for the attention being linked to a wider audience beyond academia. These platform specific differences in the reasons for the attention can at least partially be explained with both differing purposes and user types between the platforms. While Mendeley is profiled clearly as a tool to conduct research, the user base of Twitter is much more varied.

The divide between an academic audience and a wider audience was also apparent in the answers to the second question about the researchers own thoughts whether this attention could reflect or tell something about scientific or societal impact of their research. The impact of the articles frequently saved on Mendeley was described to be more connected to a scientific impact, while the articles that were frequently tweeted were thought to reflect the attention from a wider audience. But some disagreement could be seen when the researchers assessed the scientific and the societal impact of their article. The abstract nature of the term impact and the subjective opinions attached to the term made some respondents specify that the online attention gives the research and the research topic visibility, but not impact. On the other hand, in some answers the articles were seen to have some general impact and influence on societal debate. But several respondents stated clearly that they do not believe that the amount of attention on Twitter would tell anything about any possible impact of that research.

As it would appear that all the respondents recognized both of the platforms, it is possible that their answers have to some degree been influenced by their personal perception of the platforms and of their users. This could be counted for by repeating the study without revealing on which specific online platforms the articles have received significant attention. Although there were clear differences in the answers according to the platform, it is unclear how much the answers were influenced by researchers’ own perception of the type of people that are using the platforms. There was a lack of clear consensus about whether the online attention received could reflect scientific or societal impact. Opinions that the online attention contributed positively to impact in general prevailed, although some described the online attention as mere buzz. Traditional approaches to measure impact, such as citation counts, were seen among the respondents as the most important means to measure impact.

The results did, however, show a consensus among the researchers about the importance of breaking out of the ivory towers and communicating research to a wider audience. The answers often repeated the researchers’ view that the online attention received demonstrated how the researchers had fulfilled their societal duty and also how they could bring scientific viewpoints into policy making. More research is, nevertheless, needed to fully understand what the online attention some research receive could tell about societal impact of research or how science has had an impact on policy making.

Abstract
The purpose of this study is to investigate whether diffusion on social media can help to improve the international visibility of Chinese papers and thus increase citation impact. After analyzing 160,233 Chinese articles published in 2012 as well as their tweets and citations received, the results indicate that, tweeted Chinese papers, published in the same year as the same journal, received around 20% more citations than Chinese papers not mentioned on twitter. The citation advantage of tweeted Chinese paper is also found within various disciplines and by different citing source countries.

Conference Topic
Twitter, citation analysis, China, altmetrics, scientific impact

Introduction
With the significant development of the Chinese economy, Chinese scientific activity is experiencing a period of similar growth. China¹ has become the second largest source country in terms of its share of international scientific production since 2009 (ISTIC, 2010, 2015). A number of studies attempt to characterize Chinese research achievement and evaluate China’s research performance regarding almost all bibliometric topics such as collaboration network (Niu & Qiu, 2014; Wang, Wu, & Pan, 2014), academic journals (Ding, Zheng, & Wu, 2012), university ranking (Fu & Ho, 2013; Zhu, Hassan, Mirza, & Xie, 2014), and international visibility (Ren & Rousseau, 2002; Wu et al., 2004). However, this is not the case in altmetric studies that few researches try to measure the dissemination of China’s research via non-traditional sources (e.g. news report, social media, blogs, reference management tools etc.).

Although China is still isolated from the major international social media such as Twitter, Facebook, Google¹, China’s research has been mentioned in these social networks and acquires international attention. Unfortunately, so far no current study addresses whether mentions in social media can increase the citation impact of China’s research.

Although the altmetric research investigates almost all social media as tools measuring the influence of research activities, Twitter has been in the centre of altmetric research because of its coverage (Thelwall, Haustein, Larivière, & Sugimoto, 2013). Comparing to other social media, Twitter shows the largest signal related to scientific papers among non-academic, general audience social media platforms. About one fifth of recent publications are mentioned on Twitter, which is topped only by Mendeley among currently captured altmetrics (Haustein, Costas, & Larivière, 2015). Although Twitter is not accessible in China², China’s publications are tweeted internationally. These international tweets could improve the international visibility

¹ In this study, China refers to Mainland China, which is the area under the direct jurisdiction of the People's Republic of China (PRC) but excluding Hong Kong and Macau.
² People can occasionally access the Twitter by using the virtual private network (VPN) but it is illegal in China.
of China’s publication. However, no study reveals whether more international visibility may bring more citations to China’s publication or not. In addition, since Chinese scholar cannot use Twitter to promote their publications, the investigation on China’s publications provides a special environment to understand the impact of tweets on citations when the influence of self-tweets is excluded.

Although some studies have associated Twitter exposure with an overall increase of citations (Eysenbach, 2011; Thelwall et al., 2013), the direct correlations between tweets and citations have been shown to be weak (Costas, Zahedi, & Wouters, 2015; de Winter, 2015; Haustein et al., 2015). Moreover, social media and altmetrics have been heralded as democratizers of science and its reward system, as they potentially overcome the Matthew effect reflected in traditional citation-based indicators. However, low social media visibility of scientific publications from Latin America (Alperin, 2014, 2015) and Iran (Maleki, 2014) suggest that instead of leveling the playing field and contributing to global equality in scholarly communication, social media seem to widen the gap between countries. Despite being ranked second largest source country in terms of the number of publications (ISTIC, 2015), several studies show that Chinese publications still receive low international visibility in terms of the number of citations received (Ren & Liang, 1999; Ren & Rousseau, 2002; Wu et al., 2004). We do not know whether the diffusion of paper on Twitter can increase China’s international visibility and improve its citation impact.

Goals and Objectives
The purpose of this study is to investigate whether diffusion of papers on Twitter can help to increase the visibility of Chinese papers and thus help to close the citation impact gap between China and other countries. It seeks to answer the following questions:

1. Does the overall citation rate of Chinese papers shared on Twitter exceed those of non-tweeted Chinese papers?
2. How do results described above vary by scientific disciplines?
3. How do results described above vary by the source countries of tweets and citations?

Methodology
In this study, the publication and citation data were retrieved from Web of Science (WoS), which includes the Science Citation Index Expanded, the Social Science Citation Index and the Arts and Humanities Citation Index, annually index documents published in about 12,000 journals, covering all areas of research. In this study, all papers published in 2012 were retrieved (N = 1,339,279). Citations to these 2012 articles were counted until the end of 2015, which allows for a citation window of three complete years.

Altmetric.com was chosen as the data source for tweet counts, as it is the most comprehensive source of social media data associated with scientific papers (Robinson-Garcia, Torres-Salinas, Zahedi, & Costas, 2014). Tweet data includes counts collected up to June 2015.

The Digital Object Identifier (DOI) was used as the linkage between WoS and Altmetric.com data. Since the DOIs are not available in all publications, only publications with a DOI as recorded in WoS (N = 1,131,358) were included under investigation.

Based on the dataset of 1,131,358 articles, we identified three groups of Chinese papers published in 2012 for investigation: 160,233 articles have at least one Chinese author (Group 1); the first authors are from China in 145,325 articles (Group 2); and 119,268 articles only have Chinese author(s) (Group 3). In this study, the Chinese author was defined as the author...
with an affiliation to a Chinese institution. The bibliographic information such as journal title, discipline, and citations to these articles were also retrieved from the WoS. As Table 1 indicates, almost 40% of the journals contain tweeted Chinese papers in each group. These journals contribute more than two thirds of the Chinese papers.

Since the citation frequencies vary across disciplines, the comparisons between disciplines are difficult. Based on the journals in which these Chinese papers were published, all articles were grouped into 14 major disciplines based on the NSF journal classification system (See Table 2). Since Chinese scholars published very few articles in Arts and Humanities, these two disciplines were excluded from this study.

Three types of analyses were conducted to answer the research questions as above. A pair comparison of average citations received between tweeted Chinese papers and non-tweeted Chinese papers published in the same journal the same year could answer the first research question; the different results from different disciplines will answer the second research question; a further analysis investigating the geographic distribution of these tweets and citations received could answer the third research question.

Journal Comparison

Since the paper’s visibility may be influenced by various factors (e.g. journal is probably a confounding factor of the Twitter impact and citation impact), a comparison of papers published
in the same year in the same journal will provide an experiment by controlling the effect of other factors on the paper’s visibility. In this study, the pair comparison compared the average number of citations to tweeted Chinese papers with the average number of citations to non-tweeted Chinese papers journal by journal. Although more than 2,000 journals contain both tweeted Chinese papers and non-tweeted Chinese papers in each defined group, the distribution of tweets is highly skewed as Figure 1 shows. More than half of these journals only have 1 or 2 tweeted Chinese papers. In order to avoid the effect of outliers, two thresholds were set as below:

- Threshold 1: the qualified journals have at least both 10 tweeted Chinese papers and 10 non-tweeted Chinese papers.
- Threshold 2: the qualified journals have at least both 20 tweeted Chinese papers and 20 non-tweeted Chinese papers.

Eventually, less than 300 journals were selected for the pair comparison as Table 3 indicates. Since the citation data is extremely skewed in the power law distribution, the geometric mean, comparing to the arithmetic mean, is the most precise and accurate indicator for citation-based comparison (Thelwall, 2016). In order to allow the geometric mean to include the uncited articles, 1 is added to the citation counts before calculating the geometric mean and then 1 is subtracted from the result. The shift of 1 is a standard method for calculating the geometric mean of citation data (Thelwall, 2016). In addition, since the citation rate varies among different disciplines, in order to avoid the disciplinary bias, all citations were normalized in this study before counting when the comparison was among different disciplines.

Discipline Comparison

The comparison of citation rate was also conducted among 12 disciplines described above when Arts and Humanities were excluded. All Chinese papers, either tweeted or non-tweeted, were grouped into 12 disciplines based on their journals. To detect general trends and differences between disciplines, we compared, for each discipline, the arithmetic mean of the citations received for tweeted Chinese papers and for non-tweeted Chinese papers. Since few outliers (i.e. highly cited papers) might influence the average number of citations, the analysis was done not only at the paper level but also at the journal level, comparing the mean of citations of 261 journals that was included in Group 1 with Threshold 1 in the journal comparison.

Source Country Comparison

The source countries of all tweets and citations to the 160,233 Chinese papers were retrieved and identified during the data collection. If authors of the citing paper come from different countries, each source country was counted as one when calculating the number of citing source countries. The tweeter country was retrieved from the Altmetric.com who identify it based on the information provided in the twitter account information; unfortunately, the source countries of 18,589 tweets (34.4%) could not be located based on the twitter account information, which is a limitation of this study. For the top 10 source countries in terms of the number of tweets and the number of tweeted Chinese papers, both the normalized geometric mean and the normalized arithmetic mean of the number of citations to Chinese papers were compared. We focused this analysis on group 3 (Chinese author only) in order to avoid the influence of self-tweets because Chinese authors cannot tweet due to the inaccessibility of Twitter in China.

Results

As Table 4 shows, 12.1% of the 160,233 articles with at least one author from a Chinese institution (Group 1) were tweeted and received 53,972 tweets. This percentage is far below the worldwide Twitter coverage of 21.9%. This ratio in Group 2 (11.0%) and Group 3 (9.5%) is even lower, as is to be expected considering the less central role or absence of international co-authors, respectively. Papers in Group 1 have more chance to be tweeted than papers in Group 2 and 3 because international co-authors may promote their co-authored papers on Twitter.

The 160,233 Chinese papers received a total of 1,514,138 citations between 2012 and 2015. As Table 5 shows, the average number of normalized citations received by tweeted Chinese papers is about more than 50% higher than that of non-tweeted Chinese papers received in each group.

3 There is a possible issue pertaining to the accuracy of the data regarding the source countries that Twitter users can select any countries in their profile.
Journal Comparison

In the journal comparison, when comparing the geometric mean of the number of citations to tweeted Chinese papers with non-tweeted Chinese papers in each journal, we found that tweeted Chinese papers received more citations than non-tweeted Chinese papers in the majority of the journals. As Table 6 indicates, the higher threshold applied, the higher ratio of journals that their tweeted papers have citation advantage.

Tweeted Chinese papers received more citations than non-tweeted Chinese papers when comparing both the geometric mean and the arithmetic means in each group and threshold at the journal level. As Table 7, 8 and 9 shows, the tweeted Chinese papers received around 20% more citations than non-tweeted Chinese papers in average if only comparing the arithmetic mean.

Discipline Comparison

All 160,233 articles were grouped into 14 disciplines as Table 2 described above. Arts and Humanities were excluded from the data analysis because of the data size. When comparing the arithmetic mean of citations at the paper level, as Table 10 indicates, we found that the tweeted Chinese papers received more citations than non-tweeted Chinese papers in all disciplines except for Professional fields and Mathematics that the tweeted paper received less citations than non-tweeted paper. On the other hand, tweeted Chinese papers had huge citation advantage in some disciplines such as Engineering (251.0%), Physics (143.8%) and Chemistry (76.1%).

15
As we discussed above, in order to avoid the effect of the few highly cited papers on the mean of the citations, we made another comparison within the 261 journals (Group 1 with Threshold 1). 4 out of 12 disciplines were excluded because they contained less than 2 journals. As Table 10 shows, Tweeted Chinese papers had citation advantage compared to non-tweeted Chinese papers in all 8 disciplines. Tweeted Chinese papers in Mathematics received 32.3% more citations than non-tweeted Chinese papers when the effect of outliers was removed; Tweeted Chinese papers still had citation advantage in Engineering (25.2%), Physics (64.2%) and Chemistry (20.7%); but the difference observed between tweeted and non-tweeted papers in these three disciplines was reduced as compared to the paper level analysis.

Source Country Comparison

The 160,233 Chinese papers published in 2012 were cited by scholars from 198 countries, and received tweets from 154 countries. China itself contributed 47.0% of total citations (720,816/1,533,582) to non-tweeted Chinese papers while only 29.3% of the total citations (158,062/538,856) to tweeted Chinese papers were self-citations (i.e. citations received come from a Chinese paper) in terms of the source citing country. When self-citations were excluded, as Table 11 shows, the citation advantage was found in more journals in each group and threshold comparing the results as shown in Table 6. It means that tweets may bring more international citations to Chinese papers.

In addition, the source country of tweets has the influence on the citation advantage of tweeted Chinese paper. As Table 12 shows, nine countries appear in both lists of top 10 source countries in terms of the number of tweets and the number of tweeted Chinese papers, United States,
United Kingdom and Australia are ranked top 3 in both list. Although Chinese papers received more tweets from United States, these tweets did not bring any citations advantage comparing to tweets from other source countries. Both the geometric mean and the arithmetic mean of normalized citations to these papers tweeted by American are below the average. On the other hand, Chinese papers received more citations when they were tweeted by German or Japanese.

Conclusion
In this study, after investigating the tweets and citations to 160,233 Chinese papers published in 2012, we determined the differences on average citations received between tweeted Chinese papers and non-tweeted Chinese papers. The results of this study show tweeted Chinese papers received more citations than non-tweeted Chinese papers:

- From the same journal the same published year, tweeted Chinese papers received about 20% more citations than non-tweeted Chinese papers.
- When the self-citations were excluded, the citation advantage of tweeted Chines paper is bigger,
- The citation advantage of tweeted Chinese paper varies by scientific disciplines.

Since both the tweet data and the citation data were collected within the same 3-year period, we cannot conclude the causation between the tweets and citations received based on the results but indicate the correlation between whether Chinese papers were tweeted or not and the number of citations they received. In addition, there are also some other limitations in this study. The source countries of about one third of tweets could not be located; the co-authorship of citing articles inflates the number of citations when counting them by countries. In order to understand more detailed impact of tweets on citations to Chinese papers, the content of tweets as well as their relationship with the citations to Chinese papers need to be investigated for further analysis.

Abstract
The research of Altmetrics is becoming one of the most interesting hot spots in the evaluation science with the use of network data in research study. The Altmetrics study has been changing from exploratory research in the preliminary stage to argumentative research, nowadays. This paper analyzed the differences and interrelationships between citation and Altmetrics by using journals of Information Science & Library Science. After that, the star graph was drawn to visualize the relative size of citation and Altmetrics. At last, the feasibility issue of using two types of indicators in journal evaluation was discussed. The results indicated that the citation data and Altmetrics data didn't confirm to normal distribution. There were not so many journals within high impact factor division, but a lot of journals belonged to low impact factor division. The data distribution revealed that both citation and Altmetrics all displayed the long tail trend. Diffidence was demonstrated between citation indices and Altmetrics indices. The result of correlation analysis also showed a difference within different Altmetrics data. The academic quality, disciplinary difference, platform properly and other factors will work on the visibility and attention to journals on the network. If citation data and Altmetrics data were both used at the same time in journal evaluation, a more comprehensive outcome could be obtained.

Conference Topic
Altmetrics, Indicators, Scientometrics, Bibliometrics

Introduction
A series of journal evaluation indicators are promoted after the concept of Journal Impact Factor presented by Garfield. The Journal Citation Reports (JCR) published by Thomson Reuters provide Journal Impact Factor, Immediacy Index, Normalized Eigenfactor, Citable Items and Article Influence Score. Jorge Hirsch (2007) puts forward the concept of H index, then H index was introduced into the assessment of journals and was developed by Google Scholar. A series of indicators based on H index are promoted by Google Scholar (https://scholar.google.com.hk/intl/zh-CN/scholar/metrics.html#metrics) such as h-core, h-median, h5-index, h5-core and h5-median. Scopus database put forward SNIP and SJR. A number of evaluation indices are used in practice, but we found that most of the indices are based on citation though different scholars and agencies present a variety of evaluation indicators. The journal evaluation methods based on citation expose a series of questions: citation delay, citation difference between subjects, and disadvantage for young scholars with the deepening research. Nowadays, some of scholars try to apply network data in evaluation study in order to explore the feasibility issues of using network data in practice. Altmetrics is entering the field of evaluation science and becoming one of the research hot spots.
**Literature Review**

Altmetrics is short for “Alternative metric” and was studied in the year of 2008. The study originates that Taraborelli D (2008) suspects the issue of using JIF in journal evaluation and propose concepts of Distributed Scientific Evaluation and Alternative Peer Review Models. Priem and Hemminger (2010) propose Scientometrics 2.0 and make a multi-angle analysis of influence in social network data. The official website of Altmetrics was established in October 2010 and published the declaration of Altmetrics: A Manifesto (Priem, Taraborelli & Groth, 2010), symbolizing the establishment of Altmetrics.

From development in 2008 to the present, the network data available for Altmetrics research is abundant, including social media data from Facebook, microblogging data from Twitter, online reference manager data from Mendeley or CiteUlike, expert opinion data from F1000 as well as the comprehensive data from Altmetrics.com. What characteristics do the different source data have? Are there some relations and differences in citation and Altmetrics? In order to work out these questions, a number of researchers carried out exploratory research. Bornmann & Haunschild (2015) analyze users’ preferences for different label literature on F1000 among Mendeley readers. Mohammad etc. (Mohammadi, Thelwall & Haustein, 2015) take five discipline journals as study object, then the authors analyse literature coverage on Mendeley and user structure. Haustein et al apply 1.8 million journal literature included in WOS database as study object and explore the visibility of different type literature on the social media platform (Haustein, Costas & Larivière, 2014). Peters etc. select 200 articles from 50 the most commonly used journals in emergency medicine and find that there is a moderate correlation between citation and Altmetrics (Peters, Kraker & Lex, 2016). Liu etc. visualize the relationship of different evaluation indicators (Liu, Xu, Wu, Chen, & Guo, 2013).

Though Altmetrics originates from the paper level measurement for capturing view quantity, comment count, storage data on social media, online reference manager as well as export recommendation system. Nowadays, the Altmetrics data break through paper level evaluation and begins to explore the application of disciplinary analysis, journal evaluation and institutional evaluation. Chen etc. work out the multidimensional scale analysis on 18 indicators of the humanities and social sciences literature in Taiwan, which including domestic influence index, international influence index, webometrics index and social influence index (Chen, Tang, & Wang, 2015). The results combined with regression analysis and discriminant analysis show that humanities and social sciences has different interpretations in four dimensions. Moed & Halevi (2015) summary the advantages and disadvantages of six widely used indices of citation data, usage data, Altmetrics, patent data, economic data and network data, then they put forward the concept of multidimensional matrix. There are some basic literatures about using Altmetrics data to evaluate journals. Haustein etc. (Haustein, & Siebenlist, 2011) calculate Usage Ratio, Usage Diffusion, Article Usage Intensity and Journal Usage Intensity for journal evaluation by using the Altmetrics data of social bookmarking. Zahedi etc. (Zahedi, Costas, & Wouters, 2015) compare the ability to distinguish the highly cited WOS publication between Mendeley readship counts and citation impact of journal (JCS). Nuredini and Peters (Nuredini, & Peters, 2016) make the case study in 30 journals from Economic and Business studies by using the social media metrics data from Altmetrics.com. The most commonly used Altmetrics data sources for EBS-journal are Mendeley, Twitter and News data. The correlation between Altmetrics score and citation is 0.299 at the paper level, but the coefficient between them is 0.614 at the journal level. In this research, the difference and the relationship between citation data and Altmetrics data will be discussed firstly. Then a star graph will be drawn to visualize the relative size of citation indices and Altmetrics indices. Finally, the study try to construct the comprehensive journal evaluation model including citation data and Altmetrics data by the area of star graph.

The main research questions are as follows:
(1) What kind of data distribution do the citation data and Altmetrics data have?
(2) What kind of relationship do they have between citation and Altmetrics?
(3) How to use the citation dimension data and Altmetrics data to evaluate journal in practice?

Methodology
This study was restricted in the journals of Information Science & Library Science and three citation indices, including Journal Impact Factor, Immediately Index and Eigenfactor Score were retrieved from JCR published by Thomson Reuters database. Three types of Altmetrics data were obtained from Altmetrics.com website. Later, the calculation method of Journal impact factor was drawn on because the data retrieved from Altmetrics.com is based on the paper level and journal level data has to be converted. These three Altmetrics indicators are ReaderIF which represents the average number of journal readers, PostIF which indicates the average number of posts from Twitter of the journal and ScoreIF which represents the average score of the journal on the website of Altmetrics.com. The computation progress is as follows: Firstly, we figured out the total number of reader counts, comment of Twitter and score coming from Altmetrics.com for two years. Then the two years summation of reader counts, comments of Twitter and scores of Altmetrics.com was divided by the amount of 2 years articles. At last, the data reflecting the journal level was acquired. Based on the following reasons, the calculation method of Journal Impact Factor is chose: (1) Although, the social media platform with property of generating user counts instantly, this research referenced two years time window and calculated the total amount Altmetrics of the article published in the previous two years for the reason that journals have a steady number of users, concerns, or comments on social media. The average of Altmetrics data of papers published two years ago of one journal was applied to represent the evaluation index of the journal on social media, because of the paper level data only obtained from the Altmetrics.com. It is assumed that most of the literature published in a journal and received a large number of users or comments under the Altmetrics system should enable the journal obtain a higer value of ReaderIF, PostIF or ScoreIF, which reflects the journal high social concern. In addition, if a small part of the literature of a journal obtained a large number of users or comments, it could also lead the journal to obtain a high value of ReaderIF, PostIF or ScoreIF. This kind of star literature can also bring certain social influence to the journal, thus increasing the number of followers in the social media environment. Therefore, either the most of paper received extensive attention in social media or only a part of paper gained attention will make the publishing journals gain a higer Altmetrics impact factor, reflecting the high impact of journal on social media network. It is theoretically feasible and effective to use ReaderIF, PostIF, and ScoreIF as the Altmetrics evaluation index for journal. That is done in the following analysis using empirical analysis to verify this.

First of all, the literature collection published in 2012 and 2013 were gained form Scopus database for every journal. The use of Scopus database based on the following two reasons: (1) articles in Scopus database can be traced back to 1823 from the perspective of literature collection time. The Scopus database has a large coverage of papers from the Asia Pacific region at the perspective of regional literature coverage. (2) DOI of paper is available in Scopus database compared WOS database, so it's really convenient to collect Altmetrics data by using article DOI. Journal ISSN was used to collect journal paper in Scopus database. There were 87 journals in JCR, however, there were a few of journals with incomplete data, such as incomplete annual literature or missing data in citation/Altmetrics. There were 80 journals in the study sample when the journals with deficit data were removed. The study chose the reader counts from Mendeley, literature review number from Twitter and the score number from Altmetrics.com as the representation of Altmetrics data. These three Altmetrics indices represent user numbers, influence and attention degree of article uploaded
to online reference manager, social media and Altmetrics website. The following methods were applied for collecting every specific Altmetrics data. It is convenient to apply the Webometrics Analyst 2.0 developed by the webometrics study group coming from Wolverhampton University to gain the reader counts of Mendeley (Thelwall, 2009). The Mendeley application program interface (API) was embeded in Webometrics Analyst 2.0 and Mendeley reader counts for every article can be retrieved by title, authors, DOI and something else that can identify the specific article in this data collection tool. The article score and Twitter comments was obtained by calling rAltmetrics function package in R language via article DOI. At this stage, the data obtained all belongs to paper level. The process of merging paper data to journal level need to finish. There were 12 journals without Mendeley reader counts because of no DOI in the journal articles. If there were no DOI in the article, the rAltmetrics package couldn’t be applied to collect Score data and comment data. So those journal without DOI were removed from the research. There were also another 12 journals without return results by using rAltmetrics to obtain article score and Twitter comment. This study eliminated the 12 journals in the stage of data analysis in order to ensure accuracy of analysis results. Finally, a total of 56 journals were selected as study object.

Results and Discussion

Data distribution analysis of citation and Altmetrics

Indicators (including JIF, ReaderIF, PostIF and ScoreIF) were arranged in descending order according to their numeric value and then the comparison graphs (Figure 1, 2, 3) of Journal Impact Factor and Altmetrics were shown in order to explore the distribution characteristics between citation indices and Altmetrics indices.

From the whole point of view, the three Altmetrics factors in Figure 1, 2, 3 are above JIF. The trend of descending graph in the three pictures all indicate the long tail trend. The number of journal belonged to high value division is less but a lot of journals are divided into the low value division. The indicators of the high value journal are much higher than the corresponding indices value of journals belonged to the low value region. There is no obvious difference in the evaluation indices of journals belonged low value impact factors. The Matthew effect of concentration and dispersion is more obvious on the open access platform. The high Altmetrics impact factor is much larger than the low Altmetrics impact factor in the three Altmetrics indices. Although there is a high value distribution in Journal Impact Factor, but there is no huge difference between high JIF and low JIF.

It can be seen from the figure that three Altmetrics indices are significant higher than JIF, with a large difference in the descending trend of ReaderIF and JIF. The JIF of 56 journals is lower than 5, Fig.1 shows that 17 journals’ ReaderIF are higher than 5. It is found that the biggest ReaderIF is 20.038, while the biggest JIF is 4.775, indicating the diversity revealability of journals on academic environment and network environment. The primary data was checked in order to find out which journals get the biggest ReaderIF and the biggest JIF. The journal of GOVERNMENT INFORMATION QUARTERLY gets the biggest ReaderIF, with JIF value of 2.515, which focus on policy, information technology and government research as well as the usability problems of government information. The journal of JOURNAL OF INFORMATION TECHNOLOGY gets the biggest JIF, with ReaderIF value of 4.595, which focus on management science, information system and computer science. It is found that research field of journal, literature content besides journal quality will affect the attention and visibility of journal on academic system and non-academic environment via a comparative analysis.

The differences between ReaderIF and PostIF ,ScoreIF are shown in Fig.1, Fig.2, and Fig.3. Fig.1 indicates a relatively uniform distribution for ReaderIF in high value division and shows
a stable transition from the high value to low value. Although the high ScoreIF is distributed in Fig. 3, but there is a steep transition from high value to low. Only one journal belongs to high ScoreIF. That is "JOURNAL OF COMPUTER-MEDIATED COMMUNICATION", which focus on the field of Internet, communication and network technology, multimedia and wireless communication. These research field is popular in the field of Information Science and get generous attention on social media. It is also indicates that the journal also belongs to high distribution of JIF (3.541) in the study sample. Both JIF and ScoreIF reflect the better quality of the journal. Topics and scopes of the journal may have an effect on attention and influence of the literature on online open platform. Social media, online reference manager as well as other open access platform decrease the threshold of academic access, so that more people can follow with and discuss the hot topics. Digitization and internetization for journals expand the scope of academic information exchange further more bring high Altmetrics for journals.

Figure 1: Descending comparison of ReaderIF and JIF

Figure 2: Descending comparison of PostIF and JIF

Figure 3: Descending comparison and ScoreIF and JIF
Correlation analysis of citation indices and Altmetrics indices

The normal distribution test was conducted in this study before the correlation analysis. An exploratory analysis in SPSS tool was used and the normal report is shown in Table 1. 56 journals was imported to SPSS then Shaprio-Wilk test was conducted to validate the data distribution. Table 1 shows the P value is less than 0.05, so the original data doesn’t confirm to normal distribution. Then the Spearman rank correlation analysis was applied in the next step. The coefficient between citation indices and Altmetrics indices is calculated, and the coefficient matrix is shown in figure 4.

Figure 4: Coefficient matrix between Citation indices and Altmetrics indices
Previously, some scholars have studied the correlation between citation and Altmetrics data and the results show that the correlation between them is low (Mohammadi, & Thelwall, 2014). Similarly, Fig. 4 displays a positive correlation between JCR citation index and Altmetrics index at the journal level, but the coefficients were less than 0.4. The relationship between ReaderIF and Immediately index indicates the highest correlation meanwhile, the relationship between ReaderIF and Eigenfactor shows the lowest correlation. However, PostIF and ScoreIF have the highest correlation with Eigenfactor, at the same time those two Altmetrics indices all show the low correlation with JIF. Difference in correlation results of citation indicators and Altmetrics indices reflects that there is a diversity between Altmetrics data, since they were collected from different network platforms though they all belong to Altmetrics.

Correlation coefficient of ReaderIF and PostIF is 0.22 and the coefficient of 0.19 between ReaderIF and ScoreIF, reflecting weak correlation at the bottom right of Fig. 4. And the correlation relationship of 0.97 between PostIF and ScoreIF, showing strong correlation. Mendeley, Twitter and Altmetrics.com are important sources of Altmetrics data, but the correlation between the three showed big differences. Studies find that Altmetrics online research Score is mainly based on three parts: The number of social media, the influence of social media, and Tweeter (Wu, S.N & Zhao, R.Y. 2016). Twitter is a popular social network and micro blogging services website with a large number of users. Twitter is one of the keynote objects when Altmetrics.com collect the article level data and occupied a considerable proportion in the article score. Therefore, a significant correlation is shown between ScoreIF and PostIF. But the Mendeley reader counts is not counted in the paper Score. In addition, as an online academic management platform, there are great differences in the aspect of functional positioning, platform property, the audience and application nature between Mendeley and social media represented by Twitter. These are the reasons for the low correlation between ReaderIF and PostIF or ScoreIF respectively. The low correlation between ReaderIF and the other two indicators suggests that Mendeley, Altmetrics.com and Twitter are social medias and they are all important data sources in Altmetrics research. However, there are diversities between different social media platforms, wrong results may happen if only one kind of Altmetrics data was used in evaluation of scientific researches. Only by taking the multi-source Altmetrics data together to evaluate the academic achievements such as papers and journals can we get more objective social media influence.

Journal impact factor, immediate index and Eigenfactor are commonly used indexes in journal evaluation, but it is shown that the coefficient of 0.61 and 0.51 between immediately index and JIF, Eigenfactor respectively in the top left hand corner of Fig. 4, reflecting moderate correlations. The coefficient of JIF and Eigenfactor is 0.88, which reflects significant correlation. Though, the three citation indices are calculated from the perspective of reference relationship between papers, there are different mechanisms between JIF, immediately index and Eigenfactor. The immediately index is calculated using the current citation data in the year of publication. However, other two citation indices is calculated using the data of journal published after two years. There is a time effect on the index based on citation relationship. Therefore, the six indicators were all introduced into the evaluation matrix in the next analysis, and the comprehensive citation index and Altmetrics index are used to evaluate the journals.

Construction journal evaluation model by using citation data and Altmetrics data

Firstly, the star graph included the three citation indices and Altmetrics indices was drawn to show the relative size of each indicator before building the model of journal evaluation. The Eigenfactor is thousand times smaller than other indicators, so the Eigenfactor can't be showed in the star graph. In order to display all the indicators in the graph, the original data was translated with the nonlinear normalization. The method of transformation is as follows (Cai, Wang, & Liu, 2015):
Data nondimensionalize processing:

\[ r_{ij} = \frac{x_{ij} - \min x_{ij}}{\max x_{ij} - \min x_{ij}} \]  (1)

Data nonlinear processing:  \[ R_{ij} = \frac{\pi}{2} \arctan(r_{ij} + 1) \]  (2)

The stars function in R was used to construct the star graph after the nonlinear processing. Here, four journals in Q1 to Q4 journal division in JCR were respectively selected as the sample representation in each journal division to display their star graphs, because it will so miscellaneous if all journal star graphs were drawn.

![Figure 5: Visualization of journal star](image)

There are six indicators in this study, the proportion of each indicator is 60 degree angle. Length of the sector indicates the relative size of each indicator. Advantage and disadvantage of every indicator are reflected by the sector area. Fig.5 reveals that the representative journal of Q1 has the largest fan-shaped area on JIF, indicating that the journal has an advantage in JIF. Similarly, the representation of Q2 shows a big occupation in the area of JIF and Reader, reflecting a good performance in these two indicators. The sample of Q3 has advantage in ReaderIF indicator compared with other indices, however, the sample of Q4 has a balance performance on each indicator.

The star graph for every journal could be displayed with the method shown in figure 5. The comprehensive performance of the six indicators can be obtained from the star graph and the overall evaluation score also can be calculated by adding up six sector areas of the star graph. Finally, the overall score is applied to assess the journals. The formula for calculating the star graph area is:

\[ S_i = \frac{1}{2} \sin 60 \left( R_{i1} R_{i2} + R_{i2} R_{i3} + \cdots + R_{i6} R_{i1} \right) \]  (3)
$R_{ij}$ represents the data nonlinear processed. The formula above was used to obtain the star area of journals. Area size was used to measure the comprehensive level for every journal from two dimensions of citation and Altmetrics. Finally, the study made the Spearman correlation analysis between the journal ranking in JCR and the ranking in this study and a high positive correlation between the two sorted results is shown in Table 2.

The journal evaluation mode in this paper not only consider the journal academic factor but also inspect the non-academic indicators of influence on social media and reader counts compared with JCR journal evaluation system. Traditional journal evaluation system doesn't contain non reference data, such as reader counts, comment number, collection data and so on, however the comprehensive journal evaluation model in this study could avoid the defectiveness that non-citation data was not included in the evaluation system. On the other hand the citation indices no longer come first in the integrated evaluation model combined with citation data and Altmetrics, because citation and non-citation data act together on the final assessment outcome. This comprehensive evaluation model, which combines academic influence factors and non-academic influence factors, can produce more objective and fair evaluation results for journals.

### Conclusion
This study analyzed the data distribution, difference and relationship between citation and Altmetrics as well as the method of applying those two dimension data to evaluate journals by using the research object of journals in Information Science & Library Science. The research reveal that both citation and Altmetrics don't confirm to normal distribution and show the long tail distribution trend. A small number of journals belong to high value division, a lot of journals are divided into the low value journal division. The three Altmetrics indicators of ReaderIF, PostIF and ScoreIF are significant higher than citation indices. At the aspect of correlation analysis, there is higher correlation with ReaderIF and immediately index, while a higher correlation is revealed between between PostIF, ScoreIF and Eigenfactor. Though the reader counts, comment numbers and article score are all Altmetrics data, but there is a big difference in the aspects of data source, platform attribute, function orientation and target audience. So many dissimilarities result in the different visibility and attention on open access platforms. In addition, the factors of academic quality, subject field and research topic also work on the attention degree of journals in network environment. There is a significant correlation between journal ranking in JCR and the ranking calculated by star area, indicating the validation of using star area to measure journals combined with citation and Altmetrics. The journal evaluation model incorporated citation data and Altmetrics could conduct the assessment from academic
perspective and non-academic perspective in order to get a relatively comprehensive and thorough outcome compared the traditional journal assessment system. This study is an exploratory analysis of using citation data and Altmetrics data via star area to evaluate journal comprehensively. There are some deficiencies in the study: Firstly, there are only Mendeley reader counts, comment numbers and article score three parts of Altmetrics as well as parts of citation data in this study, so the comprehensive performance of journals in social network and academic system can’t be fully assessed. On the other hand, only one subject of Information Science & Library Science is selected as the study object. It is also a deficiency of no analysis to journals in the other subjects.

Abstract
Existing researches have proved that both academic reviews and library holdings can be alternative sources to assess impacts of academic books. This paper endeavors to identify correlations between the two sources, which may be useful for book ordering of libraries. Specifically, 69,263 academic reviews in Choice (Choice: Current Reviews for Academic Libraries) are collected with four metrics: recommendation levels, readership levels, numbers of interdisciplinary subjects and review contents. Then, a topic model is used to extract topics from review contents. Meanwhile, library holdings of each book are identified, including the total number of library holdings, holding regions and holding distributions based on an entropy method. Finally, correlation analysis between Choice reviews and library holdings are conducted. Experimental results reveal that books with higher recommendation levels or extensive readerships tend to be ordered more by academic libraries. Meanwhile, books with extensive readerships will be collected more uniformly by academic libraries. In conclusion, metrics derived from Choice academic book reviews can be used as indicators to recommend book ordering of academic libraries.

Keywords: book impact assessment; topic extraction; review mining; altmetric; library holdings

Introduction

Traditional book impact assessments are based on citations, such as Krampen, Becker, Wahner, and Montada (2007), Barilan (2010) etc. With the rapid development of Web 2.0, more alternative metrics are used to assess qualities of books. Donovan and Butler (2007) proved that publisher prestige can be proposed as an alternative method for the impact assessment of books. According to Torres-Salinas and Moed (2009) and Zuccala, Verleysen, Cornacchia, and Engels (2014), library holdings can give useful information for evaluating qualities of books. Shema, Bar-Ilan, and Thelwall (2014) used blog citations to measure impacts of books. In a bid to obtain more comprehensive assessment results, researchers endeavored to mine content information about books, such as Kousha and Thelwall (2016), and Zhou, Zhang, Zhao, and Chen (2016).

On the basis of Kousha and Thelwall (2015) and White et al. (2009), academic reviews and library holdings are useful sources for measuring book impacts. In this paper, we try to identify correlations between these two sources via a fine-grained analysis, which may be conducive for book ordering of libraries. Specifically, academic reviews in Choice (Choice: Current Reviews for Academic Libraries) are collected. Each review contains four metrics: recommendation level, readership level, number of interdisciplinary subject and review content. Then, we extract topics from review contents via a topic model. Meanwhile, we collect the global and regional library holding information of each book, and analyze their distributions using an entropy method. Finally, the correlation analysis between Choice reviews and library holdings shows that books with higher recommendation levels or extensive readerships will be ordered more by academic libraries. In addition, books with extensive readerships tend to be collected more uniformly by academic libraries, while books with higher recommendation levels or more topics in reviews may be non-uniformly distributed among different libraries. Hence, we conclude that metrics derived from Choice academic reviews can give suggestions to recommend book ordering to academic libraries.

Related works

This paper tries to identify correlations between two alternative metrics of book impact assessment: academic reviews and library holdings, and analyzes review contents with a topic model. Hence, in this section, we describe two categories of related works: academic book impact assessment and topic extraction.

Academic book impact assessments

Citation is a valuable measurement for evaluating impacts of academic books. Kousha, Thelwall, and Rezaie (2011) proved online citations from Google Books and Google Scholar can be sufficiently numerous to support peer review for research evaluation, according to significant correlations (about 0.7) among the three metrics: Google Books, Google Scholar and Scopus. Torressalinas, Robinsongarcia, and Lopezcozar (2012) analyzed different impact indicators referred to scientific books in Social Sciences and Humanities fields during 2006-2011 via Book Citation Index. Gorraiz,
Purnell, and Glänzel (2013) indicated that the BKCI was a first step toward creating a reliable and necessary citation data source for book impact assessments. Abrizah and Mike (2014) presented that Google Books and Google Scholar can be recommended for impact assessments of non-Western books, as 23% of 1357 books in Google Books, 37% in Google Scholar had a higher proportion cited if they were older or in English. Citation-based methods are becoming inadequate for Web 2.0, thus researchers are seeking more online information to assess book impacts. White et al. (2009) used libcitation count to assess book impact. CabezasClavijo et al. (2013) took library loans statistics as a measure of book impact. Shema et al. (2014) proved that blog citations can be used as an alternative metric for book impact assessments, according to statistically significant evidence (about 0.04 correlations between the blogged metrics and non-blogged metrics) for articles published in 2009 and 2010.

In order to assess impacts of academic books more comprehensively, content information are analyzed. Kousha and Thelwall (2016) proved that metrics derived from Amazon.com reviews of academic books could give evidence about their impacts, according to low but significant correlations (about 0.2) between amazon metrics and other metrics. Zhou et al. (2016) indicated that Amazon.cn reviews can be used to assess academic book impacts based on the significant correlations (about 0.4) between citations versus Amazon reviews.

From analysis above we can conclude that researchers are mining more interesting and comprehensive methods to obtain impacts of academic books.

**Topic extraction**

Topic modeling algorithm is a powerful and computational tool to help organize and summarize information at a scale that would be impossible by human (D. Blei, Carin, & Dunson, 2011). Classic topic modeling algorithms include latent semantic analysis/indexing (LSI) (Deerwester, 1990), probabilistic latent analysis/indexing (PLSI) (Hofmann, 1999), latent dirichlet allocation (LDA) (D. M. Blei, Ng, & Jordan, 2003) and hierarchcal dirichlet processing (HDP) (Wang, Paisley, & Blei, 2011). Advantages of each algorithm are unique. Specifically, LSI algorithm can depict the synonyms effectively, while PLSI algorithm is based on LSI algorithm and quite capable of distinguishing polysemy. Benefit from Bayesian Framework, LDA algorithm reduces over fitting significantly. Different from three algorithms above, HDP algorithm can identify topic numbers automatically.

As an effective tool, topic models are applied in many ways. Some researches focus on extracting topics in social media. Cataldi, Caro, and Schifanella (2010) proposed a topic detection technique to detect emerging topics on Twitter based on temporal and social terms evaluation, which permitted to retrieve in real-time the most emergent topics expressed by the community. Madani, Boussaid, and Zegour (2015) also focused on identifying topics expressed by users. Topic models can also be used to conduct users’ behavior survey. Roberts et al. (2014) used the structural topic model to make analyzing open-ended responses easier and more revealing. Huynh, Fritz, Mario, Schiele, and Bernt (2015) discovered activity patterns in a user's daily routine with topic models automatically.
In the present study, we aim to find correlations between academic reviews and library holdings. Differs from Kousha and Thelwall (2015), which used number-based metrics in Choice only, review contents are mined in this paper. Hence, we may get more details from Choice reviews. In contrast to existing content-level researches, which analyzed online book reviews with sentiment classification, we focus on extracting topics expressed by reviewers. It may be more suitable for analyzing contents with less sentiment expressions, such Choice academic reviews.

Research Questions
The following research questions are designed to assess whether metrics from *Choice* academic reviews are correlated to library holding statistics.
1. Are there correlations between Choice metrics, including recommendation levels, readership levels, numbers of interdisciplinary subjects and review contents?
2. Do Choice metrics correlate with library holding indicators, including library holding numbers, regions and distributions?

Method

*Choice academic reviews*
69,263 book review information from Choice Reviews Online were extracted from the *Humanities*, *Reference*, *Social & Behavioral Sciences*, and *Science & Technology* categories. Each review includes information about *title*, *author*, *year*, *review content*, *reviewer*, *recommendation level*, *readership level*, *interdisciplinary subjects* and *subject* (Table 1).

<table>
<thead>
<tr>
<th>Table 1. An example of Choice book reviews</th>

Readership Level

The readership levels assigned to Choice reviews were converted into a number, from 1 for ‘All Readership Levels’ to 8 for ‘Professionals/Practitioners’ (Table 3). As a book may have different readership levels, we make the lowest one as the final readership level, some examples are shown in Table 4.

Review contents

A topic model was used to analyze topics expressed in review contents. In this paper, we used Latent Dirichlet Allocation (LDA) (Hoffman, Blei, & Bach, 2010) to identify topics. As one review may express several topics, a threshold was used to filter topics with lower probabilities. We compared different topic numbers and thresholds, and
got optimal performances when the number was 20 and the threshold equaled 0.1. Table 6 represents samples of topics in Choice book reviews.

</tbody>
</table>

In order to analyze library holding distributions of books in different regions, an entropy method was used (Hongzhan, Lü Pan, & Yao, 2009), which can be computed by Eq. (1) - (2). If library holdings of a book are uniformly distributed, the entropy value of the book will be higher.
\[ e = -\frac{1}{\ln(N)} \sum_{j=1}^{N} p_j \ln(p_j) \]  

(1)

\[ p_j = \frac{v_j}{\sum_{j=1}^{N} v_j} \]  

(2)

Where, \( v_j \) is the holding numbers of the book in region \( j \), and \( N \) is the number of regions. Then, we obtained distribution information of books in Table 7 (see Table 8).

**Results**

**Correlations analysis between Choice metrics**

There are significant Spearman correlations among the three metrics, recommendation levels, readership levels and numbers of interdisciplinary subjects (Table 9). Specifically, recommendation levels have negative Spearman correlations (0.261) with readership levels. Hence, books with lower readership levels tended to be recommended more highly by book reviewers. Meanwhile, correlations between readership levels and interdisciplinary subjects are low but significant. Hereby, we can conclude that interdisciplinary books may be suitable for readers of higher levels.

**Figure 1. Distribution of topic numbers (n=69263).**

In order to mine more details about Choice academic reviews, we use topic models to identify topics expressed in the review contents via LDA. Then, we get numbers of
topic in each review. The descriptive statistics information about topic numbers is represented in Figure 1. The horizontal axis of Figure 1 represents topic numbers in reviews and the vertical axis represents the number of reviews. Figure 1 shows that the number of topics in individual review ranges from 1 to 5, and most reviews contain 3 topics.

Then, we analyzed correlations between topic numbers and Choice metrics (Table 10). It can be seen from Table 10 that, the number of topics correlates positively with recommendation levels but negatively with readership levels and numbers of interdisciplinary subjects. This suggests that books with more topic numbers in reviews may be recommended more highly by book reviewers. Meanwhile, reviews tend to express less topics when comment interdisciplinary books. In addition, if a book can be read by lower level readers, reviewers may express more topics in the reviews. In addition, we can see correlations in Table 10 are significant but low, which indicate that although there are correlations between topics and other three Choice metrics, they cannot replace topics. Therefore, we can conclude that it is necessary to mine review contents.

Table 10. Spearman correlations between topic numbers and other three Choice metrics (n=69263).

Correlations analysis between Choice metrics and library holding indicators

The descriptive statistics information about holding indicators is shown in Figure 2. The horizontal axis of Figure 2(left) represents holding numbers and the vertical axis represents the number of books. From Figure 2(left) we can conclude that most books have less than 500 holdings, only few books have more than 2000 holdings. Figure 2(right) represents holding regions of books. From Figure 2(right) we can see that most books have been collected by less than 20 regions, few books have been collected by more than 60 regions.

Figure 2. Descriptive statistics information about holding numbers and regions (n=61933).

Figure 3 shows descriptive statistics information about holding distributions. The horizontal axis of Figure 3 represents holding distributions of books (namely, entropy
values of books, 1 means books are uniformly distributed among all regions), and the vertical axis represents book numbers. From Figure 3 we can conclude that quite a few books are uniformly distributed, and most entropy values of books are lower than 0.5.

![Distributions](image)

**Figure 3.** Descriptive statistics information about holding distributions (n=61933)

<tr>
<td>Distributions</td>
<td>-0.120**</td>
<td>0.310**</td>
<td>0.031**</td>
<td>-0.028**</td>
</tr>
</tbody>
</table>

There are low but significant Spearman correlations between Choice metrics and library holding indicators (Table 11). Specifically, recommendation levels and have positive correlations with holding numbers (0.193), while readership levels have negative correlations with holding numbers (-0.199). It suggests that books with higher recommendation levels tend to be ordered more by academic libraries. Meanwhile, if the readership level of a book is lower, it will get more library holdings. In other word, books with extensive readerships will be collected more by academic libraries. In addition, we can see Choice review contents have no significant correlation with holding numbers. We identified correlations between the two metrics with Figure 4. The horizontal axis of Figure 4 represents topic numbers in book reviews and the vertical axis denotes holding numbers. We can find from Figure 4 that books with 3 topic numbers in reviews tend to have higher holding numbers.

Regarding holding regions, all three Choice metrics have positive Spearman correlations with holding regions, except topic numbers.

For holding distributions, all Choice metrics have significant correlations with holding distributions. Readership levels have positive correlations with holding distributions (0.310), while recommendation levels have negative correlations with holding distributions (-0.120). It can be conclude that books with extensive readerships tend to be collected more uniformly by academic libraries. Meanwhile, books with higher recommendation levels may be non-uniformly distributed.
Discussion

This paper analyzed correlations between academic reviews and library holding information. Compared with number-based analysis methods, our approach makes use of content information through the application of topic model. It is thus not simply an analysis of correlations between numerical metrics, but also an attempt to discover reviewers’ intentions and concerns. In addition, our method is not limited to the analysis of academic books, and can be applied to other forms of books, as well as to other academic entities, such as journals, articles, research papers, reports, and so on.

According to the correlation results among Choice metrics (Table 9 and Table 10), we can find the correlations are significant but low, which ranges from 0.009 to 0.261. Therefore, we can get some conclusions like books with lower readership levels tended to be recommended more highly by book reviewers, but more important is that all the four metrics are unique and irreplaceable, as they expressed opinions of reviewers from different aspects.

Regarding correlations between Choice metrics and holding indicators (Table 11), we also get low but significant correlations, which ranges from 0.014 to 0.310. Some suggestions can be provided for libraries, such as order more books with higher recommendation levels or lower readership levels. However, it is worth noting that libraries may take above correlations as references for ordering books, but in fact, ordering decisions of libraries are based on information from more sources, which may be more objective and comprehensive compared to Choice review based only, as the Choice reviews are from one single source and subjectively generated by reviewers. Hence, metrics derived from Choice reviews may give some information for book ordering, while they are not determinants.

Our study is subject to a few limitations. First, we analyzed the relations across all fields without considering disciplinary differences, which may ignore some detailed information. We collected Choice reviews of book from four disciplines, which often have different characteristics and may result to different correlations. Thus, disciplinary differences should be studied in the future. Secondly, academic reviews came from Choice only and thus may lack the diversity of reviews available from other sources. How best to collect and integrate academic reviews from different
sources is a challenging question for future research. Thirdly, the technologies of topic model extraction need to be improved. In this study, we used a classical algorithm to extract topics expressed by reviewers. However, the rapid development of technologies for natural language processing, some advanced topic model algorithms are presented. Hence, more algorithms will be tested in the future too.

**Conclusion**

This study is to our knowledge the first to analyze correlations between academic reviews and library holding information at content level. The analysis of 69,263 books found weak but often significant relationships, suggesting that Choice academic review could be a helpful reference for libraries to ordering books.

In answer to the first research question, reviewers may express more topics in the reviews when commenting books suitable for lower level readers or non-interdisciplinary books, and they often tend to recommend these books highly. In answer to the second research question, books with higher recommendation levels or extensive readerships will be ordered more by academic libraries. Meanwhile, interdisciplinary books or books with extensive readerships tend to be collected more uniformly by academic libraries, while books with higher recommendation levels or more topics in reviews may have non-uniform distributions in different libraries.

In conclusion, our method may give some suggestions to libraries on making ordering decisions, but more evidence is needed before they could be used as tools for peer judgments about individual books. The theoretical implication of our study is that future analysis of informetrics should incorporate content within the online information. In practice, our method leverages the online information and traditional library information of books, which helps libraries to make better decisions in terms of book ordering.

Abstract
In this paper, we collected the papers of virtualization research in the VIP database (CSCD source journals) from 1989 to 2016. Co-authorship network of China's virtual technology research was analyzed by analysis of basic measurement, community, small world effect and Scale-free phenomena by means of the social network analysis method. We found: 1. The Scale of Co-authorship network is little, the network is sparse and the component is more and the module is high, there is more cooperation within the community. 2. The co-authorship network expresses the characteristic of Small World effect, but scale-free property is not obvious, and we give the experimental results.

Conference Topic
Social network analysis

Introduction
Cooperation is ubiquitous in human society. It is an interactive process where people coordinate with each other in action for shared interests or their own benefits (Tan, 2000). In the era of big science, cooperation in scientific research is increasingly becoming an important factor influencing scientific production capacity, and cooperative research has become a universal phenomenon of modern scientific research (Huang, 2015). Through the research on the number of Co-author papers between China and other countries, Tianwei He found that the cooperative articles show exponential growth in the volume (He, 2009). Narin (1991) and Bárbara’s (2012) study found that co-author papers get more references than single author papers, and scientific research cooperation has become a common phenomenon and the underlying trends in modern scientific research.

Social network analysis, which originated from psychology, anthropology and sociology and other disciplines, is a kind of interdisciplinary research method (Knoke & Yang, 2015). In recent decades, social network is increasingly favored by the public and academia. In 1967, the "six degrees of separation" hypothesis was confirmed by the experiment of Stanley Milgrom (Watts, 1999). At the moment, social network analysis has been widely applied in a complex social system, such as mathematics, physics and all kinds of natural phenomena. With the emergence and development of UCient, Gephi, Pajek, VOSViewer, which are the social network visualization analysis tools, social network analysis method wins popularity among scholars. It is found that related research achievement about social network analysis increases rapidly by WoS retrieval. And SNA has developed into an institutionalized interdisciplinary research perspective (Knoke & Yang, 2015).

Scientific research paper is an important symbol to reflect the scientific research achievements of scientific research personnel and scientific research team. The research on author attribute in scientific research paper is the effective way to learn constitutions of
scientific research personnel, development trends and research frontier in different industries. Scientific research cooperation network was created by the scientific research cooperation, so co-author is a reflection of scientific research cooperation network. Scientific research co-author network as one of the most important social network has been widely used in determining the structure of scientific cooperation and status of individual researchers. Sarıgöl E who once used social network analysis method to study the co-author phenomenon in computer sector has found that author’s status has closely related to the success in terms of reference in the future in the scientific cooperation network (Sarıgöl, Pfitzner, Scholtes, Garas & Schweitzer, 2014); Sun Jianjun, Liu Chengbo and others analyzed scientific cooperation phenomenon on their focus field by using the method of SAN and revealed many valuable rules (Huang, 2015). The social relation of co-author network is stronger than that of citation network. References are made when the author is unknown, and can be extended across time and space; however, co-author works once formed, its time and community relations have been fixed, so it is more suitable for social network analysis (Liu, Bollen, Nelson & Sompel, 2005).

With the development of cloud computing and big data technology, virtualization technology has emerged and developed quickly (Lin, 2014). The essence of virtualization technology is to separate software application from bottom hardware and turns physical resources into logical and manageable resources. Therefore, virtualization technology is one of the most core technologies of cloud computing and big data, gaining wide attention in the fields of cloud computing and big data. To reflect comprehensively the co-author network and research status in the field of virtualization technology in China, this paper aims to measure the structure, characteristics and changes of virtualization technology research co-author paper network by using social network analysis method, providing a reference for further research of virtualization technology in China.

**Methods**

The data samples of this study is derived from VIP Database, with keywords "virtualization" as the theme for retrieval, retrieval time slot from 1989 to 2016. In order to focus on the virtualization research in the fields of cloud computing technology, the scope of journal was limited to “the CSCD source journal “, and data retrieval time slot is on January 20, 2017. After data filtering and deduplication, a total of 709 research papers were received.

Research hypothesis: We assume that the names of the authors of the paper are different in fields of virtualization technology research, and it is not to differentiate the weight according to the signature sequence of the authors. That is to say, the weight of every author in one article is the same.

Network construction: node of co-author network represents the author; the line in the network represents the cooperation relationship among the authors; If there is cooperative relations between the two, then add a line between two people; If there is no cooperative
relationship between the two, then add no line between two people; Line value represents the co-author times or intensity between the authors, as shown in figure 1.

In this paper, we use Gephi and R for data analysis and visual display. Gephi is an open source free cross-platform complex network analysis software on the basis of JVM, which can do exploratory data analysis, link analysis, social network analysis and biological network analysis in a variety of networks and complex system. R is a kind of free software environment for statistical computing and graphics, and is now one of the most popular platforms for data analysis and visualization. Internet has lots of free open source R package that be competent for any complex data analysis. Original data is preprocessed by Python self-compiling program in this article. First, we extracted the author of each article; Then extracted the node and edge and assigned weight to the edge in accordance with times of cooperation, forming undirected weighted co-author network; Finally, it can become recognizable data files to Gephi and R for further analysis and processing.

Results, part I: Cooperation Network

Co-author network structure and co-author number distribution

China’s co-author network of virtualization technology research is shown in figure 2, and nodes of identical color represent the same community; line color means the earliest time that relationship was established. The distribution of the number of co-authored papers is shown in figure 3, which includes 57 single author papers, 652 co-authored papers. Coauthor rate is \((1-57) / 709 = 91.96\%\); Papers that have co-author of 2-4 accounts for the most part of the total number of papers; There are the largest number of 10 cooperators who are in a co-author paper.

Analysis of the static characteristics of virtualization technology research co-author network will help us to know cooperative situation of related subject in this field; Although figure 1
clearly presented the whole situation of the cooperation with authors in virtualization technology in China, it is difficult to clearly identify the dynamic evolution process of cooperation network. In addition, network characteristics cannot be analyzed by figure 1 in different periods to reveal its law of development. Foreign scholars such as A.L Barabási, Tomassini M, domestic scholars such as Wen Wanting, Li Chengqing, they discuss the dynamic evolution and the law of development of cooperative network on the basis of the static network analysis, and they think that the essence of the analysis is to regard the dynamic evolution network as a general social network by measuring and analyzing the static characteristics and the topology structure of the network in different periods, so as to explore the change law and characteristics of network structure (Feng & Zhao, 2014).

Table 1 shows that there are little correlative papers of virtualization technology that published in CSCD source journal before 2008. In 1998, the first paper of this subject area was published by Zhu Zhigang, Xu Guangci, Shi Dingji of Tsinghua University. And the research topic is virtual reality, then related research papers is on the increase year by year, which are in a downward trend in recent years. The structure and characteristics of virtualization technology research co-author network can be reflected by the main indexes of the network. China’s whole situation of virtualization technology research co-work network and all the main indexes data of co-author network in 1998-2016 are shown in table 1.

As is known to table 1 and figure 2, the co-author network is not fully connected. The density is 0.002, node tie is sparse and overall relationship is loose. There are 1780 authors involved in scientific creation of virtualization technology area. Although some groups are closely related in the network, there are fewer opportunities for the author groups to cooperate. This may be associated with the wide aspects and fields of virtualization technology research, such as network virtualization, storage virtualization, virtual machine and virtual reality, etc.

</table>
Basic indexes include the number of papers, network scale (N), the number of network edges (E), network density and average degree. The number of nodes and edges of virtualization technology research in China is on the rise after 2002 and is on the downward trend after 2012. 2011~2012 is the peak period of cloud computing research in China. After that, the market pays less attention on virtualization and relevant technology has stepped into maturity, the focus of research is beginning to shift. Compared with network density, average degree is not restricted by the scale of network and has an advantage in terms of coherence measure, so the average degree is often used for comparison among networks with different node number (Nooy, Mrvar & Batagelj, 2012). From 1998 to 2002, our average degree of virtualization technology co-author network is about 1. From 2002 to 2009, the average degree is at around 2.5; the average degree from 2010 to 2016 is at around 3.1. It is can be seen that virtual technology research co-work network did not fluctuate much between 1998 and 2016.

Network centrality index is composed of diameter, average path length and average clustering coefficient. Diameter refers to the maximum geodesic distance in all node pairs (the shortest path between two nodes). In scientific cooperation network, network diameter represents the maximum distance that can reflect the relationship establishment between researchers. Average path length (L) refers to average value among all node pairs, namely $L = \frac{2}{N(N-1)} \sum_{i \neq j} d(i,j)$, $d(i,j)$ represents the shortest path between nodes, which can characterize the transmission performance and efficiency of the network. Average clustering coefficient(C) represents average probability that two nodes connecting to the same node are interconnected, calculation formula is $C = \frac{1}{N} \sum_{i=1}^{N} \frac{2E_i}{k_i(k_i-1)}$. Average clustering coefficient depicts the transitivity of the network, which describes the concentration of researchers and reflects the tightness of co-author relationship. From table 1, the network diameter is less than or equal to 3, and average path length are smaller than 2.1 between 1998 and 2016, which shows that there is a close relationship between researchers in the subject field, and information and knowledge can be flown and transfer effectively in the group; Average clustering coefficient is very high and there is no large fluctuation on the whole. In other words, it has very compact and relatively stable co-author groups and there is smooth flow of knowledge in groups.

Connectivity index is composed of component number, the node number proportion in constituent element, the node number in the largest component and isolated point number. Modularity can evaluate the quality of component, and there is a close link between components of high modularity in vertex of the same group, but there is only sparse connection of vertex in different groups. The distribution of component node number in virtualization technology research co-author network in China is shown in figure 4, and about 90% of the component node number is less than 10, the former three component node number is 71, 57, 54 respectively; From the observation of "node number of the largest component" from connectivity index, the biggest component of co-author network in each year has only 12 members. We can infer that small component each year can gradually merge into a larger component as the variation with time, and it represents that the scope and depth of scientific cooperation continue to expand. Although there is a lot of co-author network component and high modularity, the bigger community scale is relatively small. Small research teams in the field of virtualization technology are ubiquitous in the virtualization technology research field;
there is a close relationship in internal cooperation of small groups. However, there is loose relation of each group, and this is the view of virtualization technology having many aspects to study.

![Figure 4 the distribution of component node number](image)

**Results, part II: community**

"Birds of a feather flock together", community structure is a basic feature of each kinds of network in real life. Its basic performance is that there is dense edge between node and node within the communities and sparse between the communities. In scientific cooperation network, there is more cooperation among scientific research personnel within the communities and less cross-community cooperation. The topology structure and the overall function of the network is the result from joint effects in each community, which detects community structure in virtualization technology research fields and helps to identify team belonging of scientific research personnel and understand the topology structure and overall function in the field of cooperation network (Liu, 2013).

Community discovery as one of the classic problems of network science, aroused extensive attention of researchers for a long time, and have produced many excellent algorithms, such as KL method based on the separation and algorithm based on modularity, etc. In 2008, Vincent D Blondel puts forward the algorithm of ‘Fast unfolding’ to optimize Modularity value (Meo, Ferrara, Fiumara, Provetti, Flickr & Zhang, et al. 2008), which adopted by Gephi and can be used to detect communities. Gephi was used to generate topological graph of three major communities in virtualization technology research co-author network in China, and there are a total of 182 members in this three communities, accounting for 10.22% of the members on a whole as is shown in figure 5.

![Community 1](image) ![Community 2](image) ![Community 3](image)

**Figure 5 Topological graphs of 3 main communities**

There are 71 nodes and 204 edges in community 1, and the research involved in cloud computing, virtual machine, network virtualization, programmable network. Its members are mainly composed of National University of Defense and Technology (shown in part A),
Chinese Academy of Sciences (shown in part B), Zhejiang University (shown in part C) and Beijing University of Posts and Telecommunications (shown in part D). Wu heng is in the position of cut-vertex, connecting these two subnets of National University of Defense and Technology and Chinese Academy of Sciences. If the node is "lost", community 1 will no longer be connected. Wu heng is a postgraduate of National University of Defense and Technology, who come into the Institute of Computing Technology of the Chinese Academy of Sciences for further study after graduation. Student mobility builds a bridge for communication between the two institutions. Also at the location of cut-vertex is zhang Jianhua and Liu Yunjie. Zhang jianhua connects Zhejiang University to Chinese Academy of Sciences, and Liu Yunjie connects Chinese Academy of Sciences to Beijing University of Posts and Telecommunications. Community 1 consists of the relationship of cooperation between teachers and students, colleagues, researchers in similar area, which has strong cooperative relations of interconnectedness, is conducive to the spread of new knowledge.

Community 2 contains 57 nodes, 136 edges, and studies storage virtualization technology covering cloud computing, such as distributed storage, storage security, disaster recovery, load balancing and optimization algorithm, etc. Members are mainly composed of two subgroups of Huazhong University of Science and Technology (shown in part A) and National University of Defense and Technology (shown in part B). The cooperation between Xiao Nong and Wu Song connected National University of Defense and Technology and Huazhong University of Science and Technology. Jin Hai (the Yangtze river scholar distinguished professor of Huazhong University of Science and Technology, winners for outstanding young scholars), Wu Song (the director of parallel and distributed computing in computer institute, deputy director of service computing technology and system key laboratory of the ministry of education and the cluster and grid computing of key laboratory in Hubei province), Lu Yutong (Tianhe-2 supercomputer system chief designer) is the nodes of larger betweenness centrality, which occupies an important position and has great influence in network, and plays an important role in the expansion of the network in the future.

Community 3 contains 54 nodes, 250 edges, mainly focusing on memory virtualization, network virtualization, virtual network platform and cloud computing, etc. Members include three subgroups of Tsinghua university (shown in part A), The PLA Information Engineering University (shown in part B) and Chinese Academy of Sciences (shown in part C). Li Yongtong belongs to Chinese Academy of Sciences and Tsinghua University, connecting the two subgroups of B and C.

Results, part III: Centrality

"Centrality" index is often used by social network analysis measuring the core role and influence of actors in the network to find out some important or prominent person. In order to evaluate the status and influence of network nodes more scientific and pluralistic, centrality index has been expanded from three indexes of degree centrality (DC), closeness centrality and betweenness centrality (BC) to multiple indexes, such as increasing the indexes of eigenvector centrality (EC), PageRank (PR), AuthorRank (AR), etc.

Based on the idea of "the actor has direct connection with other actors, then the actor is in a central position", degree centrality uses the degree to measure. In scientific cooperation network, higher degree centrality of an author shows that there are more other authors having cooperation with him in publishing articles. However, it does not directly evaluate the importance of the author. As shown in figure 1, the author V3 published an article but degree is three, the author V5 co-authored two articles but degree is 1, so it is difficult to evaluate that the V3 is more important than the V5. Closeness centrality tries to measure the ability that other actors do not control an actor and calculate the distance between a node to another node. In paper cooperation network, if the closeness centrality is relative small, it means that
the author has close cooperative relationship with other authors and the information communication is unobstructed; Otherwise, there is only less cooperation and poor information communication. In a non-connected network, the distance between a node and other nodes may be unpredictable, so the index is only applied to fully connected network. Betweenness centrality measures the control degree of resources for actors. It is generally believed that more times of nodes appear in the geodesic distance of various node pairs, the higher the betweenness centrality, and its control for information exchange and resource flow is more and more important. Betweenness centrality is also applied in the unconnected network, because of many nodes in the network does not serve as a "bridge" role, and thus generates a large number of nodes with zero centrality.

In 1972, Bonacich puts forward that the eigenvector of adjacency matrix maximum eigenvalue can be a good measurement of network centrality degree (Bonacich, 2007). Eigenvector centrality value of a node is determined by the value of adjacent vertices, it not only considers the centrality of adjacent nodes, but also considers the position of the nodes in the network. Eigenvector centrality can distinguish the importance of node in the network of high-degree node and many low-degree nodes or many high-degree nodes and low-degree node, but it can distinguish the difference of nodes clearly in even distributed degree of network. PageRank is Google's core ranking mechanism, if a page has many backward chainings or is linked by the page that has many backward chainings, the page will have a high grade. In virtualization technology co-author network, when the degree of node is higher or the node adjacent to "high quality" node, PR value of the node is also higher. In the undirected co-author network, PageRank calculates the value of nodes by converting undirected edge to directed symmetric edge building binary directed network. However, in the process of converting to binary directed network will lead to the loss of edge weight. Liu X and others propose AuthorRank of using weighted sorting algorithm to solve this problem on the basis of PageRank. The theoretical hypothesis is that the connection weight represents the strength of cooperation between two authors, when edge weight is bigger and the relationship of edges is more important (Liu, 2005). Existing network analysis program is not integrated the sorting algorithm. In this paper, we use Python to realize the algorithm.

From the degree centrality, we can see that Li Yong, Jin Hai and Wu Song are more involved in the publication of papers, namely, the papers that have published having many cooperator. As is known in betweenness centrality, Zhang Jianhua, Wu Heng and Li Yong are in different scientific research group, playing an important role in the network. They are the only bridge connecting those scientific research groups. Although Zhang Jianhua and Wu Heng have little articles, this cannot prevent them from control of the flow of information. If there are no nodes, we will have a sparser network. Li Yong, Zeng Lieguang and Jin Depeng who publish the articles most, have higher eigenvector centrality. It is similar to the ranking results of PR and AR, but is clearly different from the top three centrality ranking result. The top four of AR ranking is Jin Hai, Gou Yudong, Wu Song and Shu jiwu (Tsinghua University) respectively. They have great influence in virtualization technology field, which can cultivate more creative team and lead the development of virtualization technology. In closing we think the ranking results of PR and AR are more accurate combined with the effect of the author. It is shown in table 2.

</table>

From the degree centrality, we can see that Li Yong, Jin Hai and Wu Song are more involved in the publication of papers, namely, the papers that have published having many cooperator. As is known in betweenness centrality, Zhang Jianhua, Wu Heng and Li Yong are in different scientific research group, playing an important role in the network. They are the only bridge connecting those scientific research groups. Although Zhang Jianhua and Wu Heng have little articles, this cannot prevent them from control of the flow of information. If there are no nodes, we will have a sparser network. Li Yong, Zeng Lieguang and Jin Depeng who publish the articles most, have higher eigenvector centrality. It is similar to the ranking results of PR and AR, but is clearly different from the top three centrality ranking result. The top four of AR ranking is Jin Hai, Gou Yudong, Wu Song and Shu jiwu (Tsinghua University) respectively. They have great influence in virtualization technology field, which can cultivate more creative team and lead the development of virtualization technology. In closing we think the ranking results of PR and AR are more accurate combined with the effect of the author. It is shown in table 2.

Results, part IV: Small-world effect

Small-world phenomenon is the basic phenomenon of social network, whether from natural system to social system, it can be described by social network model with complex structure and architectural feature of the coexistence of order and randomness (Liu, 2015). It is not easy to establish a mathematical model that can accurately describe the cooperation problem in the society of dynamic change. Watts and Strogatz (1998) proposed the "small world" network model to dynamically reflect the rules and characteristics of network change. Watts points out that the overall changes of network may originated from changes in the local network. For example, in the scientific research cooperation network, deleting a line but adding randomly a line at the same time can significantly change the average path length and clustering coefficient of network.

Small-world network has the feature expanding from near regular networks to completely random networks (Zhichao & Zhu, 2016), whose feature is more in line with the real model of knowledge diffusion. In a scientific cooperation network with a small-world effect, knowledge is easier to spread. The greater access of the individual to gain knowledge diffusion in the same period of evolution, the higher the average level of knowledge in the entire network (Zhichao, et al., 2016). At the same time, it can avoid the possibilities when some researchers have made progress in some scientific research field while other entrants have to start from scratch (Lai, 2012). In addition, there are more potential opportunities for cooperation in small-world network. Researchers get in touch with other researchers and establish the relationship with them, the stronger the small world effect, and the greater the probability of nodes knowing each other (Yang, 2015).

Relative short network diameter and relative large clustering coefficient are two important characteristics of small-world network. Uzzi and Spiro put forward the Q value to evaluate small-world effect (Uzzi, 2005), calculation formula is $Q = \frac{CC_{actual}}{CC_{random}} \frac{PL_{actual}}{PL_{random}}$, Where $CC_{actual}$ is the clustering coefficient for observation network and random network, $APL_{actual}$ is average path length for observation network, and $PL_{random}$ is average path length of the random network. If Q is much higher than 1, it indicates that observation network has the features of small world. Humphries (2008) and Liu (2015) have made similar conclusions through research.

According to calculation formula of Uzzi, this paper used IGraph package of R platform. We carried out 1000 simulations that take 1780 nodes, 4 adjacent point number (average degree is...
3.934), 2 probability of rewiring as parameter. Then, we calculate the average clustering coefficient and average path length distribution of random network through the results of simulation and use the Q value to evaluate the small-world effect of virtualization technology research co-author network. As is shown in figure 6 and figure 7, we know that the scope of Q value is [5.362, 6.435], far higher than 1. Thus, we can conclude that virtualization technology research co-author network of china has small-world effect, and the small-world effect is more prominent.

Results, part V: scale-free phenomenon analysis

Social network often has a small number of vertices that have a very higher degree, the rest are vertices of low degree, and this phenomenon is commonly known as the "Matthew effect". Scientific research cooperation in agency team and teacher-student team is a common way of scientific research cooperation. In addition, general researchers tend to establish scientific research relationship with the researchers who have strong scientific research ability. In scientific research cooperation network, famous scholars, team leader or postgraduate tutor usually have a high degree and other person have a low degree. The network where its degree has no obvious characteristic length is called the scale-free network. The whole scale-free networks connectivity is dominated by a small number of core nodes that have heavily connected, once it is attacked and then collapsed will lead to paralysis of the entire network.
However, there is a little influence on the stability of the network when it randomly attacks other nodes in the network, so "robustness and vulnerability" is one of the main characteristics of scale-free networks. Whether virtualization technology research co-author network has scale-free properties worth researching and analysis.

Tail on the right side of scale-free network degree distribution follows power law: if a degree distribution in the network can be expressed with power law distribution function $p(k) = Ck^{-\alpha}$ ($C$ is the normalization constant, $\alpha$ is a power value, and $\alpha \in (2 \sim 3)$), then it can be considered that the network has scale-free properties (Nooy, et al. 2012).

Scholars commonly use the way of goodness of fit test to detect whether the data distribution has certain properties. Also, the way of goodness of fit test were used to study the degree distribution of virtualization technology research co-author network whether has power-law distribution property or other properties. There are many types of statistic of goodness-of-fit; KS statistic is relatively commonly used. Under the hypothesis of data is the result of the power-law distribution; Clauset recommended that adopting the bootstrap statistical method by sampling repeatedly to carry on the goodness of fit test (Clauset, Shalizi & Newman, 2009). The method by calculating artificial data $K_5^*$ statistic is greater than the KS statistic $p$ ratio of the distance between the cumulative distribution of the observed data and the fitting power law distribution model (Yang, 2014). If the $p$ value is relative high, the assumption that the distribution of data is the result of the power law is compatible, but it cannot be ruled out whether observation data remains subject to Poisson Distribution, log-normal distributed, exponential distribution and other distribution; When it needs to rule out other distribution possibilities, we can use the same method again. If the $p$ value is very small, the power-law distribution cannot reasonably fit the observation data, choosing another distribution may be more appropriate. Clauset thinks that it is appropriate to choose 0.1 as threshold value of $p$, namely, $p > 0.1$, which the hypothesis can be considered as valid and the converse is not true. In the case of observation data collection subject to multiple distributions, likelihood ratio test is also commonly used in test. It chooses a more representative observation data model by comparing two distributions of likelihood function or log-likelihood ratios. Vuong improved the calculation method of the likelihood ratio test and gave the $p$ value that can judge a model whether good or not (Vuong, 1989). Generally, it is more appropriate for $p$ to choose 0.1 as the value.

PoweRlaw package of R contains a number of functions and methods, which can fit the sample data whether is derived from the distribution of power law, lognormal, Poisson, exponential and have a test, as well as compare model and give the $p$ value that can evaluate whether the model is good or not (Gillespie, 2014). This article uses the poweRlaw package to research the degree distribution of virtualization technology co-author network. Figure 8 and figure 9 assumed that virtualization technology research co-author network degree distribution are power-law distribution, lognormal distribution, Poisson distribution, exponential distribution and have the process and result of goodness-of-fit test calculation; Test of $p$ values were 0.004, 0.473, 0.0005, 0.667. Therefore, there is little possibility that the network degree distribution follows power-law distribution and Poisson distribution, and lognormal distribution or exponential distribution fit well. Which distribution are more suitable needs to be determined by the likelihood ratio test. Figure 10 shows the calculating process and results of the likelihood ratio test. Through the results of single tail test, the lognormal curve can fit the distribution of degree of virtualization technology research co-author network.

Discussion and Conclusions
By analyzing the virtualization technology research co-author network in China, we found some valuable phenomenon, characteristics and law in the field of the technology research.

(1) The scale of virtualization technology research co-author network in China is small, with sparse overall connection, many components and high modularity, but small in larger community. There is more small research groups in virtualization technology research area and is closely linked in internal cooperation of the groups, but very loose relationship between groups, reflecting the diversity of virtualization technology research.

(2) Three members of co-author community in the fields of virtualization technology research in China are mainly from Chinese Academy of Sciences, National University of Defense and Technology, Huazhong University of Science and Technology, Tsinghua University and other institutions. In the information communication network of scientific research cooperation,
close cooperation between groups is the basis of an academic group closely focusing on a particular direction for centralized breakthrough. Usually, small groups are based on the mutual interest and complementary field of peer experts. These small groups are the bridge and the link of knowledge activities in different disciplines, regions and organizations, which plays a very important role in promoting knowledge diffusion, knowledge transfer and knowledge spillover. If we give full attention to these small groups in the scientific research management activities, it can make scientific research management more scientific, more targeted, and management effect will be more prominent (Yang, 2015).

(3) Scientific research cooperation is usually divided into five types: employers and employees cooperation, cooperation between teachers and students, cooperation between researchers in similar areas, cooperation between researchers in different areas and the cooperation of different gender (Xie, 2006). From the community analysis of virtualization technology research co-author network in China, you can see that the cooperation between teachers and students, cooperation between the researchers in similar areas and the cooperation between the researchers in different areas are the main types of cooperation.

(4) In China’s virtualization technology research co-author network, there are two kinds of important members: one is nodes of higher AR value, such as Jin Hai, Guo Yudong, Wu Song and Shu Jiwu, etc. These scholars with high influence are usually the leader in various research institutions or research field; another one is a bridge among the groups, such as Zhang Jianhua, Wu Heng, Li Yong, Wu Yuanquan, etc. They are the main channels to obtain external knowledge and resources in the same group, also the key channel of knowledge diffusion and transfer in different groups. In terms of scientific research management, we should pay attention to these academic leaders and scholars in the "cut-point" position.

(5) Virtualization technology research co-author network in China has stronger small-world effect, the researchers can efficiently communicate in cooperation with related researchers and can easily access to the new knowledge with other research groups. Knowledge is easier to spread in the network; average knowledge level of the entire network is high. At the same time, virtualization technology research area in our country contains more cooperative opportunities, As time goes by, originally loose network may be more coherent.

(6) Different from scale-free properties of co-author network that studied by the scholars of Huang Kaimu (2015), Zhang (2012) and Meng (2009), the paper found that virtualization technology research co-author network degree distribution is unable to fit power law curve but fit well with lognormal curve through simulation. Is the cause of the data itself or caused by the characteristics of the research area, it remains to be studied.

Abstract
There are many reasons for studying the community structure in citation network, whose underlying community structure may help us understand both the obvious and the more subtle interrelations between subfields, which are so important for understand the research structure and paradigm structure of a subject. However, most methods used for citation network community detection are based on topological structure or content separately. Usually such link-based methods ignore the content of citations, and the content-based methods lack the consideration of citation networks’ topological structure, which might be crucial for accurate and meaningful community detection. In this paper, we develop a weighted method to identify the community structure of citation network. The new weighted model incorporates both the topological links and content information in citation networks to find communities. A text similarity method is used for weighting the links in citation networks and then constructs a weighted citation network to carry out community detection analysis. Two case studies had been carried out in two fields of Scientometrics and Evolving Citation Networks. Results revealed that using weighted citation edges with VSM-based nodes similarity to detect communities can improve the modularity Q value, which might mean a better assignment result. Four nodes’ movement with the direction of better appropriate of community assignation in the 188 node citation network of the field Scientometrics had also indicates the advantage of our weighted method.

Conference Topic
Social network analysis.

Introduction
In this work, we develop a weighted method to identify the community structure of citation network. There are many a kind of reasons for studying the community structure in citation network, whose underlying community structure may help us understand both the obvious and the more subtle interrelations between subfields, as well as the growth and the ebb of subfields (Chen & Redner, 2010).

Communities are the clusters of closely connected nodes within a network, which is a property found in many networks, such as biological networks, the World Wide Web, social networks, collaboration works, citation networks, et al (Girvan & Newman, 2002). To identify communities within networks, a variety of methods have been developed. A recent new and powerful method to detect communities in complex networks is the study of Girvan and Newman (2002), who boomed the community research for their new algorithm using information about edge betweenness (Newman, 2001) to detect community peripheries, we call GN algorithm. However, the GN algorithm and some other algorithms are computationally demanding, which limits their application only to small networks. Therefore, Newman (2004a) proposed a new much faster algorithm, typically thousands of times faster than previous algorithms, we call FN algorithm. FN operates on different principles to GN but gives qualitatively similar results. FN algorithm is based on the idea of modularity, with the optimization of Q values over all possible divisions to find the best communities. Modularity measure Q is calculated to know when the communities found by the algorithm are good ones (Newman & Girvan, 2004). It has become a popular approach of optimizing a modularity function to community detection (Waltman & Van Eck, 2013). Compared to the earlier community detection methods, Q requires no extra knowledge beyond the network structure itself and can be applied to any type of network (Chen & Redner, 2010).
Nevertheless, the above algorithms proposed in the literature are suitable only for small and medium-sized networks. Therefore, some optimization algorithms were introduced to produce high-quality results even for very large networks, such as citation networks with tens of millions of nodes and hundreds of millions of edges. The first existing algorithms for large-scale modularity optimization is proposed by Blondel et al. (2008), often referred to as the Louvain algorithm. The other one is Louvain algorithm with multilevel refinement proposed by Rotta and Noack (2011), which is an extension of Louvain algorithm. Built on the ideas from these two existing algorithms, Waltman & Van Eck (2013) proposed a smart local moving (SLM) algorithm. All the three algorithms rely heavily on a well-known local moving heuristic (LMH), the idea of which is to repeatedly move individual nodes from one community to another in such a way that each node movement results in a modularity increase. We do not want to discuss the details of these algorithms for the purpose of this paper is not to reconstruct or modify them, but to make more meaningful citation networks and provide for the algorithms to detect communities. The theories and steps of the algorithm could be found in these papers: Girvan & Newman (2002), Newman (2004a), Newman & Girvan (2004), Waltman & Van Eck (2013).

Benefitted from the progress of community detection algorithms recent years especially as discussed above, lots of works focusing on the community structure of many kinds of networks had been carried out, which includes citation networks.

In the next section, we outline the principle of modularity measure \( Q \), the Louvain algorithm that we use to analyse community structure within citation network, and the related works about citation networks community detection.

Based on the below related works analysis, we found that although many methods had been used to disclose the community structure of citation networks, there were still very few works focused the difference of different citation links. Therefore, this study advanced the existing works by constructing a weighted citation network to carry out community detection analysis. To our knowledge, none of the existing studies has done such work as ever. The significance of this work is that using weighted citation edges with VSM-based nodes similarity to detect communities with an improvement value of modularity \( Q \), which might mean a better assignment result. Our weighted method breaks the barriers of traditional citation network analysis that regarding all edges as the same importance. We find that which avoids some of the shortcomings of the traditional techniques. It would be very valuable for many kinds of scientists, policy makers and stakeholders to deal with it.

Related works

In this section we review some representative existing methods for detecting communities and make a brief introduction to their advantages and disadvantages.

Modularity measure \( Q \)

Modularity \( Q \) is the fraction of edges that fall within communities, minus the expected value of the same quantity if edges fall at random without regard for the community structure. If a particular division gives no more within-community edges than would be expected by random chance we will get \( Q = 0 \). Values other than 0 indicate deviations from randomness, and in practice values greater than about 0.3 appear to indicate significant community structure (Newman, 2004a).

Newman & Girvan (2004) defined \( Q \) as follows,

\[
Q = \sum_i (f_{ii} - a_i^2)
\]

where \( f \) is a \( k \times k \) symmetric matrix whose element \( f_{ij} \) is the fraction of all edges in the network that link vertices in community \( i \) to vertices in community \( j \). So they further define the row (or
column) sums $a_i = \sum_j f_{ij}$, which represent the fraction of edges that connect to vertices in community $i$. In a network in which edges fall between vertices without regard for the communities they belong to, we would have $f_{ij} = a_ia_j$.

Newman (2004b) defined $Q$ in weighted networks (edges have weights, for example, based on the number of co-authored papers between two authors) as:

$$Q = \frac{1}{2m} \sum_{ij} [A_{ij} - \frac{K_iK_j}{2m}] \delta(c_i, c_j)$$

where $c_i$ denotes the community to which node $i$ has been assigned, $A_{ij}$ represents whether there is an edge between nodes $i$ and $j$ ($A_{ij} = 1$) or not ($A_{ij} = 0$) in un-weighted networks, or the weight of the edge between node $i$ and $j$ in weighted networks. $K_i$ is the degree of node $I$ in un-weighted networks or the sum of the weights of the edges linked to node $i$, the $\delta(c_i, c_j)$ indicates whether nodes $i$ and $j$ belong to the same community. It equals 1 if $c_i = c_j$ and 0 otherwise. And

$$m = \frac{1}{2} \sum_{ij} A_{ij}$$

is the total number of edges in the network.

There is also a third formula of $Q$ can be written as:

$$Q = \sum_{i=1}^{n} \left[ \frac{l_i}{L} - \frac{d_i}{2L} \right]^2$$

Here $n$ is the number of modules, $L$ is the number of links in the network, $l_v$ is the number of links between nodes in module $v$, and $d_v$ is the sum of the degrees of the nodes in module $v$.

**Louvain algorithm**

Louvain algorithm is proposed by Blondel et al. (2008), which finds high modularity partitions of large networks in short time and that unfolds a complete hierarchical community structure for the network, thereby giving access to different resolutions of community detection. This algorithm is based on the idea of the local moving heuristic is to repeatedly move individual nodes from one community to another in such a way that each node movement results in a modularity increase. It is divided in two phases that are repeated iteratively. Assume a network with $n$ nodes. First, we begin with each one node is a community. The algorithm then uses the local moving heuristic to obtain an improved community structure. Hence, in this initial partition individual nodes are moved from one community to another until no further increase in modularity can be achieved. At this point, a reduced network is constructed. Second, we build a new network whose nodes are the communities found during the first phase. The weights of the links between the new nodes are given by the sum of the weight of the links between nodes in the corresponding two communities. Once this second phase is completed, it is then possible to reapply the first phase of the algorithm to the resulting weighted network and to iterate until there are no more changes and a maximum of modularity is attained (Blondel et al., 2008).

**Communities in citation networks**

Citation network is originated from the reference relationships. There are many researches show that there is obvious trend of concentration and discrete in citation network, and publications in the same field seems like to cite semblable publications. Community in the citation network represent related papers on a single or some closely relevant topics. Community detection method is used for finding related papers in a given field. We could find the communities in citation networks and help researchers or policy makers to watch the whole pattern of a field at a glance. Subelj et al. (2016) presented a systematic comparison of the performance of a large number of citation networks clustering methods and found that
there is a trade-off between different properties that may be considered desirable for a good clustering of publications. At present, the methods used for citation network community detection could be divided into two classes. One is based on topological structure and another is based on content, such as text similarity.

Topological structure based methods usually use the community detection algorithms in the field of complex network to carry out empirical study in citation networks. For example, Wanjantuk et al. (2004) used the random walk graph clustering algorithm basing only on the link structure of a graph that can efficiently identify highly topically related communities to identify the communities within citation graph. Kajikawa et al. (2008) tracked the emerging research domains in energy research by using citation network analysis. They used FN algorithm to divide the largest connected component into some communities. Chen & Redner (2010) investigated the community structure of physics subfields in the citation network of all Physical Review publications between 1893 and August 2007. They focused only on well-cited publications that received more than 100 citations, and applied modularity maximization to uncover major communities that correspond to clearly identifiable subfields of physics. Ren et al. (2012) proposed a new clustering model for the high clustering in citation networks and got higher clustering coefficient and the size distribution of co-citation clusters in real networks. Wu et al. (2015) developed a local community detecting algorithm to find corresponding research group. Kusumastuti et al. (2016) identified the clusters and sub-clusters of citation networks using the CitNetExplorer software to visualize timeline-based citation patterns.

Content based methods usually use traditional clustering algorithms to classify citation networks when the virtual links basing similarity are used to replace the actual links. For instance, Aljaber et al. (2010) presented a new approach for clustering scientific documents basing on the utilization of citation contexts. Chen et al. (2013) proposed a community discovery algorithm of citation semantic link network to find the semantic community in citation semantic link network. Liu et al. (2015) proposed a citation similarity based community detection method by transforming citation network to paper similarity network to detect the communities in citation networks. Comparing the above two kinds of methods we could find that topological structure based methods usually lack the consideration of content-based text similarity, while the latter methods have also ignored the networks’ topological structure. Nevertheless, both the above two kinds of methods could not fulfil the need of citation network community analysis when used separately. Therefore, there are also some studies had paid attention to this question. For example, Cohn & Hofmann (2001) described a joint probabilistic model for modelling the contents and inter-connectivity of document collections such as sets of research paper archives. Erosheva et al. (2004) explored an internal soft-classification structure of articles based only on semantic decompositions of abstracts and bibliographies and compared it with the formal discipline classifications. Pathak et al. (2008) presented a Bayesian generative model for community extraction which incorporates both the link and content information in networks and its empirical study had been carried out on an email network. Although these papers did not analyse the citation network’s community, they indeed provided a powerful idea for community detection in citation networks. Indeed, most such studies incorporating both the topological link and content information had been studied in traditional complex networks, such as.

Therefore, this study advanced the existing works by incorporating both the topological links and content information in citation networks to find communities. A text similarity method is used for weighting the links in citation networks and then constructs a weighted citation network to carry out community detection analysis.
Data and methods

Data

This paper prepared two datasets to carry out case study. One is all types of 4417 publications published in the journal of *Scientometrics* in 1978–2016 (publication year) were downloaded and chosen as base data of case study construct citation network. Data was acquired from the Web of Science in March 13 2016. The citation network consists of 1483 publications published in *Scientometrics* between 1978 through January 2016 with at least one citation (the nodes) to the other articles among the 4417 publications. At the same time, publications have no any field of title, abstract and keywords had been removed from the network. Therefore, the 1483 nodes make up a network with 28 weakly connected components through 3072 arcs. Among which the largest connected component consists of 1420 nodes, which had been used to find communities according to different weighted methods or unweighted method.

The other is the 2046 publications (article, letter, proceedings paper and review) of Evolving Citation Networks published before 2014 in WOS. Search terms to retrieval papers are: TS=((citation* and (evolv* OR evolut* OR "knowledge flow" OR path OR trajector* OR backbone)) NOT "citation classic"). The citation network consists of 340 publications with at least one citation (the nodes) to the other articles and also has all fields of title, abstract and keywords among the 2046 publications. Therefore, the 340 nodes make up a network with 32 weakly connected components through 531 arcs. Among which the largest connected component consists of 246 nodes, which had been used to find communities according to different weighted methods or unweighted method.

Although both the citation networks have more than one connected component, most nodes locate in the largest connected component. In this paper, only the largest connected components are included. On the other hand, the directed arcs in citation networks are treated as undirected edges used for community detection in this paper. Science of Science (Sci²) Tool (http://cns.iu.indiana.edu) and Gephi were used to citation network construction and community detection.

Weighted method- VSM-based nodes similarity calculation

The Vector space model (VSM) is a mathematical model first presented by Salton, Wong and Yang (1975) and generally defined by Salton (1989) as an algebraic model for representing text documents as vectors of identifiers such as index terms. It is now popular used in information filtering, information retrieval, indexing and relevancy rankings.

In VSM documents are represented as mutually independent ordered term vectors, \((T_1, T_2, T_3, \ldots, T_n)\). Each term \(T_i\) has its own weight \(W_i\) according to the contribution to the documents. Thus document \(d_j\) is represented as vector \(d_j = (W_{1,j}, W_{2,j}, W_{3,j}, \ldots, W_{n,j})\). Each dimension corresponds to a separate term. The value of a term \(i\) in the vector is non-zero if it occurs in the document. Then we use the TF-IDF weighting method to computing the values of \(W_i\). However, the TF-IDF algorithm does not consider the position of a term in a document. There are some studies show that the importance of a term is different according to the position in the document, such as title, keywords and abstract. Therefore, three groups of position weight \(\gamma\) are added to \(W_i\) based on the following formula.

<table>
<thead>
<tr>
<th>(\gamma)</th>
<th>Group 1</th>
<th>Group 2</th>
<th>Group 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0</td>
<td>2.5</td>
<td>1.5</td>
<td>When term (i) lies in keywords</td>
</tr>
<tr>
<td>1.0</td>
<td>1.5</td>
<td>2.5</td>
<td>When term (i) lies in title</td>
</tr>
<tr>
<td>1.0</td>
<td>1.0</td>
<td>1.0</td>
<td>When term (i) lies in abstract</td>
</tr>
</tbody>
</table>

Thus, the weight of term \(i\) is calculated as follows.

\[ W_i = \text{TF}(i) \times \text{IDF}(i) \times \gamma(i) \]
In the case of a term appears in more than one position in a document, the highest value of $\gamma$ is accepted.

Finally, we use cosine similarity to calculate the similarity between a pair of vectors. It has to be noted that although citation links have directions, the original citation networks that we use are regarded as un-weighted and undirected and do not have loops. In our citation networks the cosine similarity between two linked documents is regarded as the weight of the link.

**Results and Analysis**

We have used both the two largest connected components of the two datasets to perform basic tests of the significance of the communities that are discussed in this work based on the three group of $\gamma$. First, we performed the same community detection analysis described above for the two set of the two largest connected components without weights. Second, VSM based weighted method had been accepted to reconstruct citation network at the three ways of $\gamma$. Results of community detection in the two datasets are listed in table 1.

</tbody>
</table>

**Notes:** Calculated by Gelphi, resolution (Lambiotte et al., 2009): 1.0, randomize: on. Communities detection method is based on Blondel, et al.(2008).

Table 1 shows the increasing values of modularity Q through weighted method for community detection in both case of Scientometrics and Evolving Citation Networks no matter which $\gamma$ was used. However, the result could not show which group of $\gamma$ is a better choice to improve the performance of community detection. For example, $\gamma$ group 2 seems to be a better choice for the case of Scientometrics but it looks like the worse for the case of Evolving Citation Networks, for which $\gamma$ group 1 might be better. The reason might be related to the particular feature of a field or the size of a network.

Thus what we can conclude is that our weighted method truly improved the ability to find communities in citation networks when evaluated by the values of modularity Q. In order to find what this difference is, we decided to investigate further the difference between weighted and unweighted methods. Weighted method with $\gamma$ group 2 was used to be carry out comparison analysis to unweighted network. Meanwhile, in order to keep the scope manageable to get a more careful look at the nodes moving between weighted and unweighted methods, we restrict ourselves to well-cited 188 publications by k-core >4 in the 1420 nodes of the case of Scientometrics, defined as those with higher degrees, to be shown in visualization maps. Then we got five communities. We present the topics of the five communities by co-keywords in Table 2, which are patent analysis, collaboration, research evaluation, university evaluation and science mapping.
Table 2. Topics of communities in Scientometrics dataset

Fig.1 illustrates the communities of the 188 publications in both unweighted and weighted networks, which shows that four nodes move between the four networks. They are n46, n1116, n686 and n1386. Their titles are listed in table 3. In order to judge whether the move of the four nodes from unweighted network to weighted network is positive or not, we read the full texts of the four publications carefully and summarized the themes comparing to the topics of the five communities.

Table 3. Four nodes distributed in different communities in Scientometrics dataset

<table>

<td>5</td>
</tr>
<tr>
<td>n1386</td>
<td>The 100 most prolific economists using the p-index</td>
<td>5</td>
</tr>
</tbody>
</table>

Figure 1. Comparison of communities in Scientometrics
Publication n46 (Badar, et al., 2015) explored the curvilinear association of co-authorship network centrality, degree, closeness and betweenness and the research performance, which considered formal rank of the authors as a moderator between network centrality and research performance. Its theme relates to both the topics of community 2 (collaboration) and community 3 (research evaluation). But by reading the paper we found that the central theme of n46 is scientific collaboration network analysis, and the usage for research evaluation is just an extended function. Therefore, assigning n46 to community 2 might be a better choice.

Node 1386 (Prathap, 2010) developed a new indicator called performance index (p-index), which was used to rank 100 most prolific economists. Node 686 (Ding, et al., 2013) evaluated the productivity of China in the field of pharmacology/pharmacy during 2001-2010 comparing to ten representative countries. Both of these two papers had made some mapping analysis but the key purposes were to carry out evaluation analysis. Therefore, these two publications were assigned preferably to community 3 by our weighted method.

Node 1116 (Zhao & Zhang, 2011) used the methods of co-word analysis, social network analysis and mapping knowledge domains as theory basis to construct the co-word network of the field of digital library research. It presented the study status quo and the research paradigm structure of digital library in China. Although it had also made some comparative analysis to that of international digital libraries research, the main contribution is illustration by mappings but not evaluation. Therefore, on the contrary to n1386 and n 686, n1116 was moved to community 5 from community 3 by our weighted classification method.

The above analysis indicates that four nodes all move with the direction of better appropriate of community assignation through our weighted method. In fact, the four nodes are only key nodes with highly degrees among 188 nodes. There are much many nodes with lower degrees surrounded with the four moved nodes will also move with them to new communities in process of our new weighted method. In other words, our new weighted method will rebuild the research structure and paradigm structure of a subject, such as Scientometrics in this case. It might contribute to the better insight into the development of the field of Scientometrics.

Conclusion

Our study provides initial insights on the weighted method for community detection in citation network. An interesting advantage of using weighted community detection method is the fact that breaking the barriers of traditional citation network analysis that regarding all edges as the same importance. We find that using weighted citation edges with VSM-based nodes similarity to detect communities can improve the modularity Q value, which might mean a better assignment result. Four nodes’ movement with the direction of better appropriate of community assignation in the 188 node citation network of the field Scientometrics had also indicates the advantage of our weighted method.

However, by the result of this paper, we are not sure which part of a paper contributes more to the theme similarity between papers. Thus, an important question for further research is whether there is a common weights distribution feature among different parts of a paper or not, for example title, keywords, abstract and even full text.

Another problem with the citation network is that citation is strictly ordering in time and there is a problem of publication delay about months to years from a manuscript’s submission to publication or online when other authors can read it then cite it. As a result, a lot of highly relevant papers did not cite each other. That is to say, some correlative papers have no links in citation networks and suppressed the function of community detection in citation network to
depict the research structure and paradigm structure of a subject. Under this situation such kinds of highly relevant papers might be co-cited by later publications or have relation of bibliographic coupling by citing at least one common earlier publication. Thus, we suggest such publication pairs should be constructed as virtual edges and also be added selectively to our citation network. So we are facing quite a disturbing puzzle: how many or what kinds of such pairs need to be added to our network? We will take this question as one of our future research works.

We also hope that future research will further examine this question in line with deeper investigation into much more factors that could affect citation behaviour, such as co-author, co-institution, even the bias on language, institutions or countries.

Beyond all the problems identified above, we should also pay close attention to the dynamic evolving patterns of citation network, particularly on the transition of communities including merging, dividing, expanding, et al. For instance, Jung et al. (2014) proposed methods to analyse how communities change over time in the citation network graph without additional external information and based on node and link prediction and community detection.

Abstract

Knowledge network is widely applied in such fields as management science, library science, information science and pedagogy to determine the cutting-edge and popular aspects in relevant fields. By drawing the knowledge network, the theoretical system of the subject or relevant fields can be constructed and the coordination relationship between the author or organization and the nation can be analyzed. This paper proposes realizing process of the domain knowledge network based on Bibliometrics after defining knowledge network and the basic concepts. The domain knowledge network model is constructed from time-dimension, network type and research field. This research is helpful to construct and analyze domain knowledge network from different levels of knowledge unit and knowledge relation.

Conference topic

Knowledge discovery and data mining

Introduction

Problems and methods are the basic elements of any academic research. The appropriate research method is the key to solve the problem. We found that there were many disciplines and academic fields to identify the research frontier and hotspot by drawing knowledge network in recent years. Studies on the knowledge network put emphasis on the following points: ① Study on the knowledge network structure, behaviors and complexity from the perspectives of complex network, collaboration network and social network. ② Study on the knowledge network composition and activities from the perspective of knowledge management. ③ Explanation and application of the knowledge network theories in the cluster from the perspective of enterprise cluster. ④ Study on the impact of the knowledge network on the improvement of innovation capability and performance in combination with technical innovation.⑤
Study on the information service applications of the knowledge network in the Internet and digital library fields from the perspective of information technology application. It can help the researchers to construct the theoretical system of subject, to measure the cooperative relationship between authors or organizations and states, to explore issues of disciplinary paradigm. Knowledge networks have been widely used in different disciplines, such as management, library and information science, education, etc. It has become the most widely used research method to research the related issues by drawing the knowledge network in the field of Bibliometric, literature analysis, literature review, etc. in addition to frequency statistical methods. There are many scholars cannot make good use of it, though more and more scholars are beginning to use the knowledge network. Therefore, it is necessary to sort out and summarize for the method of knowledge network from the height of methodology. The paper uses CiteSpace to analyze the keywords, references, and category for visualizing domain knowledge network. CiteSpace is a Java-based application that research out by Chen Chaomei (Chen, 2006), and then the paper studies the related concepts, theoretical foundation, drawing tools, network measure, etc. It can help scholars to understand accurately.

The concept of knowledge network was firstly proposed by the Swedish industry but has not been clearly defined yet. Here are some of the most representative ideas on the concept of the knowledge network: It is an aggregate that gathers academic experts, information, and knowledge for the purpose of analysis on a special issue; it is a dynamic framework that consists of the behavioral agent, relationship, and resource system features for value creation through knowledge creation and transfer; and it is a network formed by connection among bodies of knowledge, such as people and enterprises. Recent year’s knowledge network had applied in social analysis and natural sciences (Sonnenwald and Wildemuth et al., 2001; Newman and Barabasi et al., 2006; Hall, 2010). The concept of knowledge network is divided into following level, which includes engineering electrical electronic, computer science and artificial intelligence, management, information science and library science, pedagogy, etc. In the field of management, it mainly refers to the knowledge creation, transfer, use and dissemination of the internal and external enterprises. The knowledge network can be divided into individual network, group network, organization network, enterprise alliance network, business association network, etc. from the perspective of management; the knowledge network is generally refers to the semantic network, concept network, neural network, etc. from the perspective of computer science and artificial intelligence; knowledge network is generally a kind of learning method or tool from the perspective of pedagogy; it mainly refers to the knowledge node and its structure, which is used to reflect the relationship among knowledge organization, storage, retrieval, transfer and utilization in scientific research activities from the perspective of information science and library science. The paper mainly studies the knowledge network in the field of library and information science, so the meaning of the knowledge network that appears in the following paper is belonging to the field of Bibliometric.

The knowledge network coupled with Bibliometric is often used to study collaboration networks. On the knowledge network, vertex generally indicates the storage unit for a knowledge element according to certain rules and principles (Hai, 2006). It can be a book, essay, patent, information fragment or word according to the
size. An edge is the relationship between knowledge elements, represented by the citation relationship on the citation network or word network and the co-occurrence relationship on the co-occurrence network (such as the co-word, co-authoring, and cooperation networks. Therefore, the knowledge network method based on Bibliometric can be defined as ‘it explores the research front and hotspot of subject or related disciplines by drawing different kinds of knowledge network, and it can also construct the theoretical system of discipline or analyze the collaboration between the author, organization, state, etc. which is the research method to explore the discipline paradigm.’ In a variety of specific research literature, knowledge network method is commonly used in visual map, scientific knowledge map, co-word analysis, co-occurrence analysis, etc. But it has special meaning to knowledge network method based on Bibliometric in this paper, which should have three conditions, the data is from the document database, showing by the visual map, the knowledge network is composed by nodes and tie.

Method

1). Identify the knowledge network domain which is defined by relative papers and their citations.

2). Data collection. We conducted a search on ISI Web of Science Core Citation Database. Retrieval strategy is “Topics= knowledge network AND Type= article AND Language= English”, with time span from 2007/01/01 to 2016/08/31. We removed duplicates by CiteSpace function. Finally we got 28580 bibliographic records.

3). Time slicing. We specify 1 year as the length of a single time slice.

4). Threshold selection. We selected top 50 references per time slice. In terms of threshold selection, CiteSpace allows threshold settings in three time partitions (before, during, and after) respectively at the layers of citation quantity, co-citation frequency, and co-citation factor, while other thresholds are determined by the linear interpolated values.

5). Pruning and merging. Minimize spinning tree is chosen for network pruning.

Data collection and sample

Scientific literature has both persistent and transient elements. The transient aspect of scientific literature can be characterized by corresponding thematic trends, while the persistent aspect can be characterized by salient conceptual structures (Fang, 2015). The analysis of thematic trends is based on the concept of burst detection (Chen and Song et al., 2008). We use the information contained in different fields for a standard scientific and a text-based analysis. CiteSpace can detect the emerging trends and tracking topics. We get the research field on knowledge network by visualizing mapping. CiteSpace was developed by Mr. Chen Chaomei (Cheung Kong Scholar Lecture Professor at Dalian University of Technology, and Chinese scholar at the Drexel University, USA) and his research team. It is a Java application used to identify and visualize the new trend and development in scientific researchers from scientific literatures and has become information visualization software that has great impacts in the information analysis field. Therefore, the CiteSpace is adopted to draw the Mapping of Science to disclose
the development of the knowledge network studies in China in visual mode and provide references for researchers in China, which is undoubtedly of great significance and value.

Secondly, we construe the model to propose an implementation process for literature-based domain knowledge network of a particular field, in which knowledge network is divided into structure network and relationship by choosing different information as the actor or link of the network. On the basis of the model, dimension-time, network type and level are designed to map into a cube to constitute the methodology structural framework for the purpose of creating and analyzing the domain knowledge network.

Results

Types of domain knowledge network based on Bibliometrics

The knowledge network can be divided into various types in different perspectives. It can be divided into macro knowledge network and micro knowledge network according to the level of view; it can be divided into explicit knowledge network and tacit knowledge network according to the explicit and implicit. It is meaningful to divide in accordance with the specific research object, because each domain of knowledge network is composed of node and link, different types of knowledge network can be obtained by selecting different nodes and links of knowledge. This paper argues that the knowledge network can be divided into two categories, the network of literature knowledge and the network of knowledge itself. The network of literature reflects the relationship between the existence of the association, inheritance and development, which can be constructed by the content and citation attributes. Knowledge itself reflects the cooperation, competition, etc. in different body of knowledge, which can be constructed by the attribution of author or organization, etc. in view of considering the specific application, knowledge has timeliness, and changed with the time changes. Therefore, the knowledge network is actually composed of nodes, association and time, which can form a cube of the knowledge network. (See figure 1)
Figure 1. The constructive model of knowledge network in different domain

We can get four network types from the perspective of network in Fig. 1, which includes SN network, co-word network, citation network and cooperation network; from the perspective of research level, it has macro, medium, micro network; from the perspective of time, it divided by year. SN network focuses on the similar network, which describes the relationship between two articles by keywords, for example, article A is a node in network, other article with the same keywords like article A will link to article A. these two articles are the similar research articles, which uses this method to build the network called SN network. Co-word network is the link between words when a group of keywords in the same article, which founded by the method of network known as the co-word network. Obviously, when the link is regarded as the relation between knowledge, knowledge network reflects the relation network between the knowledge itself. The relationship network of knowledge includes cooperation and citation. Cooperation between authors, institution reflects the relation network in knowledge citation, and knowledge transfer. Citation reflects the relationship between inheritance and development of predecessor’s knowledge, which explains the knowledge transfer from cited literature to citation. Thus, the types of cooperation networks and citation networks can be formed.

The realizing process of knowledge network in different domain based on literature

Knowledge is divided into tacit knowledge and explicit knowledge, which can be divided into two categories: literature knowledge and knowledge agent. Literature knowledge is a kind of explicit knowledge, while knowledge agent is the creator of literature knowledge and the inheritor of tacit knowledge. In view of the relationship of inheritance and development in domain knowledge, the paper establishes the model of knowledge network in different field form the perspective of content attribute, citation attribute. The structure and distribution of the domain knowledge network can be reflected by strength of these relationships. The different knowledge agent can produce
collaboration, learning, and competition between each other in the course of interaction with knowledge, which makes the knowledge flow and transfer. Therefore, it can build the knowledge agent networks by the link among the knowledge. The author attributes is as a unit of knowledge based on analysis of construction for knowledge network. The network of knowledge agent and knowledge structure are not two independent networks, and they are two kinds of static and dynamic forms of knowledge network in a certain field, which is one subject of two aspects. The network knowledge structure is the foundation of the network of knowledge agent, while the network of knowledge agent is the extension of the knowledge structure. The process of literature analysis to the realization of knowledge network is as showed in figure 2. From the figure, the model constructs “knowledge unit”, “extracting knowledge node”, “establish relation”, and “build visualizing network”; in the horizontal dimension, the model distinguish the characteristics of various knowledge networks and relationship between each other.

![Diagram of Knowledge Network](image)

**Figure 2. The realizing process of domain knowledge network in different domain**

In the knowledge network, the research of drawing tool is one of the main contents. It is very important to develop the visual software which is powerful, easy to use and display the image. The drawing of knowledge network cannot be separated from the use of a variety of visualization tools. Used more tools or software currently include CiteSpace, as well as social network analysis software UNCINET and Pajek from analysis of the literature. The Indiana University Library and Information Science Institute developed the large-scale network data analysis, modeling and visualization tools that are Network Workbench Tool and Sci 2 Tool. VOSviewer is developed by Holland scholar Van Eck and Waltman. Vanagepoint is mostly used by researchers. Table 1 describes the situation of these visualization tools. At present, more and more visualization tools used in the literature, which can be easily and intuitively displayed.
the research problems in front of scholars by using visual tools. This is one of the reasons for the increasing in the use of visual tools in the literature.

Method of domain knowledge network based on literature

To draw the domain knowledge network based on literature is to study and solve the problems in the academic research, such as measuring the strength of collaboration between the author, etc. It is a leap in the process, and a scientific and constructive work from the visualization to the conclusion of research. The process mainly includes two kinds: one is to judge directly from the graph description, such as discovering the size of knowledge unit, strength and their relationship by the nodes, color, size, line of connection, shape of network, etc.; the other is judging by the measurement of relative index. In this paper, we consider that the knowledge network can be measured by 4 basic indicators, which include the breadth of knowledge network, the depth of knowledge network, the strength of collaboration, the relation of knowledge link and arcs. The breadth of knowledge network refers to the number of links in the knowledge network, which means other nodes are connected to the target node. The depth of knowledge network is the number of intermediate nodes that are contained between knowledge units or knowledge nodes, the more nodes, the greater relationship, which indicates whether the knowledge nodes have direct or indirect correlation. The strength of collaboration is closely related to the knowledge nodes that are direct relation. It is generally expressed by the distance of the knowledge node, the length of the connection, and the thickness.
of the connection. The relation of knowledge link and arcs indicates that the knowledge unit exists identity relation, equivalent relation, hierarchy, rank correlation, inclusion relation, causal relation, parataxis, etc. the arcs includes in degree and out degree, which indicates the direction of knowledge node.

The basic description of the structure for knowledge network mainly includes average path length, clustering coefficient, and connectivity. The average path length refers to the average value of the shortest path between any nodes of network, which can be used to measure the distance between nodes. The clustering coefficient of network can measure clustering feature, which is the average value of all clustering coefficient, and the clustering coefficient of nodes refers to the ratio of the number of triangles formed by the nodes and the number of elements. The out degree of node is one node points to the number of edges of the other nodes; in degree of node is the number of edges form other nodes pointing to slide of one node, and the connectivity is a sum of out degree and in degree. The proportion of papers that are directly judged by knowledge network is relatively more, which reflects the advantage of the method in intuition and visualization. At the same time, it also shows that some researchers have a lack of understanding for the mechanism of visualization software.

Panorama of domain knowledge network

The intellectual landscape of the research field can be represented by CiteSpace, which can draw a network of cited references, categories and co-occurring keywords. Our study focuses on co-cited references network, co-occurring keywords and categories. Figure 3 presents the top cited literatures associated with the term “knowledge network” for 2007 to 2016. The graph consists of 28580 records, which have the highest betweenness centrality in the network, suggesting that each records as an essential resource in knowledge network. All the articles use knowledge network as a key enabling technology for pursuing research questions. As showed in figure 1, modularity Q 0.819 and mean silhouette 0.3143 indicates a good inter-cluster connections network and considerable partition of the network. In the map, there are several purple round nodes, which reveal that these are developed area of the knowledge network. There are mainly two clusters in the map, which represents knowledge subject relation network and knowledge structure network.
Figure 3. Panorama of knowledge network based on literature from 2007 to 2016

Which disciplines are involved in knowledge network? Each article indexed by the Web of Science is assigned one or more subject categories. Figure 4 shows a network of such subject categories by Pathfinder network analyzing, which indicates the most salient connections. The most common category is management, library and information science, education, computer science artificial intelligence, computer science information systems, business, mathematical computational biology, etc. The most common category is Management, which has the largest article, followed by Computer science and Business & Economics, Engineering. From the figure 4, the method of knowledge network is used in more and more disciplines.
Keywords are the refined research content in the article, and the high frequency words appear in the article and the noun phrase extracted from each article can be regarded as a research hotspot in the field. With the help of visualization software, CiteSpace, to draw the clustering map, to detect the hotspot in the field of research. We detect the high frequency words in the field of knowledge network by drawing the knowledge network. We set the appropriate parameters in the CiteSpace and select the pathfinder algorithm to draw the map, which is shown as in figure 5. Pathfinder relies on the so-called triangle inequality to eliminate redundant or counter-intuitive links, which are a complex network that represents proximity data to a much more concise and meaningful network-only the most important links in the network (Chen, 1999). The circular nodes in the map represent the key words, the size of node and its tag is proportional to the frequency of the words, and the larger nodes can be regarded as the main research topics in the field of knowledge network from 2007 to 2016. From the figure 5, we can get the larger frequency keywords as showed in table 2.

World frequency analysis is the Bibliometric methods to determine the research hotspot and developing trend in the research area. It uses keywords or subjects that appear on the frequencies in the area to explain or express the core content of literature. Due to the keywords or subject are the core content of the article, or the concentrated and refined content in the literature. Therefore, it can reflect the hotspot of the research, if the keywords or subject appear repeatedly in the literature. Table 2 is the main high-frequency keywords and high-betweenness Centrality that reflect the main research area of knowledge network by visualization software, CiteSpace. The high-betweenness centrality of a node is a graph-theoretical property that quantifies the importance of the node’s position in a network (Freeman, 1979). The high-betweenness centrality keywords tend to be found in paths connecting different clusters. This feature has been
used in community-finding algorithms to identify and separate clusters (Girvan and Newman, 2002).

Theoretical basis of knowledge network method based on Bibliometric

The method of knowledge network based on Bibliometric is widely used in current academic research, which has a very complicated reason.

(1) The growing importance of knowledge network in the academic field

From the perspective of academic research to analyze, the figures used mainly after geometric interpretation was founded by Descartes and Fermat. The academic people have further understanding for the advantage and characteristics of graph with the development of scientific technology. Such as, figure can break the limitations of time and space to make some of invisible phenomena understand easily. It can help people to discover new information by analyzing the picture, and it can easily establish the relation between experience and theory, which makes the mathematical analysis and scientific computation to carry out smoothly. Knowledge mapping is invariance in the content, in addition to mobility, intuitive and visualization. It can be kept relatively stable whether it is the summary of scientific phenomena or during the process of academic exchange communication. The knowledge mapping is the powerful tool for the scientists to use in the academic debate. The science begins when scientists separate themselves from nature into inscription of the world. Therefore, knowledge mapping plays a key role in integration of facts and theories. The knowledge mapping often shows the hidden rules because it is easy to be combined with geometry, so it has a strong ability to inspire and analyze. The application and attention in the academic field are increasing. Some academic field considers the knowledge mapping as one of the important signs in surveying the development of discipline.

(2) The development of social sciences in social network analysis method

The study of social network in various social and organizational fields has undergone extensive development over last three decades (Zaheer and G Zübüyük et al., 2010). Social network analysis is the process of investigating social structures through
the use of network and graph theories (Ozyar and Gurdalli, 2002). The social network concentrated on both personal and organizational networks with the discussing on interdisciplinary nature of network. It characterizes networked structures in terms of nodes and ties, edges, or links that connected them, which has an earlier conceptual background. It was in the 1960s that researchers from the University of Harvard included mathematical developments in the study of social relations. Social network analysis covers a lot of methods that reveal the structures of the relational data that are in social practice. With the development of social network analysis, it has formed a series of terms and concepts, as a very useful research method and thinking mode. It has already went beyond the scope of the field of sociology, which is widely used in various fields, including citation network, co-occurrence keywords, co-author citation within the field of Library and Information Science.

(3) The research and development of the network in the field of Scientometrics

The research of knowledge network begins with relationship network of literature in the field of Scientometrics. The representative literatures are as following, in 1955, a new Dimension in Documentation through Association of Ideas wrote by Eugene Garfield who propose a bibliographic system for science literature that can eliminate the uncritical citation of fraudulent, incomplete, or obsolete data by making it possible for the conscientious scholar to be aware of criticisms of earlier papers (Garfield, 2006). In 1965, Networks of Scientific Papers was wrote by Price who described in the broadest outline the nature of the total world network of scientific papers (Price, 1965). In 1973, Co-citation in the Scientific Library: A New Measure of the Relationship between Two Documents was wrote by Henry Small who defined the new kind of “coupling” and to distinguish it from bibliographic coupling, using an actual example to agree generally with patterns of direct citation (Small, 1973). In 1998, Perfetti wrote one article about co-word, and he did a detailed description, after decades of development, co-word analysis is becoming more mature; people can find affinities with researching object by co-word analysis; it can also reveal implicit or potentially useful knowledge to discover the relationship of structure and subject (Perfetti, 1998). In 2003, mapping knowledge domains was presented at a workshop of National Academy of Sciences. Various tools of mapping knowledge domains are also increasing. Mapping knowledge domains was promoted by the famous American expert, Chen Chaomei who is from Drexel University. He developed the software, CiteSpace, which is to become the most popular visualization software in academic research. “Mapping Scientific Frontiers: The Quest for Knowledge Visualization” and “Information Visualization: Beyond the Horizon” are the classics in the field of information visualization or knowledge visualization (Chaomei Chen, 2003; Chen, 2006).

(4) The development of complex network theory in the field of physics and systems science

Complex network is a graph with non-trivial topological features that do not occur in simple networks such as lattices or random graphs but often occur in graphs modelling of real systems. It is a hot topic in physics and systems science, which has become a new interdisciplinary in 21st, and it concerns with the general characteristics and universal methods of complex networks to promote the understanding of natural and artificial complex networks. People have been filled with a variety of complex networks in
nowadays. The network has become an indispensable part of life in modern times, such as the World Wide Web is composed to web pages one by one; the power network by the power station; food chain and ecological network are composed by species; social network is composed of family, neighbors, friends etc. Therefore, the world was filled with various complex networks, whether it is tangible or intangible, animate or inanimate, artificial or natural, even as the key words within the literature, which seems to not a network of things that can be studied from the perspective of complex networks.

(5) The rapid development of data visualization technology in the field of computer science

Data visualization technology is to use computer to deal with mass of data to the graphic or image displayed on the screen by computer enormous processing capacity and graphic processing technology. It involves computer graphics, image processing, computer aided design, computer vision and human-computer interaction, etc. the concept of data visualization is derived from visualization in scientific computing, but with the development of computer technology, the concept of data visualization has been greatly expanded. It includes not only the visualization in scientific computing, but also the visualization of engineering data and measured data, as well as the development of information visualization in recent years. Visualization of scientific computing is an interdisciplinary branch of science, which considered a subset of computer graphics, a branch of computer science (Lopes and M et al., 2010). The purpose of visualization of scientific computing to enable scientists to understand, illustrate, and glean insight from the data. Therefore, visualization in scientific computing refers to the visualization of spatial data sites, while the information visualization refers to non-spatial data. The application of data visualization has been very extensive, covering various fields, such as natural science, engineering technology, finance, communication and commerce. Visualization can be used to discover the complex relationships among the knowledge units as a powerful tool for knowledge discovery, and it has been paid attention by the researchers of the library and information science.

Discussion and conclusion

The domain knowledge network includes the structural network of domain knowledge network itself, and the relation network among knowledge agent. The paper put forward the realizing process of domain knowledge network from knowledge and knowledge agent and elaborated the construction of knowledge network model form different domains. We constructed the domain knowledge structure and relation network from time factor, network dimension and research domain based on Bibliometrics to reflect the domain knowledge network further.

The literature is a carrier that contains the information of scientific research achievements and scientific research activities. It can help us to solve many academic problems by domain knowledge network method based on literature. The domain knowledge network method has a special value to researchers. It has been widely used in many fields of discipline, such as scientific research, library and information science, management science, biology and medical informatics, as well as education, sports, economics and engineering technology, etc. Therefore, it is conductive to the further understanding of the academic field and the correct use of the method from the
perspective of methodology of theory to sort, profound consideration, review, and prospect.

Limitation

As a research method, there are some deficiencies in the academic field by using domain knowledge network method based on literature, mainly in the following aspects: ① Currently, studies on the knowledge network focus more on the visual form of the knowledge network structure and description on the relationship, but less on the dynamic process and evolutionary mechanism of the knowledge development. ② It is not enough to research in formation process of the hotspot and innovation trend for the evolution of knowledge network, and the prediction is not strong. ③ The strategy is inappropriate for data downloading, which cannot reach the integrity and accuracy of the data. ④ Each visual software has advantage and disadvantage. It should choose the appropriate tools for different analysis. There is no perfect visualization tool.

Abstract
In this contribution a bibliometric analysis of the computer science theses defended in Spain is carried out based on bibliographic networks and communities detection. Data was retrieved from Teseo database. Then, a filtering process was applied in order to get only theses data in which doctoral programs title match with keywords related with Computer Science. Then, we build a network with theses defense committee members from data extracted and we apply fundamentals of social network analysis and community detection techniques to analyze data and uncover novel characteristics from network structure.

Introduction
A doctoral thesis is a research job carried out by a doctoral student to obtain a postgraduate level with a higher academic rank. This consists in carrying out a rigorous research process about a chosen topic, which should have clear objectives, hypotheses and a research plan. Also it must have a detailed report of the methodology used and the results achieved, with the aim of generating significant and original contributions for a knowledge area.

Once the thesis has been completed and accepted, the student proceeds to defend his/her thesis before a committee that can be made up of three or five members, of which at least one third or two fifths (in the case of five members) must belong to the university in which the postgraduate studies have been carried out. In addition, the members of the committee can be foreign, depending on the area of knowledge in which the thesis has been developed. After the thesis defense, the student will therefore sign a document, whereby he or she, the author, permits the consultation and the lending of the thesis.

Once a thesis has been defended, it is stored in a web repository of public access, of the Secretariat of the Council of Universities (Teseo). This website allows to find the doctoral dissertations defended in Spain according to the official register of the Ministry of Education. Therefore, anyone can access this information. For instance, the author, supervisors, defense committee, title, abstract, keywords, among others.

Therefore, this information could be used to carry out a science mapping analysis (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2011b) based on bibliographic networks (Batagelj & Cerišek, 2013) in order to uncover the social (Newman, 2004) (Peters & Raan, 1991) (Glänzel, 2001), intellectual (Small, 1973) (Kessler, 1963) and conceptual (Callon, Courtial, Turner, & Bauin, 1983) aspects (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2011a).
Particularly, the relationships among the committee members could be modeled as a social bibliographic network, where the nodes will be the members, and the edges will represent members co-occurrence and this could be used to analyze patterns of collaboration of members. In Bibliometrics, Collaboration Networks could be analyzed using indicators to measure and extract the structure inherent to a set of publications; but also these could be examined as social networks to explore interactions between actors who may be researchers, groups, institutions, etc. that collaborate in the development of scientific papers on research topics (Newman, 2004). The study of these networks is done in the beginning to study the behavior of those involved and also to find patterns of collaboration. Newman et al. conducts a study of the collaborative networks between scientists in the field of physics, biomedical research, and computer science (Newman, 2001). These have all the characteristics of small worlds networks: small distance between nodes, a high clustering coefficient and the degree of distribution seems to follow a power law (Barabási et al., 2002).

So, the main aim of this contribution is to perform a science mapping analysis based on social bibliographic networks, using as data the relationships of the Spanish theses defense committee members gathered from Teseo. Particularly, our objectives are: propose Teseo as new bibliographic source for bibliometric analysis, build a theses committee bibliographic networks, perform a social network analysis, and detect the hidden social groups by means of community detection.

The rest of the paper is organized as follows: Section Methodology, shows the steps followed to carry out the analysis. Section Results and statistics, shows the output of applying the steps stablished in the previous stage. And finally, some conclusions are drawn.

**Methodology**

We have followed a set of procedures to achieve a science mapping analysis of doctoral theses data from Spain. Specifically, the object of study will be theses defense committee members. For this, the methodology shown in the Figure 1 has been established and is described below step by step.

**Data Collection**

For this study we have used data from Teseo database. Teseo is a huge repository which contains doctoral theses of all universities from Spain. It is fed on the information provided by the doctoral commissions of different universities and is regulated by the University Coordination Council. This contains information of theses defended since the year 1976 and this information is released for searches at URL: https://www.educacion.gob.es/teseo/irGestionarConsulta.do.
Thus, Teseo provides information like thesis author’s name, thesis title, thesis directors, court before which the thesis was defended, the program on the thesis was developed, university, thesis reading date, a summary of thesis topic, among other relevant data. To be able to manipulate data of Teseo web page, first, we have had to download it and for that we have constructed a small code including the combined use of Python language and the BeautifullSoup library\(^1\) as tools to extract and store great volume of structured data in web page. In this script we have considered that the URL with the information of each thesis is formed in the same way, except for a reference that is a sequential numerical code that differentiates each thesis. In such a way that the information of the same thesis is repeated every 3 reference codes. Therefore, this code runs through each URL and stores in a structure all the data of the website that are later written in a CSV file. The following Teseo information has been downloaded:

- Reference
- Title
- Author
- College
- Department
- Date
- Program
- Director
- Doctoral court
- Descriptors

Collected data has been saved in a csv file and then stored into a relational database.

**Data Storage**

We have used MySQL to store data from CSV file for future analysis but mainly to review if the data is correct, and looking for missing values, or inconsistent records. Initially 237187 theses records have been downloaded from Teseo web page, but, to do this analysis more specific, we have decided to manually filter data to focus on the study of the theses whose doctoral programs are related to the area of computer science. Thus, in Table 1 the selected keywords used to filter the theses are shown.

The distribution of theses per year is shown in Figure 2 where we can see the distributions of number of theses per year for all Teseo data and in Figure 3 is shown the distribution of number of theses about Computer Science programs per year.

---

\(^1\) [https://www.crummy.com/software/BeautifulSoup/bs4/doc/](https://www.crummy.com/software/BeautifulSoup/bs4/doc/)
After filtering process, we obtain 6528 theses with doctoral programs related to computer science and also have the names of defense committee members.

**Data Pre-processing**

A dataset composed by 6528 records (target data) have been pre-processed using RStudio tools to do different steps, which as described as follows:
As we intend to study the relationships between defense committee members, we have first had to process the Tribunal column from dataset because it can contain three or more member’s names of defense committee in a single row. Then it has been divided, so that each row contains only one member’s name to do a granular data analysis.

After we have implemented an R function to convert data, we have get a new dataset with 29937 rows instead of 6528. With this new dataset we have proceeded to build the graph and its corresponding adjacency list to relate the member’s names of defense committee who have worked together. For this we have used Igraph\(^2\) package in R. Igraph is a collection of network analysis tools with the emphasis on efficiency, portability and ease of use. It is open source and free and can be programmed in R, Python and C/C++. It provides routines and functions to create and manipulate graphs easily.

So, the adjacency list will be used to create networks that will show us the interaction of different member’s names of defense committee.

As example, let suppose a set of six theses. Each thesis has a defense committee as it is shown in Table 2. Thus, the network built from this example corpus are shown in Figure 4. We should point out that an arc between two nodes represents a relation between these committee members. Also, the thickness of the arcs represents the raw co-occurrence.

**Figure 4 Network with different sizes and different weights.**

Therefore the network will have some properties established in the scope of this analysis. On the one hand, nodes will have two properties: name and frequency. The name property is used to record the defense committee member’s name who is represented by the node and the frequency property is an integer that represents the number of times a name

\(^2\) http://igraph.org/r/
appears in the graph, this means, if a defense committee member appears 100 times then this will have a frequency equal to 100. This property has been established within the framework of this methodology, to assign a level of importance to defense committee members, therefore, those who have higher frequency values will be considered more important than those with low frequency values.

On the other hand, edges or relationships also have properties. In this case, it has been defined weight property, which represents the number of times that is found an interaction between two members.

**Graph Construction**

The adjacency list gotten in the previous stage has been used to build an undirected graph using Igraph package in RStudio with all the properties named above.

We have decided used Igraph because is a very complete library that allows the construction of graphs from structures such as data.frames in R. In addition, it allows to apply a number of methods, routines and functions to manipulate graphs facilitating the analysis of networks.

One problem with large-scale networks is that they are difficult to analyze with the naked eye. To avoid having a graph of a very dense network where we cannot easily appreciate the relationships between the nodes, we have proceeded to prune the network excluding those nodes that have relationships with a weight less than 2.

**Graph Analysis**

With the network built above we have used the Fast Greedy (Clauset, Newman, & Moore, 2004) algorithm to detect communities with the aim of discovering the structure of the network. We have applied the Igraph function that allows to assign a group to each node of the network, using the algorithm.

For graph visualization, VisNetwork library (also available in R) has been used because this library draws networks with a dynamic aspect, allowing to zoom on the network, to add tooltips, to assign different forms for the nodes, select nodes neighbors, etc.

In addition, centrality measures of nodes have been calculated to detect important nodes of the network (Freeman, 1978). We have used Igraph functions to get Degree, Closeness, Eigenvector and Betweenness from network nodes.

Referring to the concepts of centrality, it has been established some attributes:

- **Best connected member** that represents one or more theses defense committee members with the highest Degree Centrality value in the network. This means that a member has a privileged position within the network because he/she has been on a committee with more variety of people than the others. That is, it has a greater amount of connections with other different individuals. His/her importance is based on that he/she has an advantage because it is supposed to interact with more people. He/she is more independent than others and more powerful.

- **Member with the most closeness** that represents one or more members with the highest Closeness Centrality value in the network. This means the importance of the member is defined by the ties of his/her neighbors. If his/her neighbors have more connected nodes, he/she is more important.

- **The most intermediary member** that represents one or more members with the highest Betweenness Centrality value in the network. This means that the member is more accessible by others. His/her importance consists in that while more nodes need to go through him to access others he/she will have more interactions.

- **The most influential member** that represents one or more members with the highest value in the Eigen vector calculated over the network. This uncover the importance of a
members in terms of the overall structure of the network. It says a member is important if he/she is linked to more important members. Therefore, his/her power in the network depends on his/her neighbors too. A committee member with high degree connected to members with high degree too is more influential.

Then, we have used the communities’ sizes to get a subgraph with two most representative communities of the network. From this we can identify who are the defense committee members which are related to more of the others.

**Results and statistics**

Following all the steps described in the methodology we have gotten an undirected graph with 11963 nodes and 48980 edges. It is a very dense network, in which the main component is formed by 10647 nodes, while the rest of the components are formed between 3 and 20 nodes. Therefore, we have had to prune the graph as mentioned in the methodology section, excluding those members who are considered less relevant. We have gotten a new network with 465 nodes and 328 edges as can be seen in Figure 5 where the frequency of nodes is reflected in the size of these and the weight of the relationships is reflected in the width of the edges; however, it is difficult to understand just by seeing this because there is a lot of data in graph.

![Figure 5 Pruned Graph of Theses Defense Committee Members.](image)

On this network we have used the centrality measures to obtain the most important nodes, the following results are shown in Table 3 for the whole network and in Table 4 we can see the results for the pruned graph.

As in this case most of the times the measures point to the same node, placing this as the best node located in the network. In Figure 6 the pruned network is shown according to different measures. Thus, in Figure 6.a the sizes of the nodes is proportional to the degree, in Figure 6.b, the size of the nodes is proportional to the closeness centrality, In Figure 6.c the size of the
nodes is to betweenness, and finally, in Figure 6.c the size of the nodes is proportional to the eigenvector centrality.

Table 3 Centrality measures results for the whole network.

At granular level, we have chosen ten people who have higher frequency values. This means that they appear more often in the full network. In Table 5 is shown the list of members who have been part of the defense committee more times. In our analysis we have detected that those with higher frequency values do not necessarily coincide more times with the same people on the committee, at least in this area of knowledge.

On the other hand, we have applied Fast Greedy algorithm for community detection because this offers a global optimal solution in a reasonable time. Greedy strategies are based on recursive tasks where the solution of a problem depends on solutions of smaller instances of the problem. We have used the pruned network to make visualization and understanding of results easier and we have discovered 107 communities. In Figure 7 is shown how the communities are formed where each community is represented by a color.

![Figure 7 Communities detected with Fast Greedy algorithm.](image)

We have also obtained the subgraph with the two most representative communities. With this we can conclude that there are a large group of people who have been members of the Committee who are frequently related. In Figure 8 we can see the biggest community from graph detected with Fast Greedy algorithm. This have 28 nodes and 35 edges. Meanwhile, in Figure 9 it is shown the subgraph of the second biggest community, which has 25 nodes and 29 edges.
Conclusion
In this contribution, we have made a bibliometric study about data from Spanish doctoral theses in Computer Science area. We have extracted data from Teseo database website with the aim of uncover some novel information. We have followed a set of steps to find communities inside the network of Theses defense committee members, and finally we have uncover some interesting results and statistic.
We have detected that data stored in Teseo database has some flaws, such as it is not normalized, the names of the programs do not usually coincide with each other even though they are the same, besides the names of people who are in this database are usually not well written what incurs in our analysis can find two or more nodes that actually represent the same person. For example, we have found DÍAZ BRUGERA JAVIER and DÍAZ BRUGUERA JAVIER which obviously refers to the same person but his/her name is misspelled. There are also incomplete data and fields entered in the wrong columns.

As future work we propose to perform a preprocessing step on the raw data in order to normalize this, as well as to include in the analysis other types of social relations such as the relationships between theses directors and members of the defense committee and relationships between theses directors and keywords where we will surely find interesting patterns of collaboration.

Abstract
This paper investigates internationalization patterns in the language and type of social sciences and humanities publications in non-English speaking countries. This research aims to demonstrate that such patterns are related not only to discipline but also to each country’s cultural and historic heritage. We used data from Flemish and Polish databases collected between 2009 and 2014. In Flanders, on the one hand, we found that changes in the use of languages and publication types were moderate and occurred gradually over several years. In Poland, on the other hand, we found significant shifts in the use of certain publication types, sometimes from year to year. Examining the social sciences and humanities literature both as a whole and broken down by discipline, we observed similar variability over time in the proportion of work published in English and in article form. However, we found remarkable differences between Flanders and Poland regarding the most commonly used languages and publication types. Overall, we found few similarities between Flemish and Polish social sciences and humanities publication patterns.

Conference Topic
Country-level studies, Science policy and research assessment

Introduction
This study aims to advance the knowledge regarding social sciences and humanities (SSH) publication patterns in Europe. National studies on SSH research outputs in Finland (Puuska 2014), Flanders (Engels, Ossenblok, & Spruyt, 2012; Verleysen, Ghesquiere, & Engels), and Norway (Sivertsen, 2016) have reported stable patterns in terms of publication type, though in terms of publication language, academic work is gradually leaning toward greater English use. Furthermore, Sivertsen (2016) suggests that though publication patterns across countries are similar within SSH disciplines, these patterns differ between SSH disciplines. However, these studies have focused on Western and Northern European countries, rather than on Central and Eastern European countries, which have undergone various academic transformations over the past three decades, following the breakdown of Communist regimes (Kozak, Bornmann, & Leydesdorff, 2014; Kwiek, 2014). Thus, our contribution here is to demonstrate that in non-English speaking countries, internationalization patterns in the language and type of SSH publications are related not only to discipline but also to each country’s specific cultural and historic heritage. We analyze all scholarly SSH publications written by academics affiliated with Flemish and Polish institutions between 2009 and 2014. Though the presence of SSH publications in
databases like Scopus and Web of Science (WoS) has grown—and though, as a result, various research evaluation systems have come to use this presence as a criterion of productivity—these citation databases have limited coverage, particularly of scholarly publications from non-English speaking countries (Sivertsen 2014). Therefore, to develop a broader picture of publication patterns in Europe, we examine the Flemish and Polish academic databases, which offer a complete representation of SSH publications within their respective countries. We begin by describing the structure of the Flemish and Polish academic databases and defining the various publication types and inclusion criteria. We then briefly explain how the databases classify fields and disciplines, as well as how comparisons between SSH publication patterns in Flanders and Poland are made possible using both databases. Next, we describe the data and methods, as well as our findings regarding SSH publication patterns related to language and type. We conclude by discussing and interpreting the results in a broader context.

**Design and Structure of the Flemish and the Polish Databases**

Over the past two decades, several European countries have developed research evaluation systems for assessing national research productivity based on the number of published works. For instance, in the U.K., disciplinary panels evaluate the quality of publications, whereas Norway, Denmark, Finland, Flanders, and Poland have developed full-coverage bibliographic databases to underpin local performance-based research funding systems (Hicks 2012). The most well-known of these databases is the Current Research Information System in Norway database, or the CRIStin database, which collects bibliographic information from all fields and all higher education institutions. In 2008, the Flemish government established the Flemish Academic Bibliographic Database for the Social Sciences and Humanities (VABB–SHW, www.ecoom.be/nl/vabb), which collects all bibliographic references to published SSH research outputs by scholars affiliated with universities in Flanders, the northern Dutch-speaking region of Belgium. Similarly, the Polish government developed the Polish Scholarly Bibliography (PBN, www.pbn-ms opi.org.pl) in 2011 to underline its performance-based research funding system. Like CRIStin, the PBN collects bibliographic information from all science fields and all higher education institutions.

*The Flemish Academic Bibliographic Database for the Social Sciences and Humanities (VABB–SHW)*

Earlier studies have described the VABB–SHW’s methodology for collecting bibliographic data (Ossenblok & Engels, 2015; Verleysen et al., 2014). Five Flemish universities annually provide bibliographic information for publications from the previous two years. The interuniversity Centre for Research and Development Monitoring (ECOOM) serves as the database coordinator and technical operator. Moreover, the Flemish government has established an authoritative panel comprising 18 professors affiliated with Flemish universities, and this panel evaluates whether journal and book publishers fulfill the VABB–SHW’s inclusion criteria.

*The Polish Scholarly Bibliography (PBN)*

No English publication has described the PBN’s design and structure. However, the database’s records are used for Poland’s performance-based research funding system, and so the inclusion criteria and publication forms have been described in previous studies (Kulczycki, 2017; Kulczycki, Korzeń, & Korytkowski, 2017).

In Poland, all scientific units, including faculties and basic and applied research institutions, among others, must submit to the PBN all bibliographic information for their affiliated scholarly publications. The database is updated daily, and the data is verified by PBN editors.
and higher education administrators. Each scientific unit must submit its data at least once every six months. However, missing data can be added until the next cycle of scientific unit evaluation, which is conducted every four years.

Publication Forms and Inclusion Criteria

The VABB–SHW classifies each publication into one of five publication types: (1) journal articles, (2) monographs, (3) edited books, (4) book articles or chapters, and (5) proceedings papers that are published independently of special journal issues and edited books. The PBN assigns publications to one of four publication types: (1) journal articles, (2) monographs, (3) edited books, and (4) book chapters. It is important to note that in Poland, proceedings papers are classified as chapters in edited books. Hence, by merging the Flemish database’s “book articles and chapters” and “proceedings papers” classifications, these two classification systems can be compared.

Table 1 presents the inclusion criteria for each publication type in the VABB–SHW and the PBN. All publications recorded in these databases are peer-reviewed papers that contribute to the development of new insights or applications resulting from these insights (the Flemish criterion) and present an original research problem (the Polish criterion). Universities can also submit records with incomplete bibliographic metadata. In Flanders, such publications cannot be approved by the authoritative panel or contribute toward the performance-based research funding system, but in Poland, such publications may or may not be approved by the expert panels during the evaluation of scientific units. In our study, we analyze all publication types, whether approved or unapproved, because the PBN’s design and structure do not allow us to make this distinction.

Field and Discipline Classifications

In Flanders, each SSH publication is assigned to at least one of sixteen SSH disciplines (see Table 2). Moreover, publications are classified into three general categories based on the authors’ research affiliations with an SSH unit (i.e., a research group, research center, institute, or department).

In Poland, the science field classification includes eight areas, 22 fields, and 102 disciplines. For research evaluation purposes, each publication is first assigned a classification based on the authors’ affiliations with a scientific unit, and then the scientific unit is given two classifications:

1. Scientific unit types: (a) faculty, (b) applied research institute, (c) basic research institute at the Polish Academy of Sciences, and (d) other.
2. Science fields: (a) social sciences and humanities, (b) life sciences, (c) sciences and engineering, and (d) arts sciences and artistic production.

In the PBN’s final discipline classification, the original 102 disciplines are merged into 29 joint evaluation groups (JEGs), 11 of which belong to SSH fields. Different scientific unit types within the same science fields are assigned to the same JEGs according to discipline. For example, all Polish history faculties and history institutes at the Polish Academy of Sciences are classified into one JEG called “History.”

As shown in Table 2, we compared the Flemish and the Polish SSH classifications and found four congruent disciplines. Of the four, a direct comparative analysis is possible for three disciplines: “Economics and Business,” “History,” and “Law.” Two Flemish categories, “Philosophy” and “Theology,” can be merged and compared with the Polish classification “Philosophy and Theology” to form the fourth discipline for comparison in this study.

Materials and Methods

For the purposes of this paper, we analyzed data for the SSH literature as a whole, as well as for specific SSH disciplines. For our analysis of SSH publication patterns in Flanders and Poland, we used VABB–SHW and PBN data collected between 2009 and 2014. The two datasets we used are described below:

(A) Dataset A contained bibliographic information for 77,870 publications registered in the VABB–SHW and 134,111 publications registered in the PBN between 2009 and 2014. For our analysis of overall SSH publication patterns in Flanders and Poland, we used the number of publications per country as our unit of analysis, along with two nominal sub-variables, i.e., (1) publication type (article, monograph, edited book, or chapter) and (2) language (local language [Dutch in Flanders, Polish in Poland], English, or other), as well as one rank variable, i.e., the publication year (2009–2014). Dataset A included no duplicate publications at the country level.

(B) Dataset B contained bibliographic information for publications within four disciplines in Flanders and Poland, including 37,338 “Economics and Business” publications; 21,345 “History” publications; 32,285 “Law” publications; and 12,333 “Philosophy and Theology” publications. For our discipline-level analysis of publication patterns in Flanders and Poland, we used the number of publications per discipline as our unit of analysis, along with the same set of variables used in dataset A. In the VABB–SHW, publications can be assigned to more than one discipline, which means that publications assigned to disciplines in the Flemish database do not constitute distinct sets. However, in dataset B, the percentage of publications with only one assigned discipline was high, including for “Economics and Business” (92.28%), “History” (95.85%), “Law” (94.12%), and “Philosophy and Theology” (96.86%). Publications assigned to two or more disciplines were excluded from our analysis ($N = 1,042$).

Results

In the first part of this section, we describe the language and publication type occurrence frequencies in Flanders and Poland based on dataset A. We analyze the variability in the
proportion of publications in English and in article form between 2009 and 2014 in Flanders and Poland separately. In the second part of this section, we present the differences in the use of publication types and languages between SSH disciplines in Flanders and Poland based on dataset B.

Part A: Characteristics of SSH Publications Patterns in Flanders and Poland

Table 3 shows the distribution of publication types in Flanders and Poland. Though there are country-level differences for all publication types, the highest disproportion is between articles and chapters. In Flanders, articles are the most common publication type (57%), whereas in Poland, articles constitute only 26.2% of all published work. At the same time, in Flanders, chapters constitute only 32.6% of all published work, whereas in Poland, chapters constitute 55.9%.

Figure 1 displays the distribution of publication types between 2009 and 2014. In Flanders, we observed that patterns related to publication type were rather stable, whereas in Poland, we observed considerable changes of the proportions of publication types. In 2013, the most significant change occurred in Poland: the share of the articles dramatically increased. Whereas in 2009, articles had constituted 19.3% of all publications in Poland, by 2013 this proportion had increased to 44.6%. In Flanders, in contrast, articles constituted 55.4% of the total in 2009 and 57.6% in 2013.

---

Figure 1. Proportion of publication types in Flanders and Poland
Table 4 presents the most commonly used publication languages in Flanders and Poland. On the one hand, in Flanders, most publications were written in English (55.7%), and 35.8% were written Dutch, the local language. On the other hand, in Poland, only a small percentage of work was written in English (11.8%), and the local language, Polish, dominated academic work (82.7%). Both in Flanders and in Poland, a limited share of publications appeared in languages other than English or the local language (8.5% and 5.5%, respectively).

Figure 2 shows the distribution of publication languages between 2009 and 2014. The proportion of the publications in English is much higher in Flanders than in Poland. However, in both Flanders and Poland, there was an increase in the proportion of English publications. The difference in the proportion of English publications in 2009 versus 2013 was significant in both Flanders and Poland.

Figure 2. Publications in English, the local language, and other languages as a percentage of the total (all publication types)

Part B: Characteristics of the Publication Patterns According to Four Disciplines in Flanders and Poland

Table 5 shows the distribution of publication types within four disciplines: “Economics and Business,” “History,” “Law,” and “Philosophy and Theology.” The proportion of articles differed according to disciplines: articles were the dominant publication type within “Economics and Business,” “Law,” and “Philosophy and Theology” in Flanders, while within “History,” articles and chapters were both common. In Poland, chapters were the dominant publication type within each of the four disciplines.

Note: FLA (Flanders); POL (Poland)

The proportion of publications in English varied by discipline. Within “Economics and Business” and “Philosophy and Theology,” English was the dominant publication language in Flanders. Within “History,” the proportions of publications in English and Dutch were similar. However, Dutch was the dominant publication language within “Law” in Flanders. Polish, the local language in Poland, was dominant within all four disciplines in Poland.

Conclusion

As we saw in the case of Norway (Sivertsen 2014), in Flanders, it appears that SSH publication patterns related to publication language and type evolved gradually between 2009
and 2014. This observation contrasts with what we observed in Poland, where the proportions of publication types changed significantly between 2009 and 2014 and the use of English only gradually increased. We furthermore observed that the variability over time in the proportions of publications in English and in article form were similar for both the SSH literature as a whole and each of four disciplines separately.

These publication patterns are rooted in scholarly traditions (Whitley, 2000; Ziman, 1968), as the relatively stable cases of Flanders and Norway show. Nonetheless, our analysis has revealed that discipline-level publication patterns differ more across countries than SIvertsen (2016) and van Leeuwen (2006) initially suggested. It appears that similarities between disciplines depend on not only the analogies within disciplines but also the similarities between countries. In comparing Flemish and Polish SSH publication patterns, we observed few similarities that could be compared at either the aggregate level or the discipline level. In each of the four Flemish disciplines, articles were more dominant than in the Polish disciplines, and the share of English publications was significantly higher among Flemish scholars compared to Polish scholars.

In general, our findings revealed two publication pattern characteristics that must be interpreted in a broader context. The first is related to the proportions of publication types, which were relatively stable in Flanders but were subject to significant change in Poland. Since 2009, in Poland, the number of journal articles has increased, whereas the number of book chapters has decreased. The number of scholarly books has decreased significantly as well. An interpretation of these changes is possible when we identify the main underlying mechanisms. In Poland, the regulations for both the performance-based research funding system and for academic promotions changed considerably between 2009 and 2014 (Kulczycki, 2017). Furthermore, science policy in Poland has increasingly provided incentives for publishing articles and for publishing in English. As our findings show, these policies seem have achieved some of their intended effects. However, we have not analyzed the quality of the articles, for example, in terms of publication channel (e.g., top-tier journals indexed in WoS or Scopus). In other words, whether unintended effects have occurred as well remains to be studied.

The other characteristic is related to publication language, and particularly publications written in English. Belgium (Flanders) and Poland are non-English speaking countries. However, in terms of the scholars working there, internationalization in Flanders and Poland is different from other countries. An even more important explanatory factor, however, might be their respective XX-century histories. In Poland, Russian was a compulsory language at school prior to 1989, and publishing in English was not the best way to communicate research results. Moreover, presently, many Polish scholars perceive academic publishing in English as a form of communicative inequality that promotes “linguistic injustice” (Hyland 2016).

Abstract
Competitive research grants become more and more important in the careers of young scholars. If grants are making careers, the decision for the grant winners is important and needs to be fair, consistent and transparent. In this research in progress paper, we present evaluation criteria for research proposals from early career researchers in the humanities. We apply a bottom-up procedure to identify evaluation criteria that reach consensus among the humanities scholars themselves. We identified 23 aspects pertaining to 9 criteria for the assessment of research proposals. There are no differences between the selection of aspects that reach consensus among the scholars regarding whether the applicant is a doctoral student or a postdoc, nor did we find differences in the selection of aspects between disciplines. We found slight differences in the ratings between tenured and non-tenured scholars and between women and men. Tenured scholars and women each emphasized an additional aspect.

Conference Topic
Science Policy and Research Evaluation

Introduction
Competitive research grants become more and more important in the careers of young scholars (van Arensbergen, van der Weijden, & van den Besselaar, 2014a, b). The acquisition of such grants is seen as a sign of quality of scholarship by senior researchers (see e.g. van Arensbergen et al., 2014a, b) as well as in evaluation procedures (see e.g. Ochsner et al., 2012). This process is closely linked to the shift to the notion of excellence in higher education policy. If a higher education institution adheres to the notion of excellence, it has to recruit excellent scholars. Therefore, governments and universities focus on talent selection processes and increase the support for early career researchers. Research policy implements ‘excellence’ amongst others through competitive research funding and temporary positions for early and mid-career researchers (van Arensbergen et al., 2014b; van den Akker, 2016). While competitive funding first concerned Science, Technology, Engineering and Medicine (STEM) disciplines due their need for expensive infrastructure and large teams (Krull and Tepperwien, 2016), in the humanities the acquisition of competitive grants has not been very important in the past. However, the change to a focus on talent selection and temporary employment applies also to the humanities. Therefore, the assessment and selection of research proposals become more and more important in the humanities as well.

While there are studies on peer and panel review, they focus mainly on selection biases and fairness (see e.g. Bornmann, Mutz & Daniel, 2008; Bornmann, Mutz, Marx, Schier &
Daniel, 2011; Lamont, 2009). There is a lack of knowledge about what quality of research proposals means and how it can be identified, especially so in the humanities (see e.g. Hemlin, 1993). Little is known about what criteria peers have in mind when evaluating a proposal and even less how they weight these criteria. However, judging a work without criteria is inconsistent and not adequate for judging merit, as Thorngate, Dawes and Foddy (2009) conclude their comprehensive research on decision making. They found that judging separately according to specified criteria reveals more consistent results (Thorngate et al., 2009, p. 26). Such intra-rater reliability (in distinction of the inter-rater reliability) is of utter importance when judging merit (i.e. a reviewer would give the same rating for application A when rating application A before application B or after it; or give the same rating at a later point in time). It is not only crucial to have reliable judgments as a basis in the review process. When deciding for future careers, it is also important that the criteria are explicit and clear so that young scholars do know what to deliver and, in case of a negative evaluation, how to improve. Furthermore, explicit criteria serve transparency. All these points are important for the judgment of merit to be fair and consistent (Thorngate et al., 2009). The growing importance of research grants for the further career of young scholars makes it particularly important that the best applicants are awarded the grant. Therefore, an adequate procedure for selecting the best proposals must be applied.

In this research in progress paper, we present quality criteria for the ex-ante assessment of research proposals from early career researchers in the humanities. Applying a bottom-up approach we base the evaluation criteria on scholars’ ratings of quality criteria regarding their adequacy for the use in such an assessment situation. Particularly, we are investigating the following research questions: a) are there differences between the criteria for evaluating the proposals from PhD students and those for evaluating proposals from postdocs? b) is there a common set of quality criteria across disciplines that can be used to adequately judge research proposals? c) do tenured professors emphasize other criteria than the young scholars themselves? d) are there gender differences regarding the preferences for criteria?

This paper is organized in the following way: First, we present the approach and methods used to identify the important quality criteria for a specific evaluation situation. We then present the methods with which we investigate differences in the preferences for quality criteria between sub-groups of our sample: level of the grant (PhD or postdoc), discipline, academic status and gender. We finally conclude regarding the differences between sub-groups of the sample reflecting the generalizability of our results.

Methods and data used

For the selection of the criteria to be included in the evaluation sheet, we designed a questionnaire containing nine criteria, specified by 23 aspects, for judging the quality and potential of the research proposal. We draw from our previous research in which we developed a catalogue of criteria for research quality in the humanities in a strictly bottom-up procedure, i.e. the scholars formulated their own criteria during several steps and using different methods (Ochsner, Hug & Daniel, 2014). Based on this catalogue, we selected, adapted and expanded the criteria to the evaluation situation of ex-ante research proposal assessment of early career researchers and added some criteria usually used in such evaluation situations (i.e., information about the applicant). The questionnaire was sent out to all Swiss scholars holding a doctoral degree in the humanities (theology/religious studies were excluded due to another project fielding a similar survey at the same time in these disciplines). The scholars were to rate the criteria for their suitability for the evaluation of research proposals. To do so, they had to give their agreement on a 6-point scale with a statement that consisted of a generic part and a part specific to the aspect that is rated. The generic part read: ‘A project application is assessed appropriately, if the assessment considers whether...’ while the

Using the ratings, we identified criteria and aspects that reach consensus among the scholars. An aspect reaches consensus when it is clearly approved by the majority (at least 50% of the scholars rate the aspect with at least a ‘5’) and only a small majority disapproves the aspect (less than 10% rate the aspect negatively, that is with a ‘1’, ‘2’ or ‘3’).

To answer our research questions, we identified differences in the ratings of the aspects between different sub-groups of our sample using standardized effect sizes, i.e. Cohen’s d (Cohen, 1988). We applied a threshold of Cohen’s $d=0.2$ as suggested by Cohen (1988), who proposes the rule of thumb that $d>0.2$ equals a small effect, $d>0.5$ a medium effect, and $d>0.8$ a large effect. Because our sample is a full population survey (i.e., all humanities scholars in Switzerland were invited to participate) and not a random sample, we cannot use inferential statistics but use bootstrap resampling with 1,000 replications to estimate the stability of the results instead, using bootstrapped 95% stability intervals. This serves to account for the effect of possible outliers and as a measure of stability because not all humanities scholars in the population respond to the survey (see Schneider & van Leeuwen, 2014).

**Results**

The questionnaire was sent out to 2,609 humanities scholars of whom 916 filled in the questionnaire. This amounts to an overall response rate of 35%, which is a very good response rate compared to similar survey projects (see e.g. Braun & Ganser, 2011; Cardoso, Rosa & Santos, 2013; Giménez-Toledo & Román-Román, 2013). The response rate differed between disciplines in the sense that scholars from law studies participated to a quiet smaller degree: While the response rate in language and linguistics amounted to 38% and in history and cultural studies to 41%, the response rate among law scholars was at 24%. This can be explained by the fact that in law studies, our sample contained a significant number of persons that are primarily active as lawyers or judges and teach irregularly at the university. Those scholars did not participate (many of them sent us an email with the excuse that they felt it was not appropriate for them to answer the questionnaire due to a certain distance from academic life).

From the 23 aspects assigned to 9 criteria that the scholars rated, 13 aspects pertaining to 6 criteria reached consensus (see table 1). All aspects that reached the threshold of not more than 10% negative ratings also reached a median of 5. Therefore, we only list the results for the percentage of negative ratings as this was the decisive criterion. As the bootstrapped stability intervals show, the results are quite stable.

The important criteria for the evaluation of research proposals of young humanities scholars are their originality, feasibility, rigour, relevance, complexity and variety. Originality is defined by the aspects identifying gaps in existing knowledge, using innovative data, presenting new findings. Feasibility is defined by a realistic timetable and resources. Rigour is defined by the aspects appropriate research process, expression of the state of research and choice of method as well as a stringent argumentation and understandable language. Relevance is defined as academic relevance. Complexity is defined as making complexity visible. Variety is defined as contribution to the variety of research.

Looking at the Cohen’s d, we find little differences in general. Almost all coefficients are below the threshold of $d=0.2$. Between the assessment of proposals from doctoral students and postdocs, only two aspects reach a $d>0.2$: independence ($d=0.20$) and the applicant’s publication list ($d=0.30$) are rated less favourably for the assessment of proposals from doctoral students than for those from postdocs. However, for both groups, the two aspects do
not reach consensus. Therefore, the selection of criteria for the assessment of proposals from doctoral students is the same as for those from postdocs.

Table 1. Overall mean, percentage of negative ratings (with bootstrapped 95% stability intervals in parentheses), and Cohen’s d of subgroups for the ratings of the aspects

</table>

Note. Doc=proposals from doctoral students; postdoc=proposals from postdocs; Lang.=language and literature; HistCult=history and cultural studies; Law=law studies
Regarding disciplines, we find six aspects reaching a Cohen’s $d>0.2$ (i.e. independence, innovative data, new approach, state of research, cultural heritage and societal relevance), but only two aspects, for which ratings are different to a greater degree: the criterion cultural heritage is rated much higher in the disciplines language and literature as well as history and cultural studies than in law studies ($d=0.6$ and $d=0.65$), while societal relevance is rated much higher in law studies ($d=0.7$ and $d=0.5$). But again, the aspects do not differ regarding consensus. Thus, while we find disciplinary differences regarding the ratings of some aspects, the selection of aspects that reach consensus does not change between disciplines.

We also find differences between the ratings from tenured and non-tenured scholars. From the criterion rigour, tenured scholars rate all aspects bar one higher than non-tenured scholars: research process ($d=0.29$), state of research ($d=0.20$), choice of method ($d=0.20$) and argumentation ($d=0.23$). Furthermore, tenured scholars rate the applicant’s CV ($d=0.34$), his or her diploma ($d=0.23$) and his or her publication list ($d=0.39$) higher than non-tenured scholars. The applicant’s CV reaches consensus among tenured scholars as an important criterion for the assessment of young scholars’ research proposals while it does not reach consensus among non-tenured scholars. Other than that, the selection of aspects reaching consensus does not differ between tenured and non-tenured scholars.

Regarding gender, we only find two aspects that reach the threshold of Cohen’s $d=0.2$. Women rate the variety ($d=0.20$) and the applicant’s diploma ($d=0.21$) higher than men. Variety reaches consensus among women but not among men (the bootstrapped stability interval for men amounts to 0.07-0.12), revealing slight gender differences regarding the ratings of the criteria and aspects for the assessment of young scholars’ research proposals.

Conclusions

In this research in progress paper, we investigated the criteria and aspects that humanities scholars feel important and adequate to assess research proposals by young humanities scholars. We found that 23 aspects pertaining to 9 criteria reach consensus among the scholars: originality (identifying gaps, innovative data, new findings), feasibility (timetable and resources), rigour (research process, state of research, choice of method, stringent argumentation, understandable), relevance (academic relevance), complexity (making complexity visible) and variety (variety of research).

Regarding our first research question, whether there are differences between the criteria for evaluating the proposals from PhD students and those for evaluating proposals from postdocs, we found that there are no such differences. The same selection of criteria reached consensus for both evaluation situations. Regarding our second research question, whether there are disciplinary differences between the evaluation criteria, we also found that the same selection of criteria reached consensus in the three groups of disciplines we investigated. However, there were some differences in the means between disciplines that are related to the topics of research in the disciplines: scholars in language and literature and in history and cultural studies emphasised more the criterion cultural heritage than scholars in law studies, while scholars in law studies rated societal relevance higher. This points to the fact that while the same evaluation sheet can be used in all disciplines, the weighting of the criteria (can) differ by discipline. The third research question focused on differences between tenured and non-tenured scholars. We found very little differences, however, the applicant’s CV reached consensus among tenured scholars but not among non-tenured scholars. Finally, we investigated gender differences in the ratings. Regarding gender, the differences are rather small as well and only one criterion, variety of research, reached consensus among women but not among men. Thus, we can conclude that the 23 aspects pertaining to 9 criteria are rather generally applicable in the assessment of research proposals from early career researchers in the humanities.
Regarding the application of the criteria in the assessment of research proposals, it remains to be noted that we present findings from the perspective of the scholars themselves, thus referring to the academic quality of the proposal. In funding decisions, also criteria put forward by the funder might be added. In the further analysis of our data, we will delve deeper into the relation of the criteria for the assessment of proposals by early career researchers and general quality criteria identified in our previous research (Hug et al., 2013) as well as the interrelations of gender, tenure and disciplines regarding the ratings of the evaluation criteria.

Cognitive and organizational classification of publications in the Social Sciences and Humanities

Abstract
We study the discrepancy between two ways of classifying publications in the social sciences and humanities (SSH): on the basis of the journal’s contents (cognitive) or on the basis of the organizational structure of departments, faculties etc. (organizational). Using data from 43,191 journal articles (co-) authored by Flemish SSH researchers in 2005–2014, we compare the organizational classification with a cognitive classification based on OECD Fields Of Science. In virtually all cases, the cognitive discipline with the most publications is the one that most closely matches the organizational discipline, although there are great differences between disciplines. At a higher aggregation level, we find that 70% of publications from the humanities are published in humanities journals, while this is only the case for 53% of publications from the social sciences. Social sciences are shown to be closely linked to medicine and health sciences. The spread of publications over cognitive disciplines, including non-SSH disciplines, can be partially explained by the assignment of some journals to multiple FOS fields as well as multidisciplinary collaboration.

Journals, databases and electronic publications; Science policy

Introduction
Publications, publication channels, and authors can be assigned to disciplines on the basis of different criteria. The most straightforward criterion is presumably the contents of the publications, but in practice other criteria are frequently used as well. Daraio and Glänzel (2016) distinguish between four types of classifications:
- cognitive: based on content of publications or publication channels;
- administrative: based on responsibility from the point of view of a government or research policy;
- organizational: based on internal organizational structure;
- qualification-based: based on education and competencies.
In this paper, we focus on the tension between organizational and cognitive classifications. Whitley (2000) has pointed out the “degree of separation of control” between the praxis of research and “administrative structures of work organizations.” In the case of Flanders, Belgium, for instance, the organizational structure of universities – departments, faculties, etc. – is traditionally mainly dictated by educational needs rather than research. One might expect that in practice some or all of these criteria tend to coincide, that is, that the four criteria will generally lead to a publication or its authors being classified in the same discipline(s). At the same time, it is clear that this is not absolute: for instance, a researcher with formal training in economics may carry out computer science research while working in a physics department. Relatedly, it has been shown that researchers from the same organizational discipline may be quite different in terms of publication patterns (Verleysen & Weeren, 2016a, 2016b).
Daraio and Glänzel (2016) give the example of the Flemish Academic Bibliographic Database for Social Sciences and Humanities (VABB-SHW), a comprehensive database of social
sciences and humanities (SSH) output in Flanders. The number of publications in the VABB-SHW is a parameter in the Flemish BOF-key university funding system (Verleysen, Ghesquière, & Engels, 2014). Contrary to Web of Science – another parameter in the BOF-key –, which uses a cognitive classification, VABB-SHW classifies publications according to the authors’ departments or research groups and is hence based on organizational criteria. The mapping of organizational structure to disciplines is carried out by the respective university’s research administration together with ECOOM-Antwerp, which oversees the development and maintenance of the VABB-SHW.

Daraio and Glänzel remark that the organizational classification “is acceptable for the purpose of funding allocation and in line with the original task of VABB, above all, because the necessary affiliation information is available also in the WoS data. However, for fine grained evaluation exercises the combination of the two classification types remains problematic.” In addition, a cognitive classification has the advantage of allowing easier comparison with the situation in other countries (Ossenblok, Engels, & Sivertsen, 2012; Pölönen et al., 2017).

In general, not much is known on the extent of the discrepancy between cognitive and organizational classifications. We explore this tension using data from the VABB-SHW. Specifically, we focus on the following questions:

1. To what extent is there a mismatch between cognitive and organizational classifications?
2. How is this mismatch different across disciplines and organizational units?
3. How fuzzy are the boundaries between the SSH and other fields of research?

Data and methods

Data were obtained from the VABB-SHW (https://www.ecoom.be/en/vabb). All 43,191 journal articles published in the 10-year period 2005–2014 and classified as peer-reviewed in view of the Flemish funding system were taken into account. These articles were published in, in total, 8,683 journals. If a journal had separate ISSNs for print and online versions, these were considered as the same journal.

Each journal was assigned to one or more disciplines from the OECD Fields Of Science or FOS (OECD, 2007). This was done as much as possible by relying on the journal’s classification in Web of Science, Scopus, the Norwegian CRIStiN database, and the UDC or DDC classification in the ISSN.org database. For each of these, a concordance table was used to translate to the FOS classification. A limited number of journals did not have a subject indication in any of the aforementioned data sources and was classified manually and independently by two people.

The following refinements were made to the FOS classification:

- History and archaeology was split into History and Archaeology;
- Languages and literature was split into Languages and linguistics and Literature;
- Philosophy, ethics and religion was split into Philosophy and ethics and Religion.

The rationale behind the refinement was to obtain cognitive classes that correspond more directly to VABB disciplines. Apart from the groupings Humanities general and Social sciences general, only the VABB discipline Criminology does not have a direct counterpart in the refined FOS scheme, where criminology is classified under Law. From the perspective of FOS, only Social and economic geography (besides Other humanities and Other social sciences) does not have a clear counterpart in VABB.

For each pair of VABB discipline and FOS field, we determine the number of publications assigned to both. Because the absolute numbers of publications vary between VABB disciplines and FOS fields, we use the share of publications, expressed as a percentage. This can be done from the perspective of a VABB discipline – share of publications from that discipline assigned to a FOS field compared to all publications from that discipline – or from the perspective of a
For the purposes of the present paper, we will mostly consider things from the perspective of VABB disciplines, i.e. the organizational classification of the publications. Note that publications can be assigned to more than one VABB discipline (in case of collaboration; 44%) as well as more than one FOS field (12%). Indeed, it seems plausible that interdisciplinary collaboration is one of the driving forces enabling researchers to go beyond their own organizational discipline (van Rijnsoever & Hessels, 2011). To assess the strength of this effect, we separately consider the set of publications assigned to only one VABB discipline and one FOS field (N=25430 or 59%).

In addition to visual representations using heat maps, we will quantify the concentration of a VABB discipline in FOS fields using the Gini index (Gini, 1921). This index is directly related to the Lorenz curve (Rousseau, 2007) and varies between 0 (perfect evenness) and 1 (perfect unevenness, i.e. concentration).

**Results**

First, we compare the share of publications from the six top-level FOS fields in the aggregated organizational fields of **Social sciences** and **Humanities**, using all 43,191 articles. This is summarized in Figure 1. In both cases, we see that the majority of publications is published in the corresponding FOS field, although the share in humanities (70%) is much larger than in social sciences (53%). Moreover, publications authored by researchers from the humanities appear in social science journals in 14%, whereas this is only 3% for the reverse case. The top-level FOS field of **Medical and health sciences** is the second largest recipient of publications from scholars affiliated to Social Sciences (30%).

![Figure 1](image-url). Heatmap of publications classified according to organizational unit (rows) and journal content (columns). Data are reported for top-level classifications and standardized per row.

Figure 2 provides a more detailed view. The order of disciplines is taken from the FOS classification (OECD, 2007); VABB disciplines mirror the order of the closest corresponding FOS fields. The rough ‘diagonal’ line in the right-hand side of the picture indicates that, overall, the organizational affiliation is at least an approximation of the intellectual content of publications. Gaps in the diagonal are explained by the fact that some FOS fields have no direct counterpart in VABB disciplines. Because the FOS field of **Health sciences** is classified under **Medical and health sciences**, the first row (Social health sciences) does not show up as part of the diagonal. We also point out that some pairs of disciplines, like linguistics and literature or philosophy and theology, are shown to be closely related.

The intensity of cells in the diagonal indicates the extent to which a VABB discipline corresponds to a FOS field. The disciplines with the highest correspondence are **Law** (79.7%), **Criminology** (74.0%, mapped to FOS field Law), and **Theology** (66.4%). On the other hand it can be seen that some disciplines have a much weaker disciplinary profile, such as **Sociology** (21.0%), **Social health sciences** (26.8%), and **Communication studies** (29.2%).

**Social health sciences** is the only organizational discipline that actually has a higher share of publications in another FOS field than the one we considered to be the closest corresponding: 32.1% of its publications appear in **Clinical medicine** journals. Several other VABB disciplines
also appear regularly in medical journals, like *Psychology*, *Sociology* (sociology of health), and *Philosophy* (ethical issues).

![Heatmap of publications classified according to organizational unit (rows) and journal content (columns). Data are standardized per row.](image1)

**Figure 2.** Heatmap of publications classified according to organizational unit (rows) and journal content (columns). Data are standardized per row.

![Difference in percentage points between shares based on single-assignment publications and shares based on all publications](image2)

**Figure 3.** Difference in percentage points between shares based on single-assignment publications and shares based on all publications

In the analysis presented above, a confounding factor may be the fact that some publications are assigned to multiple VABB disciplines and/or multiple FOS fields. In order to rule out this
factor, we also calculated the share of publications from FOS fields in each VABB discipline, taking only single-assignment publications into account, i.e. publications that are assigned to one VABB discipline and one FOS field. Comparing these shares with the ones obtained by taking all publications into account gives an indication of the importance of this factor and the ways it affects the results.

Figure 3 visualizes the difference between shares based on single-assignment publications and shares based on all publications. Red shades indicate that the percentage calculated using only single-assignment publications is higher than the one using all publications, whereas blue shades indicate that the percentage for single-assignment publications is lower. In general, the share based on single-assignment publications increases for the FOS field that corresponds best to a given VABB discipline and decreases for most of the other FOS fields. The exception is, again, Social health sciences, where we only see an increase for FOS field Clinical medicine. The strongest increase is observed for Archaeology (+21.3 p.p.), while the strongest decrease is found for Sociology’s involvement in FOS field Clinical medicine (−9.3 p.p.).

It is no coincidence that a strong effect can be observed for the field of archaeology, since this is typically a discipline that strongly relies on multidisciplinary collaboration with fields like chemistry and earth sciences as well as with other humanities disciplines. In other words, multidisciplinary collaboration should be considered an integral part of some, if not all, disciplines, and cannot be simply disregarded.

These findings clearly indicate that some organizational disciplines are relatively concentrated in terms of in which cognitive fields articles are classified, whereas others are more spread out. This can be quantified using a concentration measure like the Gini index (Gini, 1921). The results (Table 1) are related to, but not interchangeable with, the results regarding the match between FOS field and corresponding VABB discipline. While all disciplines are relatively concentrated over FOS fields, the difference between the most and the least concentrated ones – Law and History of arts respectively – is considerable. As one might expect, the Gini index that is based on single-assignment publications only is higher in all cases than the one based on all publications.

Conclusions
Different types of classification do not always yield the same results. In this paper, we have examined the discrepancy between cognitive and organizational classifications in social sciences and humanities, using the example of the Flemish VABB-SHW database. Our results show that all organizational disciplines are to some extent prone to publishing ‘outside’ one’s own discipline but there are great differences between disciplines: while almost 80% of law publications end up in law journals, this is less than 30% for communication studies. At a higher aggregation level, we find that 70% of humanities publications are published in humanities journals, while this is only the case for 53% of social sciences publications. Social sciences are shown to be closely linked to medicine and health sciences; this is partially due to the inclusion of Social health sciences as a social science in the organizational classification but also to other social sciences like sociology. The spread of publications over cognitive disciplines, including non-SSH disciplines, can be partially explained by the assignment of some journals to multiple FOS fields as well as multidisciplinary collaboration.

Acknowledgments
This investigation has been made possible by the financial support of the Flemish government to ECOOM.

Abstract:
This research in progress paper presents current research on the different approaches to the definition, documentation and application of peer review processes to scholarly books and book publishers. The documentation concerning how peer reviewed scholarly books are considered in the Norwegian, Finnish, Danish, Flemish and Spanish evaluation systems and national CRIS(s) has been analyzed and juxtaposed. The synthesis of the documentation includes the distinctive features of each definition of scholarly book’s peer review. Inclusion or exclusion of the evaluation system as well as the weight given to peer and non-peer-reviewed scholarly books are also analyzed. The existence of a common denominator to all systems seems plausible and would facilitate an eventual aggregation of different information systems. Such common denominator might be defined as the least number of common features across the different countries concerning how peer review in scholarly books is considered in their evaluation systems. Nevertheless, that common denominator might be more clearly identified once more evaluation systems are analyzed as per extracting general conclusions. This would entail coordination among researchers and transparency by publishers. It is concluded that peer review of scholarly books is a highly relevant feature of scholarly output; also, the need of basic research on scholarly books’ peer review practices becomes clear from the diversity of approaches observed. Further research would involve quantitative analysis of peer-reviewed publishers in the different countries.

Keywords: Scholarly book publishers, peer review, research evaluation, information systems / CRIS.

Conference Topic
Science communication

Introduction:
The Association of American University Presses (AAUP), which represents a global community of independent scholarly publishers, demands “high standards of editorial quality and peer review” from all its members. AAUP was recently able to complete a Handbook of Best Practices for Peer Review (AAUP, 2016). This is a sign that independent peer review is now accepted as just as necessary in scholarly book publishing as in scholarly journal publishing in the fields where monographs and book
chapters play an important role in research communication, namely the social sciences and humanities (Giménez-Toledo et al., 2015).

Peer review has also increasingly become a delineation criterion in national or regional systems providing data for the measurement or assessment of scholarly publishing in books. This is the case in Norway (Sivertsen and Larsen, 2012; NSD, 2017) Finland (Pölönen & Ruth, 2015), Denmark (Ingwersen & Larsen, 2014), Flanders (Verleysen & Engels, 2013) and Spain (Giménez-Toledo et al., 2015). Either at the level of the publisher (e.g. Norway’s Cristin system) or at the level of the individual book (e.g. Flanders’ VABB-SHW and Spain’s CNEAI (BOE, 2016), peer review by external experts in the field is required. This requirement may even be expressed in the definition of scholarly publishing on which the system is based. The requirement of peer review may also be present in information systems and international databases that are not directly linked to research assessment, such as DOAB, Scopus, Book Citation Index, Kriterium or Open Edition.

Nevertheless, peer review practices may be even more diverse in scholarly publishing than in scholarly journal publishing. Most scholarly publishers are hybrid in the sense that books representing original research and oriented at scholarly publications are only a part of their publishing profile. Books for students and wider audiences can be just as important for the publisher, and not only scholarly criteria, but also commercial criteria, may play a role in the decision what to publish. Not all publishers that frequently review manuscripts from academia apply the same rigorous selection processes. ‘Peer review’ can be understood in several different forms in the case of scholarly books.

This work has the objective of analyzing how the ‘peer reviewed’ criterion is actually being applied when categorizing or classifying scholarly publishers in national or regional systems for research assessment and bibliometric measurement, mainly in the case of Social Sciences and Humanities. Exploring and comparing the different practices carried out internationally can provide mutual learning and harmonized guidelines as a next step. A further step could be an integrated international information system that includes also scholarly book with standardized information on publishers. Two existing projects, the so-called VIRTA solution originating from Finland, and ERIH PLUS, so far covering only journals, have such international integration as one of the aims.

The existence of national information systems is crucial since it allows better understanding and reflecting on the publishing diversity of a country – both in terms of number of publishers, scholarly fields or publishing languages. But it should be possible to compare those categorizations of scholarly books across Europe. For that purpose, comparing how peer review is defined, and how this definition delineates the data in practice, is necessary. We also need to understand how the applied definition influences bibliometric measurement.
Scholarly book publishing in the humanities and social sciences takes place and is important both at an international and at a national level. The project may result in mutual learning between to two levels, which can be useful for the publishers as well.

In Finland and Belgium, a specific label for publishers and books – respectively – has been introduced for the aid of delineating peer reviewed scholarly publishing. Both countries, as well as Denmark and Norway, monitor lists of approved scholarly publishers with peer review procedures as a delimiting criterion. In Spain, the review processes described in SPI (Scholarly Publishers Indicators) is used as a reference by evaluation agencies. This set of countries has been selected because in all cases they count with lists of publishers and detailed specifications concerning how peer review is considered in evaluation processes, although it is among the aims of this line of research to comparatively study peer review in the evaluation systems of other countries. Also, supra-national evaluation systems might count with specifications concerning the peer review of books, but these have not been the focus of this research since the study of national evaluation processes offers a more detailed and specific ground for further convergence or integration.

Methodology

In this first approach to the commonalities on the treatment of scholarly books’ peer review, the documentation and information publicly available at the country level in each case are analyzed and summarized. The methodology primarily consists on the search, download and analysis of documents available in the websites of the four previously mentioned systems, or in the legislation concerning the databases. The set of fields reflected in the juxtaposition table have been chosen according to the frequency and relevance of their appearance in the documentation analyzed.

Results

The following table (1) reflects how peer review is defined in each country, concerning specifically peer review practices for scholarly books.

The Norwegian and Danish systems apply a specific definition of peer review, while the Finnish and Flemish systems apply an explicit set of conditions that series and individual titles (only individual titles in the case of Flanders’ GPRC, Guaranteed Peer Review Content label) must meet in order to obtain the label attributing the publisher or the title a controlled and certified peer review process. In Spain, the criteria which publishers must meet for entering the evaluation system are set in the evaluation regulations and SPI (Scholarly Publishers Indicators) provides the information on peer review which is afterwards considered by evaluation agencies. In the case of Flanders, since the general set of conditions is different from the specifications for the GPRC label, an entry for each type of information has been added to the table below.

</table>
Transparency concerning peer review practices: The inclusion of an approved scholarly publisher in the Norwegian and Finnish information systems requires the existence of publicly available information provided by the publishers concerning their peer review practices. In the case of the Flemish system, there is no formal requirement for the publishers to have publicly available information concerning their peer review processes. However, the Authoritative Panel that controls what data enters VABB-SSHW, make a decision on the use of peer review by publishers in the system. In the BFI Danish scheme, there is also no formal requirement of publicity concerning the use of peer review by publishers, but any publication channel in the system is expected to be able to provide proofs in that sense. In the Spanish case, the requirement is implicit in the evaluation regulations concerning the use data from SPI with regards to scholarly publishers’ peer review procedures.

Preliminary conclusions

The analysis of the definitions and uses of peer review on scholarly books in the different countries allows for the following preliminary conclusions:

1. Peer review is a delineating criterion for the evaluation of scholarly outputs in the form of books, monographs and book series. It is present in all four systems and an explicit prerequisite for the inclusion of a publication channel as suitable for further evaluation.

2. There is a diversity of approaches to defining peer review and applying it in the evaluation process: from the specific definitions and requirements in the case of the Finnish and Flemish labels to the use of existing information on scholarly publishers’ peer review practices by evaluation agencies in the case of Spain.
3. Peer review of scholarly books needs further research to find out which features should define the due criteria for peer review processes, which weight would be appropriate to attribute to peer reviewed contributions and which level of analysis is optimal in terms of cost and precision (from publisher to individual titles).

4. The possible influence of commercial criteria in peer reviewed scholarly publishing should also be studied further.

5. Lastly, further research is needed to lay the basis for international data integration and comparable measurements.

We also expected to see how specific publishers (international or national) are classified, in terms of peer review practices, in the different information systems. The possibility of creating a shared list for all of the systems will also be investigated. Another possible line of further research would include the study of peer review and evaluation practices applied to book series such as the Finnish quality label and, in the case of Spain, the UNE (Union of University Presses) quality label for series (Academic Publishing Quality Label / APQ: CEA-APQ, 2017). The above mentioned Handbook of Best Practices for Peer Review (AAUP, 2016) may serve as a kind of yardstick for the comparison of systems.

Abstract
During several decades Soviet academic psychology community was isolated from the West, but after the collapse of the Soviet Union each of the 15 countries went its own way in economic, social, and scientific development. The paper analyses publications from post-Soviet countries in psychological journals in 1992–2016, i.e. 25 years after the collapse of the Soviet Union. Results show that 15 post-Soviet countries have produced in sum less than one percent from the world output in psychological journals. There is a huge diversity in the number of papers between 15 post-Soviet countries. Russia, Estonia, and Lithuania are the leaders among them. Authors of the more than 90% of all post-Soviet countries’ papers are affiliated with these three countries. The most intensive collaboration is between Russia, Estonia, Lithuania, and Georgia and between three Baltic countries. Post-Soviet countries also differ in publication patterns.

Keywords
Post-Soviet countries; psychological journals; bibliometric analysis

Introduction
Internationalization and global communication and collaboration are the key attributes of the contemporary science. To be a part of international community means publishing papers in international journals and in English language because English is a lingua franca for science today. This is true for the majority scientific fields including psychology. Despite the fact that psychological academic community was relatively open for international communication in the early Soviet period (Yasnitsky, 2010, 2011) and a number of Soviet psychologists and behavioural researchers were recognized by the international community (Aleksandrova-Howell, Abramson, & Craig, 2012; Haggblom et al., 2002) a long time Soviet academic psychology community was isolated from the West. Ideological pressure in social sciences and the Iron Curtain leaded to almost full isolation from western scientific community. After the collapse of the Soviet Union each of the 15 countries, which were parts of the Soviet Union, went their own ways in economic, social, and scientific development. There were a number of administrative reforms and initiatives aimed at improvement and development of scientific research systems in post-Soviet countries during the last decades (Abbott & Schiermeier, 2014; Kristapsons, Martinson, & Dabyte, 2003; Raudla, Karo, Valdmaa, & Kattel, 2015; Schiermeier, 2010; Turko, Bakhiturin, Bagan, Poloskov, & Gudym, 2016).

There are several bibliometric studies of scientific developments in the former Soviet countries (Allik, 2008, 2015; Fiala & Willett, 2015; Gzoyan et al., 2015; Kozak, Bornmann, & Leydesdorff, 2015; Markusova, Ivanov, & Varshavskii, 2009; Markusova, Jansz, Libkind, & Varshavsky, 2009; Zavadskas, Kirvaitis, & Dagiene, 2011). But these studies usually consider only several countries and analyze publications from all fields as a whole

125
output or focus on natural/computer sciences. While social and behavioural sciences were given little attention. The main goal of this paper is to provide a bibliometric analysis of publications from 15 post-Soviet countries in psychological journals. This study tries to answer the following research questions. What is the contribution of the former Soviet countries into the world psychological science? How do the academic communities of psychologists in these countries collaborate with each other and how they are integrated into the international community?

Data and Methods
Data were obtained from Web of Science (Clarivate Analytics, ex-Thomson Reuters), the online version of the SCI-EXPANDED and SSCI, on 20th February 2017. An advanced search by fields Web of Science Category (WC), Country (CU), and Year Published (PY) was conducted. We searched articles with at least one author affiliated with one of 15 post-Soviet countries in journals belonging to at least one psychology category: Psychology; Psychology, Applied; Psychology, Biological; Psychology, Clinical; Psychology, Developmental; Psychology, Educational; Psychology, Experimental; Psychology, Mathematical; Psychology, Multidisciplinary; Psychology, Social. The retrieved results were limited by document types (‘article’ or ‘review’), language (English), and year of publication (1992–2016). The full search string is in Appendix. With this search strategy 1950 articles were found. All available information about these 1950 articles was downloaded. For the data preparation, analysis and visualization we used R, a programming language and environment for statistical computing (R Core Team, 2016). All results described in this article, were extracted and calculated by the authors' own R script. Additional packages were used: ggplot2 (Wickham, 2009), readxl (Wickham, 2016), stringr (Wickham, 2017), stringi (Gagolewski & Tartanus, 2016), reshape2 (Wickham, 2007).

Analysis of the international collaborations was conducted by the freely available computer program VOSviewer (version 1.6.5) (van Eck & Waltman, 2010). Data on international collaborations were saved from VOSviewer and visualized by the igraph package (Csardi & Nepusz, 2006).

Results and Discussion
In sum 15 post-Soviet countries produced 1950 papers indexed in SCI-EXPANDED and SSCI. It is 0.34% from all 581,425 articles in psychological journals published by all countries. The share of the papers in psychological journals from these countries increased from 0.01% to 0.61% during the considered interval (Figure 1). Though it is still less than one percent from the world output, there is a growth in the contribution of post-Soviet countries to the world output in psychological journals. Spearman's rank correlation between publication year and the percentage of the post-Soviet countries’ papers from the world output in psychological journals is 0.78 (p < 0.001). It is interesting that this growth is accompanied by a decrease of the share of all papers from post-Soviet countries in the world journals (Figure 1). Spearman's rank correlation between publication year and the percentage of the post-Soviet countries’ papers from the world output in all journals is –0.45 (p = 0.025).
Figure 1. The share of the post-Soviet countries in the world output in psychological journals and in all journals (authors’ calculations based on SCI-EXPANDED and SSCI data).

Three countries have the largest number of papers: Russia, Estonia, and Lithuania (Table 1). Authors of the more than 90% of all post-Soviet countries’ papers are affiliated with these three countries. Figure 2 shows distribution of papers from post-Soviet countries in psychological journals between 1992 and 2016. The analysis shows that Russia and Estonia are the leaders during all this period. Before 2011–2012 there was a slow linear growth of the number of papers in both countries, but after that there is a sharp rise in the number of papers from these countries. Perhaps, this rise can be explained by several policy decisions and initiatives in Russian and Estonian academic systems, which have affected all scientific fields.
including psychology. In Russia these are grants to support scientific research projects implemented by the world’s leading scientists at Russian institutions of higher learning (in Russia, so called “megagrants”) and Russian Academic Excellence Project “5-100” aiming to maximize the competitive position of a group of leading Russian universities in the global research and education market (Schiermeier, 2010). Previous research showed that every fifth Russian article published in psychological journals in 2015 was supported by megagrants (Lovakov, in press). In Estonia this is primarily project-based funding of research (more than 80% of research funding is project-based) (Allik, 2015; Raudla et al., 2015).

The number of papers from Georgia has also increased in recent years. Eight post-Soviet countries (Armenia, Azerbaijan, Kazakhstan, Kyrgyzstan, Moldova, Tajikistan, Turkmenistan, and Uzbekistan) have less than 20 papers in psychological journals during the last 25 years. This means less than one paper per year.

![Figure 2. The number of papers in psychological journals from post-Soviet countries (only countries with 20 and more papers).](image)

Psychology is a complex discipline, this is reflected by several special psychological categories in SSCI. Table 2 shows the distribution of papers across nine psychological categories. Papers from the post-Soviet countries are presented in journals from all categories. But most of the papers are concentrated in journals from four categories: multidisciplinary, experimental, social, and biological. The papers in journals from other categories are poorly represented. The distribution of papers between categories remains unchanged during all the analyzed period. Due to the limitations of the journals classification into WoS categories it is useful to look at the papers' distribution among the journals itself. Table 3 shows top 10 titles with the highest number of post-Soviet publications for three periods. In 1992–2000 papers from biological and cognitive science journals dominated among the post-Soviet countries’ papers. But after 2000 papers from social and personality journals also emerged. The authors from the post-Soviet countries still publish rarely in the prestigious journals on clinical psychology.

</table>
The probable explanation may be that social sciences were under ideological pressure to a greater extent than natural and life sciences during the Soviet period. Therefore, after the collapse of the Soviet Union the social part of psychological science was more isolated and backward than the natural one. For this reason, in the 1990s, researchers from the social part of psychological science found it more difficult to produce research and publish papers that may become competitive at the international level.

Figure 3 shows the percentage of international papers in all countries together, as well as separately for Russia and Estonia. In the first period (before 2000), the share of international articles among articles of all countries in psychological journals ranges from 0% to 50%, and in the second period the share varies around 60%. Whereas the collaborations between post-Soviet countries were only episodic and only between several countries in the 90s. It means that right after gaining independence former members of Soviet Union were publishing papers by themselves or in collaboration with some other countries, but not in collaboration with post-Soviet countries. It is possible that at that time it was easier or more profitable to collaborate with other countries, because most of post-Soviet countries were in economic and political crisis.

On the regular basis papers in co-authorship with researchers from other post-Soviet countries emerged only in the 2000s. The greatest diversity in the co-authorship of researchers from post-Soviet countries is observed in the period from 2001 to 2010. The most intensive collaboration was between Russia, Estonia, Lithuania, and Georgia. Researchers from three Baltic countries also collaborate between each other. Even during the whole period from 1992 to 2016 not all post-Soviet countries collaborate with each other in psychology. Three of the fifteen countries (Kazakhstan, Tajikistan, and Turkmenistan) do not have any papers published in co-authorship with other post-Soviet countries (Fig. 4D). The small number of papers in psychological journals from these countries is the main reason.

![Figure 3. Percentage of papers with international collaboration in psychological journals (authors’ calculations based on SCI-EXPANDED and SSCI data).](image-url)
Country-based analysis

Further bibliometric analysis is based on aggregate indicators, which are informative only for countries with significant enough number of papers. Due to this, in further analysis we will consider papers from only seven post-Soviet countries (Byelarus, Estonia, Georgia, Latvia, Lithuania, Russia, and Ukraine) with more than 20 papers.

Russian papers concentrate mostly in journals from Multidisciplinary, Experimental, and Biological categories (Table 4). More than half of Estonian papers distribute between journals from Multidisciplinary, Experimental, and Social categories. Lithuanian papers are published mostly in journals from Multidisciplinary, Experimental, Developmental, and Clinical WoS categories. Papers from all post-Soviet countries published in journals from Educational, Mathematical, and Applied WoS categories are relatively rare.

Figure 4. Co-authorship networks of post-Soviet countries for the whole period from 1992 to 2016 and for three periods (1992–2000, 2001–2010, 2011–2016, and 1992–2016) separately. The more thick the edge, the closer the collaboration is among the researchers from the countries.

Note: Top journals are those from the first or second quartiles at least in one psychological WoS category.

Table 5 shows characteristics of papers from seven post-Soviet countries. Based on these data it is possible to identify several publication patterns among countries. Georgia, Latvia, and Lithuania have the highest average number of authors per paper, the highest average number of countries per paper. It means that these countries have published a lot of papers in big international collaborations. At the same time, Georgia published only 24% of papers where an author from this country is a first author, whereas Latvia and Lithuania have nearly a half of such papers. In psychology the order of the authors should reflect their contribution to the article (Publication Manual of the American Psychological Association, 2010). The first author or reprint author usually has the largest contribution to the paper. Thus, Lithuania published papers both independently (34%) and in international co-authorship including big collaborations. And Georgia and Latvia published papers mostly in big international co-operation. Russia and Ukraine also have low percentage of papers where authors from these countries are the first authors and where all the authors are affiliated with the same country. Thus, authors from these countries mostly published papers in international collaboration where they are not the main authors. In contrast, Estonian and Byelorussian authors published half of their papers without international collaboration, and in more than half of their papers they are the main authors.

Conclusion

We have analysed publications from post-Soviet countries in psychological journals in 1992–2016, i.e. during 25 years after the collapse of the Soviet Union.
The main conclusion of our research is that the output of psychology papers in the leading international journals is rather poor after the dissolution of the USSR, but the ways of development of psychological science in the countries which formed the Soviet Union differ significantly. Bibliometrics shows this very well.

In sum, the former Soviet republics have produced less than one percent of the world output in psychological journals. However the growth of post-Soviet countries’ share in the world psychology is observed.

There is a huge diversity in the number of psychology papers between 15 post-Soviet countries. Russia, Estonia, and Lithuania are the leaders among them. Countries also differ in their publication patterns. Authors from one group of countries (Georgia and Latvia) published papers mostly in big international collaborations, while authors from another group (Estonia and Byelorus) published a lot of papers without international collaboration or, if in collaboration, then their author was usually the main author of the text who has the most important contribution to the paper.

More detailed investigation on how the development of academic psychology has become so different in various post-Soviet republics needs an analysis on the institutional level, this will become an interesting topic for a further research.

Acknowledgments
The paper was prepared within the framework of the Basic Research Program at the National Research University Higher School of Economics (HSE), and supported within the framework of a subsidy by the Russian Academic Excellence Project ‘5-100’.

Global overview of unmanned aerial vehicles research: country-level and organisation-level bibliometric analysis

Maxim Kotsemir¹

¹ mkotsemir@hse.ru
National Research University Higher School of Economics, Institute for Statistical Studies and Economics of Knowledge, Moscow (Russia)

Abstract

This study proposes the global bibliometric overview of unmanned aerial vehicles (UAVs) research in Scopus database in 1985 – 2015. This study detects key countries in this field of research as well as the major centers of excellence (organisations) in UAV research. We analyse publication activity of leading countries and organisations as well as the level of citation of their UAV publications. Special section is devoted to the analysis of cross-country collaboration links. For plotting the map of international collaboration in UAV research, VOSviewer software was used.

Keywords: Unmanned aerial vehicles; UAV; aviation; publication activity; Scopus; VOSviewer; bibliometric analysis; international collaboration; citation analysis; scientometrics.

Conference Topic:
Journals, databases and electronic publications
Country-level studies
Mapping and visualization
Introduction

Unmanned aerial vehicles (UAVs) become a new special sector on aviation industry. The application of unmanned aerial vehicles is widespread: from giant global Hawk to micro aerial vehicles used in precise agriculture. Unmanned aerial vehicles research is related with many different fields of science. First there are spheres of research directly related with aviation science. UAV research posts new questions in fields of aerodynamics. The key questions here is how to measure, control and improve the aerodynamic characteristics on UAVs of untraditional forms: flying wing, spherical UAVs, UAVs with flexible and flapping wings, insect-like UAVs, quadricopters, etc. Principally new avionics is needed for UAVs. In avionics for UAVs the key role plays artificial intelligence controlled avionics or avionics system that are remotely controlled by human. New paradigm of flight management systems (FMS) is needed. With the fast development of unmanned aerial vehicles industry the new challenges for aviation safety (primarily related with antiterrorist control) arise. UAVs also change the essence of military aviation.

It should be said that there was only several examples of bibliometric analysis of research in the field of aviation and aerospace industry:

- Studies devoted to the bibliometric analysis of aerospace and aeronautical journals (Meskoob and Tanbakouei, 2012; Nageswara Rao et al. 2014; Aswathy and Pal, 2015);
- General bibliometric analysis of specific subfields of aerospace science (Ganguli, 2008; Evans, et al. 2008, 2009; Rezadad & Maghami, 2014; Rojas-Sola and Aguilera-Garcia, 2014);
- Technological mining in specific subfields of aerospace science based on bibliometric and patent analysis (Nakamura et al., 2010, 2012; Xu and Hua, 2014; Li and Guo; 2015).
- Analysis of publication activity in some organizations (and its divisions) related with aerospace research (Stephens, 2013; Nakamura, Kajikawa, and Suzuki; 2014).

This paper is among the first studies that provide the global overview of publication activity in field of unmanned aerial vehicles. This study detects key countries and key centers of excellence in this field.

1. Methodological issues

To run the bibliometric analysis on unmanned aerial vehicles (UAV) it is needed first to determine the field of search for these publications. Two greatest multisubject science citation databases that are recognized by the international scientific community and have well-developed interface for a bibliometric analysis are Scopus and Web of Science. These databases among other possibilities for bibliometric analysis allow the user to search any term (as well as combination of terms) in title, abstract and keywords of publications. In this paper, Scopus database was used since Web of Science database does not have the system of unique author identifiers and unique organization identifiers. Therefore, the possibilities for the analysis of publication activity of individual organizations and authors in Web of Science are seriously

1 The various aspects of research on the aerodynamic characteristics of unmanned aerial vehicles are studied in e.g. Ansari et al., Curet et al., 2013.
2 Some examples of research on avionics in application to unmanned aerial vehicles are e.g. Naruoka et al. 2009; Sudha Rani and Ramadoss, 2015.
3 Examples of studies on flight management systems within UAV research are: Koo et al., 1999; Pasaoglu et al., 2016.
4 Discussion on problems of hacking and hostile takeover of UAV control can be found in: Kim et al., 2012; Dulo, 2015.
5 Examples of studies on military application of UAVs are: Tozer at al., 2000; Gowtham and Gnanasundari, 2015.
constrained in contrast to Scopus⁶. Moreover, in Scopus the number of publications on unmanned aerial vehicles in different periods is 1.5 – 3.5 times higher than in Web of Science.

To detect publications on UAVs the search in title or abstract or keywords of publications was done the following terms (and all forms of them): unmanned aerial vehicle; unmanned airborne vehicle; unmanned flying vehicle; pilotless aerial vehicle; pilotless flying vehicle; unmanned aircraft; pilotless aircraft; unmanned helicopter; pilotless helicopter; unmanned copter; pilotless copter; unmanned plane; pilotless plane; unmanned drone; pilotless drone; air drone; aerial drone; flying drone; quadrocopter; quadricopter; micro aerial vehicle, micro air vehicle; micro flying vehicle; micro aircraft system. Such abbreviations like UAV, UAVs, MAV MUAV etc. were not included into the search query in order not to take irrelevant words like “User Antenna View”; “Mars Ascent Vehicle”, “Modular Acoustic Velocity Sensor” etc. We should understand: when we search for the word “unmanned Ariel vehicle” in title, abstract or keywords of the publication we take into our analysis not only publications devoted directly to unmanned aerial vehicles but also publications where the word combination "unmanned aerial vehicle" is simply mentioned. On the other hand mentioning UAV-related term(-s) in abstract or keywords of a given publication means that this publication is at least indirectly related with unmanned aerial vehicles. Moreover, the search only in the title of publications is a very narrow approach. In many cases author may not mention the word "unmanned aerial vehicles" in the title when the publication is devoted to use of some material or some technologies in unmanned aerial vehicles or new ways of application of UAVs. Therefore, in our case we treat all publications where the above mentioned UAV search terms are mentioned in title or keywords or abstract as publications related with unmanned aerial vehicles. All types of documents and all types of sources were included in the analysis.

2. Country-level analysis of publication activity in UAV studies

Since more or less stable dynamics of publications in Scopus database starts since 1985, we analyse the dynamics of publication activity on UAVs for the period of 1985 – 2015. There were several periods of rapid growth of global number of UAV publications in Scopus: 2001 – 2007 and 2012 – 2013.

Figure 1. Evolution of unmanned aerial vehicles research in Scopus in 1985 – 2015.

Notes: All types of documents and sources indexed in Scopus are included in the analysis. The analysis was done in 2nd decade of January 2016.

⁶ See more on advantages and limitations of Scopus vs. Web of Science in e.g. Meho and Yang, 2006; Falagas et al, 2008; Archambault et al., 2009; Vieira and Gomes, 2009; Shashnov and Kotsemir, 2015.
The United States is the major player in global UAV studies (Figure 2). For 1985 – 2015 USA contributed 35.8% of global come of publications on UAVs. The other big player is China whose contribution for 1985 – 2015 was 20.4%. The rocket growth of publication activity in UAVs in China started in 2005. The share of China in global volume of publications on UAVs has increased from 4.9% in 2002 to 26.5% in 2015\(^7\). The share of the United States on the contrary decreased from 68.8% in 2000 to 23.7% in 2015 (Table A.1). The contribution of any other country into global volume of publications in UAVs was less than 5% for 1985 – 2015.

In the Europe the leaders on number of publications are Western European countries – UK with 935 publications on UAVs for 1985 – 2015 (4.5% of global volume of publications), Germany with 872 publications (4.2%) and to a less extent France with 724 publications (3.5%). Among Eastern European countries the leader is Poland with 227 publications for 1985 – 2015 (1.1 % of contribution into global volume of publications). It is followed by the Russian Federation (169 publications, 0.8%), Czech Republic (116 publications, 0.6%) and Ukraine (99 publications).

In South America the leader is Brazil with 286 publications (1.4% global volume of publications) on UAVs for 1985 – 2015. It is followed by Argentina with 37 Publications. In Africa the leaders are Algeria – 67 publications on UAVs (0.3% of global volume of publications) and South Africa – 57 publications. In Asia the other important players (in addition to China) in UAV research are South Korea with 794 publications for 1985 – 2015 (3.9% of global volume of publications) and Japan with 603 publications (2.9%).

*Figure 2. Key countries in UAV research in Scopus in 1985 – 2015*

Notes: All types of documents and sources indexed in Scopus are included in the analysis. The analysis was done in 2nd decade of January 2016.

World average level of citations of UAV publications for 1985 – 2015 is 3.29 citations per one publication. In terms of citations on UAV publications, the domination of the USA was much higher than in terms of publication activity. USA received 66.4% of all citations on UAV publications. The average level of citation of publications of the USA is 6.10 cites per document. China received 15.1% of world volume of publications, while UK 9.1%. Meanwhile in China the level of citation was much lower than in the USA – only 2.43 cites per document. In general, countries with the highest level of citations per one UAV publication have low level

\(^7\) Such a situation of the rocket growth of publication activity in China can be seen not only in UAVs studies but also in many other fields of science (see Kotsemir 2012a, 2012b).
of self-citation and quite high level of integration in international scientific collaboration (Figure 3).

Figure 3. Countries with the highest level of average citation in unmanned aerial vehicle research

Notes: All types of documents and sources indexed in Scopus are included in the analysis. The analysis was done in 2\textsuperscript{nd} decade of January 2016.

The highest level of citation per one publication ("cites per doc" further) has Switzerland: 11.24. In Hong Kong the value of this indicator was also very high: 10.25 cites per doc. Among countries with more than 50 publications on UAVs in Scopus for 1985 – 2015 the lowest "cites per doc" ratio has Ukraine – only 0.33 citations per publication. In some countries cites per doc ratio was lower than 1.00: Romania (0.79), Russian Federation (0.89) and Pakistan (0.94)\footnote{The problem of very low relative levels of citation in Russia, low level of citation in Asia vs. Europe, very high level of citation in Switzerland can also be seen for the total volume of publications both in Scopus and Web of Science databases (see Kotsemir 2012a, Kotsemir 2012b).}. In general, Western European countries have the highest level of citation per publication among macro-regions\footnote{This phenomenon can be seen for the total number of publications (see Kotsemir 2012a, Kotsemir 2012b).}. In the Asian region the highest level of cites per doc have countries with quite small number of UAV publications. It is already mentioned Hong Kong (with 10.25 "sites per doc" value; 61 publications) and to a lesser extent Israel (7.14; 170) and Singapore (6.58; 257). For comparison China, the second major player in UAV research with 4201 publications, has only 2.43 citations per one publication in average. Other Asian countries with big number of UAVs publications have low value of "cites per doc" indicator: Republic of Korea (3.78 with 794 publications); Japan (4.09 with 603 publications). Russia and Ukraine have the highest level of self-citation among countries with 50 and more publications on UAVs. 49.7\% of publications of Russia on UAVs was cited by authors of these publications. For Ukraine this figure is 44.7\%. Quite high share of self-citation has Finland (34.0\%) (see Table A.2 for details).
3. International collaboration in unmanned aerial vehicle research

Figure 4 depicts the map of cross-country collaborations in unmanned aerial vehicle research in Scopus for 2000 – 2015. This map was plotted using VOSviewer software. The dominance of the United States and China is clearly seen on this map. The United States can be treated as metaintegrator on this co-authorship map due to its dominating role in UAVs research.

Figure 4. Collaboration map of countries in the field of unmanned aerial vehicle studies in Scopus for 2000 – 2015, coloring based on geographical location

Notes: All types of documents and sources indexed in Scopus are included in the analysis. The analysis was done in 2nd decade of January 2016. Country statistics is taken through proceeding Countries are colored based on geographical location: Green bubbles – Asia; Blue – Oceania; Magenta (dark pink) – North America; Violet – Europe; Olive – Africa; Orange – South America

We also can see other key players on this map such as UK, Australia, Japan, South Korea, France, Germany, Italy and Brazil. There are two clusters of collaboration: Asian cluster with the dominance of China, South Korea and Japan European cluster, where key nodes are Italy, Spain, Germany, and France. Australia is included into intercontinental collaboration: cooperation with UK, France, USA, Canada, South Korea and China have high importance for Australia. It should be noted nevertheless that Asian partners for Australia are far less important for Australia than European and North American ones.

According to description from it official website: “VOSviewer is a software tool for constructing and visualizing bibliometric networks. These networks may for instance include journals, researchers, or individual publications, and they can be constructed based on co-citation, bibliographic coupling, or co-authorship relations”. VOSviewer also offers text mining functionality that can be used to construct and visualize co-occurrence networks of important terms extracted from a body of scientific literature”. Its names VOSviewer takes from (Visualization Of Similarities viewer). See more on http://www.vosviewer.com.
China with 3299 publications on unmanned aerial vehicles in Scopus in 2000-2015\textsuperscript{11} has only 354 co-authorship links. China takes here "publish or perish" strategy. Chinese authors are publishing very actively in the field of unmanned aerial vehicles primarily with each other without active (in comparison to the whole volume of publications on UAVs) integration into international scientific collaboration. Other leading Asian countries in UAV research also have low share of integration in international collaboration. India has 77 co-authorship links per 303 publications Republic of Korea has 174 co-authorship links per 646 publications. In leading European countries the level of integration into international scientific collaboration is much higher, than un Asia. United Kingdom has 353 co-authorship links per 786 publications, Germany – 317 co-authorship links per 742 publications, France – 408 co-authorship links per 629 publications.

4. Key organisation in UAV studies

The analysis of publication activity for organisations\textsuperscript{12} with the biggest number of UAVs publication is synthesized in Table A.3. US and Chinese organisations hit global ranking of centers of excellence on absolute number of UAV publications (Figure 5).

![Figure 5. Key centers of excellence on UAVs research in Scopus in 1985 – 2015.](image)

Notes: All types of documents and sources indexed in Scopus are included in the analysis. The analysis was done in 2\textsuperscript{nd} decade of January 2016.

The most productive organisation in UAVs studies in Scopus in 1985 – 2015 is Northwestern Polytechnical University (China, Xi'an) with 592 publications (14.1\% of contribution into total number of Chinese publications). It is followed by: Northwestern Polytechnical University (China, Xi'an) with 457 publications on UAVs (10.9\% of contribution into total number

\textsuperscript{11} Since VOSviewer detects country names from bibliographical descriptions of publications more accurately than Scopus automatic affiliation matching mechanisms the number of publications for each country after proceeding their descriptions trough VOSviewer software is higher than when user takes country data directly from Scopus database.

\textsuperscript{12} We should note here that due to inaccurate indexation of organisation affiliation name by Scopus search engine some publications of a given organization are not linked with this organization automatically. This problem is more serious in non-English speaking countries (see Kotsemir and Shashnov, 2015 on more details on this problem). In other words, Northwestern Polytechnical University (China, Xi'an) in fact has more than 457 publication on UAVs in Scopus for 1985 – 2015.

142
of Chinese publications); Wright-Patterson AFB (Air Forces Base) (USA, Dayton) with 442 publications (6.0% of contribution into total number of US publications); Nanjing University of Aeronautics and Astronautics (China, Nanjing) with 428 publications (10.2% of contribution into total number of US publications). The highest level of citations per one UAV publication among organisations with 75 and more UAV publications for 1985 – 2015 have UC (University of California) in Berkeley (USA, Berkeley): 23.2 cites per doc and University of Pennsylvania (USA, Philadelphia): 22.7 cites per doc. Chinese organisations dominate in the global ranking of organisations on number of publications on UAVs. Meanwhile, they have low level of citations (Figure 5). This figure also show that among the top countries on UAVs studies US organisations have in general higher level of citations per one publication. Table A.3 also helps to detect the key national centers of excellence in UAV studies. E.g. in Switzerland 62.0% of national volume of UAVs publications was done by Eidgenossische Technische Hochschule Zurich (163 publications on UAVs for 1985 – 2015). In Singapore the main national centres of excellence on UAV studies are National University of Singapore (54.1% of contribution into national volume of UAV publications) and National Cheng Kung University (34.2%) (Table A.3). Linkopings Universitet with 90 publications contributed 44.1% of the total number of UAV publications in Sweden.

5. General findings and conclusions

This paper proposed the bibliometric overview of unmanned aerial vehicle research in different countries. The analysis shows the strong domination of the USA in terms of publication activity and number of citations received. Meanwhile we can see the growing importance of China in the last years. By 2015 China became the second greatest country in UAV research. Meanwhile in terms of citations European countries as well as USA and Canada take the leadership while Asian countries (except of small countries like Singapore and Hong Kong) lags behind the leaders. On the level of organisations the US and Chinese organisation are the most productive in UAV research. Meanwhile leading Chinese organisations have much smaller number of citations per one publication than their “competitors” from the USA, Canada and Western Europe.

Several possible directions of further research can be proposed. One of the possible ways for development of this research is a more detailed analysis of international collaboration in UAV studies with focus on individual organisations. The other potential development of this research is running the semantic analysis. Using VOSviewer or the other similar software, we can derive different terms from titles, keywords and abstracts of publications on unmanned aerial vehicles. Further using the algorithms of natural language processing and cluster analysis based on co-occurrences of terms and words in titles, abstracts and keywords of UAV publications most important topics of UAV research can be detected.

Abstract

We developed a systematic methodology for identifying the under-cited (or not-so-highly cited) Sleeping Beauty (SB) publications and tried to figure out their key characteristics. Based on the identification framework of “beauty coefficient” (B) introduced by Ke et al. (2015), taking into account the whole citation history of the publications concerned, we substituted yearly citations in “beauty coefficient” with yearly accumulative percentage of citations, and eliminated the denominator in “beauty coefficient” since the curve of a given document’s accumulative citations is always monotonically increasing if only the document is cited. The value of the modified beauty coefficient is denoted as Bcp. We also redefined the awakening year, sleeping length and sleeping depth within the Bcp framework with the intention of avoiding arbitrary thresholds as much as possible. We tested the new index using the data of SB articles identified from Science and Nature. The results showed that Bcp is more sensitive in identifying the “lower level SBs”, which refers to the case when the total citations and the maximum annual citations of SBs are not so high in comparison with other typical SBs. Bcp works better than B in at least two aspects: (1) it “punishes” the situations when the SBs experienced early citations instead of continuous sleeping; (2) it allows for comparing the extent of delayed citation impact of publications in different fields with different citation patterns. We also figured out some key characteristics of such SB publications and pondered some policy implications about the associations of SB publications with transformative research, research front and research evaluation.

Introduction

A “Sleeping Beauty” (SB) in Science is a publication that goes unnoticed (or “sleeps”) for a long time and then, almost suddenly, attracts a lot of attention, or “is awakened by a Prince” (van Raan, 2004). This concept is actually a quantitative description of “delayed recognition of scientific achievements”, a phenomenon widely discussed in sociology of science (Garfield, 1989). “Premature discoveries” and “transformative innovations” are crucial for the development of science, but they are often initially neglected or resisted by the scientific community and thus are often subject to delayed recognition (Trapido, 2015). In this paper, we try to propose a systematic identification method of SB publications, in order to extend the application scope of citation analysis, and discussed implications for identifying potential “ahead of time” discoveries or transformative research, and shorten time lag for original research to get recognized.

There are three types of methods for identifying SBs in science, i.e., citation curve fitting, arbitrary thresholds setting, and parameter-free index, which were described at full length in our foregoing paper (Du & Wu, 2016). Each of the three methods has both advantages and disadvantages.
Firstly, it is not precise and accurate for identifying SB publications with citation curve fitting since it is inefficient to mine massive publications based on manual observation.

Secondly, the arbitrary thresholds methods include average-based and quartile-based criteria, as well as their combinations. Average-based criteria directly or indirectly referring to van Raan’s definitions on sleeping period, sleeping depth, awakening period and awakening intensity (van Raan, 2004), could better define the never cited or poorly cited papers in sleeping period. While quartile-based criteria could better reflect the extent of citation delay in the entire citation life time of an article. The former is based on a more strict threshold, and the latter a more moderate threshold. But it is statistically difficult to operate for the latter since one paper’s citation history should be compared with that of all papers across the research fields (Costas, Van Leeuwen, & Van Raan, 2010). Both the average-based and quartile-based criteria are arbitrary definitions and do not take into account different citation patterns in various research fields. For example, van Raan defined four main variables, (1) length of the sleep in years after publication; (2) depth of sleep in terms of a maximum citation rate during the sleeping period; (3) awake period in years after the sleeping period; and (4) awake intensity in terms of a minimum citation rate during the awake period. The four main variables can be tuned. He denoted the SBs with these variables with [5,1,4,5] in (van Raan, 2004) and [10,1,10,5] in (van Raan, 2015, 2017). The combination of average-based with quartile-based criteria enhanced the accuracy for identifying sleeping beauties, but the combined method increased complexity and reduced transparency.

Finally, the two main parameter-free index include Citation Delay (Wang, Thijs, & Glanzel, 2015), a contrary indicator of Citation Speed (Wang, 2013), and Beauty Coefficient (Ke, Ferrara, Radicchi, & Flammini, 2015). In our foregoing paper (Du & Wu, 2015), these two parameter-free indices were used to identify SBs published between 1970 and 2005 in the four most prestigious clinical medicine journals, i.e., New England Journal of Medicine, The Lancet, Journal of the American Medical Association and British Medical Journal. We found that because Citation Speed takes the citation curve of the whole citation window into account, by it one could identify the continuingly highly cited papers with "very long" life cycle but could not directly distinguish SB publications. Beauty Coefficient was proved to be a good indicator to identify a SB, but it fails to cover the citation curve after the paper receives its maximum annual citations. Nevertheless, considering three factors including scientifically designed, transparently calculated and simply applied, the Beauty Coefficient is still a relatively better measure.

(Li & Ye, 2016) proposed four rules that should be adhered to in distinguishing SBs in science: (1) the early citations should be penalized; (2) the whole citation history should be taken into account; (3) the awakening time of a sleeping beauty should not vary over time; and (4) arbitrary thresholds on sleeping period or awakening intensity should be avoided. In this paper, we tried to combine the framework of Citation Delay and Beauty Coefficient to propose a new parameter-free index for distinguishing the under-cited sleeping beauties in science.

**Methods and Materials**

**Beauty Coefficient, B**

Beauty Coefficient is based on the comparison between its citation history and a reference line, drawn from its publication year to the year of the peak of citations. Let's call \( t \) the time...
interval after publication and $c_t$ the citation history of the paper. If $c_{tm}$ is the maximum of $c_t$, the straight line $\ell_t$ that connects the point $(0, c_0)$ and $(t_m, c_{tm})$ analytically is described by the equation:

$$\ell_t = \frac{c_{tm} - c_0}{t_m} \cdot t + c_0$$

$(c_{tm} - c_0)/t_m$ is the slope of the line $\ell_t$. For each $t < t_m$ we can compute the ratio between $\ell_t - c_t$ and max{1, $c_t$}, and the definition of B is achieved by summing over these values.

$$B = \sum_{t=0}^{t_m} \frac{t_m}{t_m} \frac{c_{tm} - c_0}{t_m} \cdot t + c_0 - c_t \max\{1, c_t\}$$

The advantage of B is that it does not rely on arbitrary thresholds or on certain percentage. By it we can investigate this phenomenon at a systematic level. But we do not agree with (Ke et al., 2015)’s argument that B can be calculated for any given paper that received at least one citation. For example, for a given paper, if the maximum number of citations received just in the publication year and the yearly citations decreased in the following years, i.e., $c_0 = c_{tm}$, then the reference line does not exist, and thus the value B could not be calculated.

One of the disadvantages of this definition is the high importance given to the peak. B works really well with top class SBs that after discovery have huge numbers of citations every year, but for lower level SBs with less total citations, it gives some unwanted results: many of the papers we had found as SBs had very low B values.

The other obvious disadvantage of B is that the denominator max{1, $c_t$} does not penalize; instead, it may advance early citation accumulation. This runs against the intention of the authors (Ke et al., 2015). We hold that the role of the denominator is just to avoid division by zero, and calculating the ratio with a denominator could lead to the lost of the original information of the citation history.

### Modifying Beauty Coefficient

So, to avoid the dependence of Beauty Coefficient on just one year’s citation history and to reduce the sensitivity of the measure to such extreme SBs, we propose a new measure in order to discover the SBs in the not-so-highly cited publications. Such under cited publications were often ignored in bibliometric related research.

Based on the identification framework of “beauty coefficient” (B) introduced by Ke et al. (2015), taking into account the whole citation history of the publications concerned, we substituted yearly citations in “beauty coefficient” with yearly accumulative percentage of citations, and eliminated the denominator in “beauty coefficient” since the curve of a given document’s accumulative citations is always monotonically increasing if only the document is cited. The value of the modified beauty coefficient is denoted as Bcp. The new beauty coefficient value Bcp for a given paper is based on the comparison between its citation history of annual accumulative percentage and a reference line that is determined only by its publication year and the share of citations in this year, the maximum accumulative percentage of citations received in a year (100% within a multiyear observation period), and the year when such maximum is achieved:

$$Bcp = \sum_{t=0}^{t_m} \frac{1 - c_0}{t_m} \cdot t + c_0 - c_t$$
Similar with (Ke et al., 2015)’s definition, we gave a plausible definition of awakening time—the year when the abrupt change in the accumulation of citations of SBs occurs. We defined the awakening time $t_a$ as the time $t$ at which the distance $d(t)$ between the point $(t, c_t)$ and the reference line $t = t_m$ reaches its maximum:

$$d(t) = \frac{1 - c_0 \cdot t - c_t \cdot (1 - c_0)}{\sqrt{(1 - c_0)^2 + t_m^2}}$$

The awakening time reflect the year when the abrupt change in the accumulation of citations of SBs occurs, not the abrupt change from one year’s citations to other year’s citations. Being able to pinpoint the awakening time may help identify possible general trigger mechanisms behind the said change.

In Figure 1, the reference line denotes that a given paper’s annual citations is equal. Bcp > 0 denotes delayed citations and Bcp < 0 early citations. For a given paper, if the total number of citations received only in the publication year and the yearly citations after publication is zero, then the value of Bcp is -(n-1)/2, n is the age of a given paper. In contrast, if the total number of citations received only in the last year and the yearly citations after publication till the last year is zero, then the value of Bcp is (n-1)/2.

**Figure 1. Illustration of the definition of the new beauty coefficient and the awakening time of a paper.**

In should be noted that the framework of Bcp allows comparing the extent of delayed citation impact of publications in different disciplines with different citation patterns. Bcp depends on the relative shape of the graph shown in Fig. 1 but not on the total number of citations.

**Dataset**

Two parameter-free indices, i.e. Beauty Coefficient (B) and the modified Beauty Coefficient (Bcp) were used to identify sleeping beauties articles published between 1970 and 2005 in *Science* and *Nature.* The total period in which the SBs and their citation data are searched for
is 1970-2015. Thus, 2005 is the last year for publications having in total a ten year time span until 2015. Articles with at least 200 citations, in total 20,000 publications were included in the following analysis.

**Results**

*Bcp works better than B*

*A case study in (Li & Ye, 2016)*

As for the example shown in (Li & Ye, 2016), two papers P1 and P2 were published in the same year, received the same number of citations, but had different citation curves as shown in Fig. 2. Both of them received no citation in the publication year, and reached citation peak at the age of twenty. Citations of P2 were received earlier than those of P1.

![Figure 2. Assumed articles P1 and P2. The upper graph A and bottom graph B are under B framework (yearly citations) and Bcp framework (yearly cumulative percentage of citations), respectively](image)

In terms of beauty coefficient, they have the same reference line. It is calculated that $B_1 = 164.75$ is smaller than $B_2 = 177.95$, although P1 accumulated citations later than P2. It is strange! But within our Bcp framework, it is calculated that $Bcp_1 = 5.075$ is larger than $Bcp_2 = 1.075$. Obviously, P1 has a delayed citation impact than P2. From this case, we can see the new beauty coefficient is better than B. Next, we will validate the new index through a large-scale bibliographic dataset.
We selected top 1% (N=200) sleeping beauty publications with B and Bcp, respectively. There are 133 papers occurred in both top 1% list either by B or by Bcp, and 134 ((200-133)*2) papers only occurred in top 1% list by one index but not by the other index. So, we mainly analyze the 134 discrepant papers. Within our Bcp framework, we redefined two variables: (1) length of the sleep: years in the sleeping period, i.e., the time interval between publication year and awakening year, (2) depth of sleep: the accumulated percentage of citations in the year before the awakening year, that is the accumulated percentage of citations at the end of sleeping period. The difference test between B and Bcp is shown in Table 1.

Significant at the 0.05 level (2-tailed); ** Significant at the 0.01 level (2-tailed)

The average length of sleep of sleeping beauty publications identified by Bcp is significantly smaller than B. In other words, the awaking year identified with B framework is often delayed estimated than Bcp because of the computing mechanism. The average depth of sleep of sleeping beauty publications identified by Bcp is significantly smaller than B. That is to say, Bcp works better than B in penalizing the early citations. Although not statically significant, the total citations and annual maximum citations of sleeping beauty publications identified by Bcp is also smaller than B. Bcp is more sensitive for in identifying “the lower level SBs”, which refers to the case when the total citations and the maximum annual citations of SBs are not so high in comparison with other typical SBs.

We then selected top 0.1% (N=20) sleeping beauty publications with B and Bcp, respectively. There are 12 papers occurred in both top 1% list either by B or by Bcp, and 8 papers only occurred in top 1% list by one index but not by the other index. So, we mainly analyze the citation curve of the 8 discrepant papers. As is shown in Fig. 3, we found that in contrast with B, Bcp works well in penalizing early citations, so that, at parity of the total citations received, the later such citations accumulate, the higher the value of the proposed measure. Bcp takes into account the entire, rather than the partial, citation history of an article, so the extreme sleeping beauty publications identified with Bcp showed a continually increasing trend in terms of annual citations. Such articles demonstrated a delayed but durable citation impact.
The extreme SBs identified by Bcp tend to be the landmark publications of a specific research field and the SBs are often technique and application-oriented work.

As is shown in Table 2, in terms of content analysis, we could see that the top 10 SBs identified by Bcp were all the landmark publications of a specific research field, such as “the first report on …”, or “the classic theory about …”. Three papers were Nobel laureate’s publications. For example, John Maynard Smith’s concept of protein space proposed were assessed by Nature that “1970 Foreshadows concepts now widely applied in studies of molecular evolution, such as genotype-phenotype mapping” (http://www.nature.com/nature/focus/maynardsmith/). It appears that high quality publications tend to encounter delayed recognition and thus showed delayed citation impact.

One is perhaps more inclined to believe that Sleeping Beauties relate to more fundamental and basic, and less to application-oriented work. But a surprising finding is that half of the SBs are application oriented and significantly more cited in patents than ‘normal’ papers (van Raan, 2015, 2017). The scientific non-patent references (SNPRs) represent a bridge between science and technology although they do not necessarily indicate the direct scientific basis of the invention described in the patent. In this study we focus on a particular phenomenon, namely the extent to which the extreme SBs show up as SNPRs. Patent publications were gathered by searching the lens.org, created by Cambia (a non-profit organization in Australia dedicated to facilitating innovation) and Queensland University of Technology. The platform lens.org has linked the world's patent information to most of the scholarly literature with collaborations with CrossRef and National Library of Medicine. We group patent publications describing the same invention in ‘patent families’ to prevent double counting. As is shown in Table 2, six of the top 10 SBs identified by Bcp have been cited by patents, and the SB’s first citation in a patent usually appears to be earlier than the awakening year.

Concluding remarks

In this paper, we developed a systematic methodology for identifying SB publications and figured out their key characteristics. We tested the new index using the data of SB articles identified from *Science* and *Nature*. The results showed that both B and Bcp worked well with top class SBs, but Bcp is more sensitive for the lower level SBs, i.e., the total citations and the maximum number of citations received in a year is moderate. Bcp works better than B in at least two aspects: (1) it “punishes” the situations when the SBs experienced early citations instead of continuous sleeping; (2) it allows for comparing the extent of delayed citation impact of publications in different fields with different citation patterns. We also figured out some key characteristics of SB publications. The extreme SBs are application oriented and significantly more cited in patents than ‘normal’ papers. The SB’s first citation in a patent usually appears to be earlier than the awakening year. These findings demonstrated the potential technical and application-research properties of Sleeping Beauties. Based on the above mentioned analysis, we pondered some policy implications associated with SB publications.

The first is SB publications and transformative research. According to Thomas Kuhn’s “paradigm” concept, there should be two types of innovative research, i.e., cumulative processes and revolutionary breakthroughs. The latter is also called transformative research, which refers to research that shifts or disrupts established scientific paradigms. Identifying potential transformative research early and accurately is important for funding agencies to maximize the impact of their investments. It also helps scientists identify promising emerging works and focus their attention on them. Therefore, it is imperative for us to spare no effort to avoid delayed recognition and to detect SBs as early as possible, in order to promote potentially valuable but not readily accepted innovative research. Transformative research tend to be neglected or resisted by the scientific community initially and this neglect or resistance could be regarded as the key clue for the early prediction of sleeping beauty literature. Publications belonging to so-called transformative research, even when less frequently cited than others, should be given special attention as early as possible, because they may suddenly attract many citations after a period of sleep. We hold that scholars in both scientometrics and library and information science (LIS) should initiate the research for identifying transformative ideas. One could identify transformative research through some text terms (such as "disagree", "overcome", "break", "dispute"...). In order to discern such potential transformative research, we could observe whether the relevant documents get early citation from patents or not, because many Sleeping Beauty documents tend to be technical research in nature and application-oriented.

The second concerns SB publications and research fronts. The research front(s) studies based on citation analysis and visualization methods were one of most important topics in informetrics. However, research front and research frontier are different terms, which translated into same Chinese Word. The former usually took the "fast-highly cited papers" as basic data, and latter tend to be revealed by the delay-highly cited papers from the perspective of scientists, as is shown in terms of the landmark characteristic of the top ten sleeping beauty publications identified with Bcp. The Bcp index proposed in this paper may be used to identify the papers at the sleeping-awakening interface, which provided new tools for arousing attention of the science community to previously overlooked but important research.

The third is SB publications and research evaluation. Since the major achievements often encounter delayed recognition than the hot tracking research, it is recommended that citation
delay reflected by Bcp can be used as an important index to evaluate the academic quality of papers and it is suggested to moderately extend the evaluation cycle. In bibliometric-based research assessment, one should give special attention to papers with a higher value of Bcp, because such papers accumulate their citations slowly and show a longer and durable citation impact.

Abstract
This study investigates the use and citation of CiteSpace, a freely available tool for analysing, detecting and visualizing trends and patterns in scientific literature, by examining how it is used and cited among the articles published in English and Chinese core journals. Results show that CiteSpace is widely used in China along with a substantial uncitedness. The number of Chinese articles using CiteSpace is obviously increasing, while the citation rate of CiteSpace is not increasing over time. Many Chinese authors do not provide sufficient information for identifying CiteSpace. Findings also show that CiteSpace used in English core journal articles is more likely to receive citations than that used in Chinese core journal articles. Moreover, our results demonstrate that there are significant differences in citation counts between sections containing CiteSpace.

Science policy and research assessment

Introduction
Software is important to scientific research: it assists scientists to identify research questions, analyse data, visualize the results and disseminate knowledge; indeed, “just about every step of scientific work is affected by software” (Howison et al., 2015, p. 454). However, the academic value of software has long been undervalued and, even worse, has been ignored in the current publication-driven scientific reward system. Recent years have witnessed a tremendous growth in software which is freely available for academic use (Hannay et al., 2009; Huang et al., 2013). As the value of data is increasingly recognized and a considerable amount of freely available software packages are used in the scientific community (Howison & Bullard, 2016; Thelwall & Kousha, 2016), some scholars argue that software should also be valued as an academic contribution (Hafer & Kirkpatrick, 2009; Piwowar, 2013). The US National Science Foundation (NSF) has recognized software as a valid research output since 2013 (NSF, 2013). Software has also been listed as a scholarly contribution in the UK Research Excellence Framework 2014 (Research Excellence Framework, 2013). Yet, many funding institutions, policy makers and administrators have not recognized software as a valid type of research products (Piwowar, 2013). Therefore, measuring the impact of software is imperative, because which will enable us to have a better understanding of the value of software and help to incorporate software as an integral component in research evaluations and scholarly communication.
Although citation counts is widely used to assess the impact of journal articles and monographs (Kousha, Thelwall, & Rezaie, 2011; Song & Kim, 2013; Cartes-Velásquez & Manterola Delgado, 2014), it still needs to investigate the current status of software citation practice before using citation counts to measure the impact of software. A few studies examining the citation of software in scientific articles have found that software citation practice is not yet customary. Howison’s study on 90 biology articles has found that considerable software packages mentioned in the articles were not formally cited (Howison & Bullard, 2016). Our previous study on articles published in PLOS ONE has also found a similar result (Pan, Yan, & Hua, 2016). Therefore, it is worth investigating the usage of software in full-text scientific articles to demonstrate the academic impact software.

In this article, we examined how software was used and cited in different journal articles and factors affecting citation rate of software. CiteSpace (http://cluster.cis.drexel.edu/~cchen/citespace/; Chen, 2004, 2006), a freely available software tool for analysing, detecting and visualizing trends and patterns in scientific literature, was chosen as the analysis target. As a representative bibliometric mapping analytical tool (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2011), CiteSpace has been used around the world and obtained the most intensive usage in China (Ping, He, & Chen, 2017). We collected journal articles that mentioned CiteSpace by searching several databases including Web of Science and three Chinese databases, and then conducted a content analysis of these articles. We assessed the differences in citation rate of CiteSpace among journals and disciplines. Moreover, we examined whether there were differences between articles which mentioned CiteSpace in the topic fields (including title, keywords and abstract) and articles which did not mention CiteSpace in the topic fields. Overall, we aim to provide a solid foundation for understanding and improving software citation and description, which will enhance software’s status as research outputs and benefit the developers of software.

Data and Methods
The Web of Science (WoS) database and three Chinese full-text journal article databases, including CNKI, Wanfang and CQVIP, were selected as data sources for articles mentioning CiteSpace. “CiteSpace” and “Cite Space” were used as search terms. The time span was limited to 2004-2016 when CiteSpace was developed and largely spread in the world. First, we searched WoS (limited to Science Citation Index Expanded, Social Science Citation Index and Arts & Humanities Citation Index) for all journal articles containing search terms in the topic fields with title, keywords and abstract. Then we retrieved and downloaded the full text of these articles. In total, we obtained a set of 50 full text articles after discarding non-research articles (e.g., editorials, summary of conferences, comments and letters). Second, we searched for search terms in the topic fields (the same as WoS) of CNKI, Wanfang and CQVIP databases, and then limited articles to these published in Chinese core journals. The journals indexed in the Chinese Science Citation Database (CSCD) or Chinese Social Science Citation Index (CSSCI) or Chinese Core Journals List compiled by Peking University (CCJLPU) were regarded as core journals in this study, because CSCD, CSSCI and CCJLPU are widely used for research evaluation in China. We also downloaded the full text of these articles and manually discarded non-research articles to get the second article set. Among the three Chinese full-text journal article databases, only CNKI database provides full text search. To obtain more papers mentioning CiteSpace, we searched CNKI for journal articles containing search terms in the full-text field, and then limited the journals to Chinese core journals. Later, we further refined the results by selecting research articles mentioning search terms only in paper body as the third article set. A total of 1,418 articles (50 from WoS database, 1,368 from Chinese databases) were collected for this study. The search work was ended on 22nd February 2017. Because the three Chinese databases use different subject
classification systems, a journal indexed in more than one of the databases might be assigned to different domains. Since the journals indexed in CSCD has been included in WoS, we assigned each of these journals with articles using CiteSpace to a unique Journal Citation Reports (JCR) subject area based on the subject area that most of its articles belong to.

A content analysis was conducted to investigate the use and citation of CiteSpace in scientific articles. A content-analytic coding scheme for mentions and citations of CiteSpace was created based on the work of Howison & Bullard (2016) and shown in Table 1. Three coders were trained to code these articles. Before they began to code the articles separately, the inter-coder reliability was measured by calculating Fleiss’ kappa (Fleiss, 1971) using ReCal3 (http://dfreelon.org/utils/recalfront/recal3/; Freelon, 2010). The Fleiss’s kappa was scored at 0.951, which is considered as an almost perfect agreement by Landis and Koch (1977).

Finally, Chi-square tests were used to explore the differences of citing behaviour for CiteSpace between English and Chinese Journals. In addition, we also explored the differences between sections containing CiteSpace for citation counts.

Results

Overview

We identified 45 full text articles using CiteSpace in the 50 articles from WoS and denoted these articles simply as WoS group. It was noting that this study focused on papers using CiteSpace rather than papers mentioning CiteSpace. That is, only articles that were affected by CiteSpace were included for analysis. We allocated 45 articles to countries based on first author’s country of origin. We found that China, USA and Brazil had 30 (67% of 45 articles), 11 (24%) and 4 (9%) articles respectively. The left four articles separately came from Romania, Turkey, England and South Africa. This finding is consistent with a recent study on logs of interactive events, which found that China and USA were the top two countries with the most intensity usage of CiteSpace (Ping, He, & Chen, 2017). We identified 1,020 articles using CiteSpace from the gathered 1,368 Chinese articles. Figure 1 displays the distribution of the 1,020 articles across the 274 journals. We observed that most journals (84% out of 274) published less than five articles using CiteSpace, while four journals published more than 50 articles.
Characteristics of the mentions of CiteSpace

The 45 English journal articles are distributed across 18 JCR disciplines. Computer science, information and library sciences, and cell biology have more articles using CiteSpace than other disciplines. They have, respectively, 18, 4, and 4 articles. The 1,020 Chinese journal articles are distributed across 36 JCR disciplines. We found that most disciplines published less than 20 articles using CiteSpace. Table 2 presents the disciplines containing more than or equal to 20 articles using CiteSpace. It suggests that CiteSpace is more frequently used in information and library sciences, management, and education.

The descriptions of software provided in the articles are valuable for identifying and finding software. Among the 1,020 Chinese journal articles, 435 (43%) articles provided the version information of CiteSpace that they used in title, abstract, or article body. In addition, 433 (42%) and 21 (5%) articles, respectively, mentioned the author and the websites of CiteSpace in abstract or article body. It suggests that Chinese authors did not provide sufficient information for finding CiteSpace.

Characteristics of the citation of CiteSpace

Thirty-seven out of 45 (82%) English journal articles provided a formal citation of CiteSpace in the reference list, while 499 out of 1,020 (49%) Chinese journal articles made a formal citation to CiteSpace. The substantial higher citation rate of CiteSpace for the English journal articles might due to all the English journal articles containing CiteSpace in the topic field. In
contrast to the citation rate of software (44%) found in the work of Howison & Bullard (2016),
our citation rate of CiteSpace for Chinese journal articles is slightly higher. This might be
explained by citeable items are provided in the website of CiteSpace.
We then examined the cited references related to CiteSpace. Among the 37 English journal
articles, 34 articles cited a publication related to CiteSpace. 2 provided a citation to a website,
and 1 cited a user’s manual. It shows that authors are more likely to cite publications than
websites and user’s manuals. Twenty-eight articles cite the article “CiteSpace II: detecting
and visualizing emerging trends and transient patterns in scientific literature”, which was
We also found that authors who published in Chinese journals prefer to cite related
publications; 464 articles (93% out of 499 articles) cited a related publication. The top 10
most highly cited items for CiteSpace within Chinese journal articles are shown in Table 3. It
is worth noting that the second most highly cited article is the Chinese version of the first
most highly cited article. Among the top 10 most highly cited items, four publications and the
blog are in Chinese. These Chinese references contribute to the wide use of CiteSpace in
China.

We next compared the citation rates of CiteSpace between different article sets. Thirty-seven
out of 45 (82%) English journal articles provided a formal citation of CiteSpace in the
reference list, while four hundred and ninety-nine out of 1,020 (49%) Chinese journal articles
made a formal citation to CiteSpace. The substantial higher citation rate of CiteSpace for the
English journal articles might due to all the English journal articles containing CiteSpace in
the topic field. In contrast to the citation rate of software (44%) found in the work of Howison
& Bullard (2016), our citation rate of CiteSpace for Chinese journal articles is slightly higher.
This might be explained by citeable items are provided in the website of CiteSpace. We then
classified the 1,020 Chinese journal articles into two groups based on whether they contained
CiteSpace in the topic fields or not. The first group, including 528 articles that contained
CiteSpace in the topic fields, was denoted as Chinese topic group. The second one, including
492 articles which did not contain CiteSpace in the topic fields, was denoted as Chinese main
group. Table 4 shows the usage and citation of CiteSpace in the three article groups during the period of 2007-2016. We can find that there is an over upward trend in the number of articles using CiteSpace in Chinese journal article sets. The average citation rate of the three paper sets is 0.82, 0.59 and 0.39 respectively. The citation rate of CiteSpace out of WoS group is higher than that of two Chinese groups. Moreover, the citation rate of CiteSpace out of Chinese topic group is higher than that of Chinese main group.

Note: A indicates the number of papers using CiteSpace; B indicates the number of papers that provided a formal citation of CiteSpace in the reference list; C indicates the citation rate of CiteSpace which was calculated by B/A.

To further determine whether there is a statistical difference of citing behaviour for CiteSpace between English and Chinese Journals, we employed Chi-square test to compare the citation rate of CiteSpace between WoS group and Chinese topic group using SPSS (SPSS, version 20; IBM Corp., Armonk, NY). A statistically significant difference between the two groups was found (p < 0.05, Table 5). CiteSpace used in English core journal articles is more likely to receive citations than that used in Chinese core journal articles. Moreover, we also assessed the differences between sections containing CiteSpace for citation counts by comparing the citation rate of CiteSpace between Chinese topic group and Chinese main group. We found that Chinese topic group has a lower uncitedness than Chinese main group (p < 0.05, Table 5). We hold that authors put CiteSpace in different sections based on the importance of CiteSpace to their research. That is, authors tend to mention CiteSpace in their articles’ title, keywords and abstract when CiteSpace is very important to their research. While CiteSpace is not very important to their research, they are more likely to mention CiteSpace in article body. Therefore, to some extent, CiteSpace that is important to research is more likely to receive citations.

We classified the 1,020 Chinese articles, according to the disciplines that their journals belong to. We then calculate the citation rates of CiteSpace for the disciplines which contain more than or equal to 20 articles. As shown in Table 6, the citation rate of CiteSpace varies from one discipline to another ranging from 0.29 (Sport sciences) to 0.57 (Communication). It
demonstrates that software citation practices are far from common within the scientific community. A lot of efforts are needed to examine software attribution and improve software citation practices.

Conclusion and Future Work

This paper is part of a large effort to examine the attribution, citation and impact of scientific software. In this article, we collected a total of 1,418 full-text articles from English and Chinese databases, and then undertook a context analysis of these articles to how CiteSpace is used and cited among the articles published in English and Chinese core journals. Moreover, we explored the differences of citing behaviour for CiteSpace between English and Chinese Journals, as well as the differences between sections containing CiteSpace for citation counts. Results show the number of Chinese articles using CiteSpace has increased year by year. CiteSpace was more frequently used in information and library sciences, management, and education. Our results also demonstrate that many Chinese authors did not provide sufficient information for identifying CiteSpace in their articles or provide a formal citation of CiteSpace in the reference list. In addition, findings show that there is a significant difference in citation rate of CiteSpace between English and Chinese Journal articles. Findings also demonstrate that articles containing CiteSpace in title, keywords and abstract are more likely to make a formal citation to CiteSpace than those containing CiteSpace in article body.

Our future work includes collecting more English full-text journal articles using CiteSpace to corroborate the findings of this study. We tend to gather still more articles citing the publications related to CiteSpace. We are also interested to explore the difference of citing behaviour for CiteSpace between Chinese and foreign authors. In addition, we would like to investigate how CiteSpace is diffused over time and across disciplines. Research helps to incorporate software as an integral component in research evaluations and scholarly communication.

Abstract
China has a long and proud history of world leadership in science, technology, and industrial innovation, but in the past two centuries it has experienced a period of political and economic instability that has challenged that leadership. However, since its political consolidation in the middle part of the 20\textsuperscript{th} Century and the subsequent introduction of economic reforms in the late 20\textsuperscript{th} Century, China's rise in science has been meteoric. This rise was first detected by the scientometric community through its indicators, but it has now become obvious. Indeed in 2017 the question, "Will China come to lead world science?" is becoming to some, "Does China already lead world science?" This paper tries to make the case that the answer is "yes" (or at least "soon")—but the answer depends on which metrics one considers. China already leads many countries (including the U.S.) in some measures of GDP, scientific paper production, researchers, plus high technology manufacturing and exports, China recently passed the European Union as a whole in R&D investment. Even in some of those indicators where China has not yet taken the lead, reasonable forecasts predict that it soon will. However, there are some indicators where China is still far behind. For example while rising, it still lags the U.S. and EU in citations in Western publications, and will take years to catch up. It may take decades for China to overcome its lag in Nobel prizes, but the Chinese have a very long view of such goals. Here, these quantitative measures are supplemented by qualitative ones from WTEC assessments and by survey results of scientists and the public, which present a more nuanced conclusion. While Chinese leadership may be difficult for Westerners to accept, it can be viewed as China merely regaining its historical position of leadership in science and technology.

Conference Topic
Country-level studies

Introduction
This paper is the latest in a series by the authors reviewing scientometric indicators to illustrate trends in world leadership of science and technology (S&T). The first was presented at the 2003 ISSI conference in Beijing to measure who was leading the race, but the contestants were then only the United States (U.S.) and the European Union (EU)—the People’s Republic of China (PRC) was not yet a contender (Shelton & Holdridge, 2003). But the spectacular progress of China quickly upended the race. At the 2009 ISSI conference in Rio, indicators and forecasts were presented for a race among the U.S., EU, and China (Shelton & Foland, 2009). The last bullet in that presentation was:

- "I predict that, if present trends continue, the PRC will lead the world by 2017."

In 2017 ISSI is back in China, so how did that 2009 prediction hold up? It was based on forecasts of a dozen traditional indicators with data through 2005. The 2009 paper did not include qualitative assessment by peer review or surveys, which can present a different perspective. And some new indicators have recently emerged that ought to be considered.
Why does it matter which nation leads the world? One reason is the same as in sports, a race can inspire everyone to try harder. Nations struggle to find resources to fund their researchers, and viewing progress as a competition can help with motivations. While science provides global benefits, location does matter for economic prosperity and national security.

Since the 1950s, one goal of the U.S. government has been maintaining world leadership in science, mathematics, and engineering, and there is wide acceptance in the United States of the premise that it remains ahead, albeit with growing doubts. The Chinese Mid- to Long-Term S&T Development Plan (2006–2020) set a goal of doubling national R&D investment intensity to 2.5% of GDP by 2020. China is on track to achieve this goal, as confirmed by the most recent update, a plan for 2016–2020 (McLaughlin, 2016). This increasing investment has clearly paid off in China’s rise in science.

Some bibliometricians were alert to China’s advance in indicators like publications: (Moed, 2002), (Jin & Rousseau, 2005), and (Leydesdorff & Zhou, 2005). In 2006 Zhou and Leydesdorff (2006) made the case that China could already be considered a leading nation in science, particularly in nanotechnology.

This paper will update some of these indicators and provide additional ones. Simple extrapolations then allow some insight into what is likely to happen next in the race for world leadership. The paper will also contrast quantitative results with qualitative indicators, such as survey results from recent surveys conducted by the Pew Foundation and by WTEC. To save space, some data is posted in supplementary material at (Basu, et al., 2017).

**Quantitative Indicators**

There are many metrics that could be used to rank nations. Table 1 lists a selection that the authors consider to be relevant here. Most indicators contain the year when China passed the U.S. and EU, or a forecast of when it is likely to do so. Both the current EU28, and the EU27 without the UK, are shown. Each indicator will be discussed briefly in turn.

**Table 1. S&T Indicators. Entries are for the latest year available. The years (or ?) in parentheses are when China passed the U.S. or EU, or is forecast to pass. EU27 is the EU without the UK.**

</table>
**GDP**

Gross Domestic Product is a nation's output in goods and services. To compare nations one can either use the prevailing exchange rate or purchasing power parity (PPP) weights to compensate for local prices. In the first case, the U.S. still leads China by $18.5 trillion to $11.8 trillion. However, with the more realistic PPP weighting, China passed the U.S. in 2014 and EU28 in 2015 to lead the world in this overall measure of economic output. The pattern in Fig. 1 is typical of many indicators: China starting far below the U.S. and EU, rising rapidly, so that it passes the others or can be forecast to do so soon. Such extrapolations are linear for the U.S. and EU, but quadratic for China, which provides a better fit to the data. All figures use red triangles for China, blue diamonds for the U.S. and green squares for the EU.

**GERD**

Gross expenditure on research and development (GERD) is the most common indicator of national investments in R&D from both public and private sectors. It has been available for decades from (OECD, 2017). There are some 35 member states, plus 7 others that supply comparable data, called the OECD Group (OECDg) here.

For many years, the U.S. led the world in GERD, with the EU as a whole not far behind. However, China has been rapidly increasing its GERD investment, passing the EU28 in 2014. An extrapolation of these trends suggests that China will probably pass the U.S. to lead the world in 2018.

One GERD variant that is particularly useful is the percentage share of world GERD from a particular country. Shelton (2008) has shown that this is a driver for paper share, which explains China's rapid rise in publications at the West's expense. Fig. 2 shows GERD share based on percentages of the OECDg. Using worldwide data from (UNESCO, 2017) would change these curves only slightly, since the OECDg accounts for more than 90% of the world's GERD. Note: EU27 reflects the Brexit departure of the UK.

![Fig. 1. GDP, $Trillions with PPP weights.](image1)

![Fig. 2. Percent GERD share of OECDg nations.](image2)

**Researchers**

The source for full time equivalent (FTE) researchers is (OECD, 2017). While the Chinese passed the U.S. in 2011, they are not likely to pass the EU28 curve until late in the next decade (Fig. 3). However, if the number from the UK is subtracted from EU28, the Chinese already led the world in this indicator after 2014.

**PhD Degrees in Science and Engineering**

The latest Science and Engineering Indicators volume from the National Science Foundation (NSF) has data on PhD degrees (NSB, 2016). In Fig. 4, the 2012 EU figure comes directly from
this source, but is estimated in other years from data there for six large EU countries. China was on track to pass the U.S. until 2009, when they put in a new emphasis on quality. China did pass the U.S. in 2007 in natural science and engineering degrees only. Also there were about 4000 Chinese S&E PhD graduates of U.S. universities in 2012, many of whom went home. The EU will likely retain the overall lead in this indicator indefinitely, even with the loss of the UK.

![Fig. 3. Full time equivalent researchers. The Chinese figure was adjusted in 2009.](image1)

![Fig. 4. PhD degrees in science and engineering. EU is estimated.](image2)

**Paper Shares**

Shelton and Foland (2009) forecasted scientific paper publications in leading nations based on a model that connected publication shares of the Web of Science (WoS) to R&D investment shares in the OECD group of nations (Shelton, 2008). The data available then ran through 2005 when China's output was small fraction of those of the U.S. and EU. Still the model forecasted in 2009 that China would pass the other two about 2017 to lead the world, based on national plans for investments.

The model is a linear relationship between the $i^{th}$ country's share of R&D investment $g_i$ and its share of (fractional count) papers $p_i$, indexed by WoS. The constant of proportionality $K_i$ is called the relative efficiency, and it varies by country—some are more efficient than others. The equation is most useful for countries where $K_i$ is fairly constant, as it has been for the EU, U.S., and China, since the mid-1990s.

$$p_i = K_i g_i$$

To evaluate the success of the model, one needs to compare publications measured on the same basis as the 2005 data, which came from the NSF Science and Engineering Indicators series. These biennial volumes presented data for decades based on a proprietary subset of the journals in the WoS, using fractional counts. With the latest (NSB, 2016) volume, a switch was made to Scopus (Côté, Roberge, & Archambault 2016), making checks of long term trends more difficult. Shelton and Foland (2017) have extended the NSF series with a program to analyze samples of WoS hit lists. The results were checked against another series from the Fraunhofer ISI institute (Frietsch Helmich & Neuhäusler, 2017).

The results show that the 2009 forecast was reasonably accurate (Fig. 5). It now seems likely that China will indeed pass the U.S. about 2017. Its crossover with the EU28 is likely to be a year or two later (2020) than originally forecast, but because of Brexit, China now seems likely to also pass EU27 about 2017 to lead the world in this key WoS indicator. Similar conclusions
can be reached from the Scopus database (NSB, 2016, Fig. 5-24); China likely passed the U.S. in 2014, and linear extrapolations suggest that it crossed EU27 in 2016 to lead the world in scientific publications.

**Patents**

One patent indicator is the count of patents granted in the domestic patent offices of several countries (WIPO, 2017). In 2011 China's own patent office (SIPO) passed the totals in each of the U.S. Patent and Trademark Office (USPTO), the Japan Patent Office (JPO), and the European Patent Office (EPO). For international comparisons, it is better to use an indicator like the Patent Cooperation Treaty structure, which allows filing of patent applications in multiple countries with a single application. The PCT's increasing popularity makes it a fair way to compare countries in a neutral database (OECD, 2017). Figure 6 shows a forecast that China might take the lead in this measure in about 2021.

**Citations**

Citations are a good measure of quality of individual papers, but need at least two normalizations to be credible as an indicator of national quality. One is by field, because some disciplines tend to cite many more references than others. Another is by year, since citations take many years to accumulate. One measure that does both is the Average Relative Citations (ARC) data available from (NSB, 2016). These are based on Scopus through 2012. The ARC is the average across a geographic region of the relative citations for each publication. The relative citation in turn divides each publication's citation count by the average citation count of all of the same type of publication in that field and year. ARC values are presented for the year of publication, showing the counts of subsequent citations.

A chart is available in the supplementary material. It shows that the average U.S. paper gets about 40% more citations than the worldwide average paper, and that figure is fairly constant with time. China is far behind, but gaining. Of course, most of these citations come from Western journals in English; if domestic Chinese journals were included, the picture would be far different. However, in some targeted fields China has actually passed the U.S. in a related measure, the number of highly cited researchers.

**Highly Cited Researchers (HCRs)**

This metric is based on the 250 top cited researchers in the disciplinary categories defined in the WoS. Data on HCRs were earlier given by Thomson Reuters, but since 2016 the data is published annually by Clarivate Analytics (2016). Table 2 indicates the distribution of highly cited researchers in the top countries in two time blocks; the period 1981-1999, and the year 2016. A decade ago, the U.S. had the largest number of citations and also the largest number of highly cited researchers amongst all countries. More recently, there has been a rapid increase in
the number for China and a decline in the number of HCRs in the U.S. China has risen from rank 18 to fourth place in 2016.

In the earlier period there were just 9 HCRs (0.2% share) in China; the number has grown to 185 (5.7% share) in 2016 (Basu, 2006; Basu and Ghosh, 2017). In total terms China is still far behind the U.S., but in certain strategic areas, the HCR numbers are comparable. In particular, in the subject area of materials science, China has 46 HCRs as compared to 43 in the U.S. (Table 3). China is now actually ahead of the U.S. in HCRs in two strategic areas, engineering in addition to materials science.

High-Technology Manufacturing and Exports

A scientometric indicator that can be viewed as the bottom line of the innovation cycle is the performance of high-technology (HT) industries. Data on HT exports have been complied on a cash basis for decades by the OECD (2017). Figure 7 shows that China took the world lead in this measure in 2005 (NSB, 2016). However, these export measures of industrial output do not capture the nuances of where manufacturing really takes place. Recently a new dataset has been developed by the OECD and the World Trade Organization for manufacturing output on a value-added basis, which avoids double-counting of imported components. This more accurate
data, as summarized in (NSB, 2016), allows development of much-improved models that tie these key outputs to inputs like R&D investment (Foland, Fadel & Shelton, 2015). Figure 8 shows some national time series for this measure. Percentages are based on current dollars at the prevailing exchange rate. China likely took the world lead by 2016.

Nobel Prizes

Nobel Prizes are the gold standard metric for scientific excellence (see Table 1). (There are also prizes for literature, peace, and economics, but they are not included here.) Scientists often migrate during their career, which makes counting their nationality somewhat inexact; the approach here is to credit both the country of birth and country at the time of award (Nobel, 2017). Western countries have accumulated a huge head start since the prizes were first awarded in 1907. It will take China a very long time to catch up, but it could compete sooner in prizes in recent years.

Qualitative Indicators

Anecdotal Information from WTEC International Studies

WTEC has conducted over 70 international technology assessment studies since 1989 on behalf of the NSF and other U.S. government agencies, each focused on a field of science or engineering. Most involved site visits by a panel of U.S. experts to leading laboratories, factories, and funding agencies. Because of the expense of study tours, the study topics and the sites to be visited are chosen with extreme care. Prior to 2000, none of the panels visited China, which was an indication that it was not yet considered to be among the leading nations in the topics at hand.

However, since 2000, ten WTEC study panels have traveled to China and conferred with over 400 Chinese researchers. Some of these meetings were during visits to leading labs; some were during workshops organized by WTEC in China. The fact that visits to the PRC were deemed essential to the more recent WTEC studies is another metric of China’s rising status as an international power in S&T.

While space precludes discussion of findings from all these studies, one example can illustrate the trends seen by WTEC panels. This is supercomputer technology, which has been explicitly a race for world leadership since at least 1980. In 2004 WTEC sent a delegation to Japan, which had briefly taken the lead in the race. At the time, China was hardly present in the "Top500" list of supercomputers in operation, much less in development of its own models. However, its progress was rapid, and by 2009 another WTEC delegation evaluated software for modeling and simulation at 59 sites worldwide, including nine in China, where the panel was impressed with their progress. Fast forward to 2016, when China now clearly leads the world.
in supercomputers, with not only the fastest ones, which are also made with indigenous components, but also with as many installed machines on the top500 list as the U.S. (Top500, 2016). While the U.S. and EU still have plans to compete for leadership, they seem to be falling further behind.

An analysis of the findings from other WTEC studies yields a variety of qualitative indicators of (anecdotal information on) China’s rising S&T leadership. The major conclusions are: (1) China is following a long-term S&T investment strategy, including a strong focus on topics of relevance to technology-based economic development and national security. (2) Similarly, China’s long-term strategy for developing its S&T education and high-technology workforce has been extremely effective. (3) As a result, there is an increasing number of specific researchers and institutes that were deemed by the visiting WTEC panelists to be doing world-class work. A synopsis is available in the Supplementary Information (Basu, et al., 2017)

Evidence from Expert Surveys
1. Pew Foundation Survey
The Pew Foundation has periodically surveyed members of the public and members of the American Association for the Advancement of Science (AAAS) for their opinions on the status of U.S. S&T (Funk & Rainey, 2015). While diverse, many AAAS members are life scientists. Some of the findings from the Pew survey are:
- Less than half of AAAS members surveyed believed the U.S. leads the world in scientific achievements. It was 45% in 2014, down from 49% in 2009.
- Responses on this question from the general public are far lower: 15% in 2014, vs. 17% in 2009.
- 29% of AAAS respondents believed the U.S. is the leader in industrial R&D innovation.
- 40% of AAAS respondents believed the U.S. leads in basic research, and 46% believe it leads in doctoral training in S&T.

Pew’s synopsis of the most important findings from the most recent 2014 survey are:
- Both the public and scientists see U.S. scientific achievements in a positive light. But they are critical of K-12 STEM education.
- Scientists are also still largely positive, but less upbeat than five years ago [2009].

2. WTEC Surveys of Scientometrics Authors and WTEC Panelists
WTEC recently conducted a survey to complement the Pew survey with expert opinions on world leadership in S&T. Two samples were queried, each with N = 100 valid responses: (1) authors of recent papers in Scientometrics and (2) experts who have served on WTEC international assessment panels. Both groups can be said to have special knowledge of national standings in S&T. Questions and responses from both samples are available at (Basu, et al., 2017). Two key questions concerned current overall leadership in S&T, and the respondents’ opinions on the status 20 years from now. A chart summarizing the results is shown in Fig. 11. Both groups rated the U.S. as currently leading the world in S&T. However, both groups also agreed that the U.S. position will decline in the next 20 years. About half of both samples thought that China might assume world leadership in 20 years.

U.S. K-12 education in S&T was rated by the WTEC survey respondents as inferior to China's, consistent with international studies like (PISA, 2017). The current K-12 student cohort will be a key part of the scientific workforce during the next 20 years. While there may be systemic problems with the U.S. K-12 S&T education system on average across the whole country, in most countries S&T leaders are likely to come from elite K-12 institutions. Thus, the notion
that its K-12 S&T education in general is deficient does not necessarily mean that the U.S. will not produce an adequate number of world-class S&T leaders for 20 years hence.

More immediately, Fig. 12 shows that, like the AAAS members, many respondents believe the U.S. currently leads in doctoral education. However, if the U.S. is no longer able to attract doctoral program graduates to remain, current advantages in the U.S. doctoral programs may not be translated into future S&T leadership.

Impact of Decreased Accessibility of U.S Science and Engineering Education.

One consideration with respect to science education that may be an important factor in these comparisons between countries is the accessibility of science and engineering education. Raw talent in S&T is not restricted to those of wealthy means. Therefore societies that expect to lead the world in S&T need to nurture those individuals who have that talent, regardless of their economic backgrounds. Because success in science and engineering education requires not only high intelligence, but also hard work, it may even be more likely that gifted individuals of limited means with a strong work ethic, are more likely to excel in these fields than those who have grown up in a life of ease.

A couple of decades ago, technical education in the U.S. was far more affordable than it is today. In the mid-20th Century it was possible for Americans from low-income backgrounds to excel at the K-12 education level, qualify for top-flight U.S. undergraduate programs, and work hard to pay their way through these programs. Then, having excelled at the undergraduate level, these Americans qualified for graduate programs supported by the U.S. Government, and went on to become leaders of late-20th Century science and engineering. And those leaders were accompanied by many of the world's best from abroad. It is not clear that this continues to be the case: College education is increasingly out of the price range of Americans of modest means. Real costs of attending universities have doubled and doubled again in the last 50 years or so, while salaries have stagnated, rising only 10% or so in real terms. And recently there is doubt about whether those talented immigrants will continue to come to the U.S.

Altmetrics Results

Altmetrics are statistics obtained from social media and online resources counting mentions, downloads, reads, tweets, recommendations, Facebook entries and so on, about research papers. They indicate informal ways of noting the relevance of the content, and its importance to the reader. Some of these can culminate in citations, but usually that is a small percentage. The advantage of using altmetrics instead of citations has been discussed by many; see (Fairclough,
2015) and references therein. For one, they give an indication of potential usefulness of a scholarly work much earlier than is possible for citations. Citations take a long time to accumulate, the time delay starting from the point of submission of a paper, through the peer review process, publication delays, being seen by the reader, and finally, the time taken to incorporate the work as a reference. In the case of altmetrics, the paper may be available early, say from an Open Access repository (even prior to publication), and information about it can be immediately tweeted or communicated through blogs, etc. The measure of attention, or altmetric score, given to a paper depends on the frequency of tweets about the paper, as well as the number of downloads, reads etc., on various social media platforms. By this method, one can utilize the enormous data generated on social media based on numerous individual actions, and use it to generate some crowd-based insight.

For country-level estimates, countries differ in terms of altmetric scores, but this is not only due to the quality of their papers. Some countries like China have restrictions on using Twitter and Facebook. Therefore a Chinese paper would lose out on contributions to its altmetric score from readers in China. One of the favoured sites for obtaining altmetric data is Mendeley, a reference manager used by scientists, typically for reference storing and sharing. Mendeley has been examined for reader counts and found to be a useful source of early impact information. It also correlates well with citations (Thelwall, 2015; Wang, 2016). However, some biases such as national dominance of some countries in the use of Web-based social media, and (expected) dominance of junior colleagues over senior (due to greater facility of the young in the use of new technology), are factors that need be taken into account. Thus proper interpretation and international comparisons may be difficult for Web indicators because there are basic national differences in the extent of use of the Web, and as a result there can be large differences in the uptake of the social websites (Thelwall, 2015).

In 2016, results of a study were released by Altmetric.com that looked at 17 million mentions of 2.7 million articles published the previous year. The mentions included news stories, blog posts, tweets, Facebook posts, Reddit posts, articles in F1000 (a manually curated list of excellent papers), Wikipedia citations, and mentions on Mendeley. Researchers from over 440 institutions contributed to the papers that made up the Top-100 list for 2016, with authors spread out over 42 countries. Of the top 100 papers by altmetric score are five papers from China at ranks 3, 43,64, 84, and 86 (Altmetric, 2017).

*One paper was later retracted*

Table 4 shows that only a few Chinese papers got enough attention to be in the top 100 papers by the Altmetric Attention Score. The U.S. and EU have approximately the same number of papers in the list (many of them are common due to collaboration). The Altmetric score per paper is approximately the same for the EU, U.S., and China, but the score per author is considerably higher for China. This is largely due to collaborative papers.
Conclusions
This paper has presented a variety of measures of national science leadership to examine the case for China's resuming its historical leadership of science and technology. Generally, quantitative indicators show that China has made enormous progress in S&T. Some of these indicators show that China is already in the lead, and others forecast that it soon will be.

Qualitative indicators like survey results are less sanguine about China's position; few respondents think that China now leads the world or soon will. However, they believe that China is improving its position and many think that it might pass the U.S. in 20 years or so.

Of course, there are many benefits of science and technology, regardless of where the R&D is done. Science can lead to better healthcare, cleaner air and water, solutions of problems like global warming, improved communications that allow more extensive cooperation and collaboration, and many others. Most of these benefits can accrue to everyone, regardless of their nationality.

Abstract
In Chinese society, guanxi (interpersonal relationships) are involved in everyday social interactions. In the processing of peer review, interpersonal relationships between experts and person to be reviewed often interfere the objectively assessing of evaluation, leading to the review invalid or injustice. According to the requirement of different review and the setting of review threshold, this paper proposes a bold scientific evaluation idea for reasonable quantitative analysis of these relationship. The selection of assessment experts refers to quantitative evaluation of interpersonal relationships and review threshold. In the reviewing process, the selection of expert is combined with a review of appraisal results to make the evaluation result more credible. To verify the feasibility of this study, the instance will be reviewed in the experts’ interpersonal relationships, which will be refined and applied in practical assessment.

Conference Topic:
Science policy and research assessment

Introduction
As one of the highest credibility and most widely used evaluation method in research assessment system, peer review plays an important role in scientific research resource allocation. However, in the processing of project review, guanxi (interpersonal relationships) between experts and person to be reviewed often interfere the objectively assessing of evaluation, leading to the review invalid or injustice. In the reviewing process, expert’s avoidance principle is always applied to reduce the impact of guanxi of experts, making sure that the review is objective and valid. In practically review, with a signal avoidance principle, the review could face dilemmas like the less choice and harder selection of experts. Therefore, how to face the various interpersonal relationships of experts, how to apply the avoidance system flexibly, and how to ensure the justice and authority of the evaluation to the maximum extent are all worth studying.

Kostoff (1997) defines the system of peer review as a comprehensive one, which requires assessment from peer experts of various types rather than from a certain domain. Fisher (1999) focus on the influence of moderators during the review process. Bloom (1999) deems that a rational setting process is the key to obtain high-quality evaluation results. Callaham (2001) deeply studied the phenomenon of conservatism in the process of peer review. Bornmann (2011) investigate scientific peer review. Gleditsch and Nordas et al. (2017) introduced peer review system of Journal of Peace Research. Using public information about the identities of 9000 editors and 43000 reviewers from the Frontiers series of journals, Helmer and Schottdorf et al. (2017) show that women are underrepresented in the peer-review process, that editors of both genders operate with substantial same-gender preference (homophily), and that the mechanisms of this homophily are gender-dependent. Moustafa (2017) investigate either open peer-review fully or blind it wholly. Price and Flach (2017) set up a computational support for academic peer review.

Some scholars have also studied the guanxi in China. Wei and Liu et al. (2010) examined the role of political skill in the dynamics of supervisor-subordinate relationship in Chinese firms,
found that supervisor-subordinate guanxi mediated the relationship between political skill and career development of the subordinates. Gao and Knight et al. (2012) aims to identify critical aspects of Chinese-Western intercultural guanxi relationships that have largely been ignored as a domain for study in international business and industrial marketing, and to suggest a way forward. Chen and Chen et al. (2013) review research on Chinese guanxi and social networking in the past twenty years and identify the major perspectives, theories, and methodologies used in guanxi research at micro and macro levels. Li and Qiu et al. (2016) conducted a quasi-experiment to investigate the effects of two significant cultural values, face and guanxi, on Chinese customers' behavioral responses to hospitality service failures. Zheng and Zhang et al. (2017) study the secrecy capacity of large-scale wireless networks with social relationships. Firstly, this paper summarized and analysed the genetically, industrial, geographical relations between experts and person to be reviewed and weight the possibly influences caused by these social relationships. Secondly, according to the requirement of different review and the setting of review threshold, this paper proposes a bold science evaluation idea for reasonable quantitative analysis of these relationships. The selection of assessment experts is reference to quantitative evaluation of social relations and review threshold. In the reviewing, the chosen of expert is combined with a review of appraisal results, so as to make the evaluation result more credibility. Thirdly, to verify the feasibility of this study, the instance will be reviewed in the experts’ social relations of Shandong Province which will be refined and applied in practical assessment. Chose Shandong Province as an example, for two reasons: firstly, the science and technology development of Shandong Province has synchronized with China’s overall development, secondly, as a province, if avoidance expert in some project review, there will no experts are available. This improved comprehensive evaluation method, not only provides the corrected evaluation of social relations affected by evaluation experts, but also reduces the subjective influence of social relations through different term weighting. This pilot trial have many positive effects, such as the effective and impartiality evaluating in science and technology consulting, and the optimal promotion in technological resources allocation.

Research method

The influence of various interpersonal relationships on peer review

Every expert involved in peer review, who is "social man", has his own interpersonal relationships network. There are a variety of interpersonal relationships between the experts. It is obvious that their social networks are mainly divided into three aspects: kinship, business relationship and friendship relationship. These three kinds of interpersonal relationships affect the peer review to varying degrees.

In this paper, relative relationship is divided into two types of interpersonal relationships: family and relatives. The former mainly includes spouses, parents, children, brothers and other immediate family members. This type of relationship has the most direct impact on peer review, and should be taken a strict avoidance action in the actual review generally; The latter refers to the relatively distant relatives of kinship, and there is no need to strictly avoid it in the actual assessment.

The business relationship, as an important part of the interpersonal relationship network, consists of the most abundant interpersonal relationships, including leaders, colleagues, academic circles, students, teachers, students and so on. In the actual review, these relationships are usually avoided. But there will be many drawbacks if we avoid it absolutely.

Friendship is a relationship based on the common hometown, region, community, hobbies, views and other factors, including the fellow-townsmen, friends, e-pals and so on. Friendship relationship is difficult to obtain, and the definition of it is also a little subjective. In many cases,
we have to ignore the impact of these relationships on the review when finding the interpersonal relationships of experts involved in peer review. However, most private relations (such as genetic relations) involve the privacy issues of experts and can’t be obtained by the current scientific research from the channels such as citizenship. Therefore, this paper mainly chooses expert relationships, which can be obtained from the public information and related to the academic work of the experts. This includes affiliated organization relationships, such as the same workplace, interdepartmental relationships, as well as scientific research collaboration relationships, such as project cooperation, academic exchanges, and collaborative researches and so on.

**The acquisition of interpersonal relationships**

The access to the various relationships included in this paper is shown in Figure 1.

---

**Figure 1. Access to the various relationships included in this paper**

a) All data of the information about teachers, classmates and students should be cleaned according to the expert’s personal resume, so that the accuracy about the information can be guaranteed.

b) This paper obtain the information about the expert’s Chinese papers’ co-authors through visiting the Chinese Knowledge Website (http://cnki.net) and combining the information with the expert’s personal resume, and obtain the information about the expert’s English papers’ co-
authors through Web of Science. The information about both Chinese and English papers are then compared and checked to delete the duplicate data. And finally it draws a list of the expert’s collaborators.

Develop a self-programming, construct an author’s cooperative matrix by processing, cleaning, counting, and analysing the downloaded data of paper-cooperation with the self-programming. Normalize the data, that is, give the statistical frequency distribution of the probability distribution analysis. The linear function conversion is as follows:

\[ Y = \frac{(X - \text{MinValue})}{\text{MaxValue} - \text{MinValue}} \]

in which, \( X \) is the frequency of paper-cooperation, \( Y \) is the assignment of the normalized frequency of paper-cooperation, \( \text{MaxValue} \) and \( \text{MinValue} \) are the maximum and minimum values of the cooperation frequency respectively.

Build the author’s cooperative matrix into the social networking analysis software UCINET, use the built-in Netdraw to carry out the central potential analysis, and draw the network of the expert’s paper-cooperation.

c) Sort out the different relationship between the expert and others, construct the corresponding relationship matrix, and build the constructed matrix into the social networking analysis software UCINET. Use the built-in Netdraw to carry out the central potential analysis, and draw the interpersonal relationships network, in which the value of the interpersonal relationships is represented by the Width of the relationship line.

**Weight setting**

Taking the operability and credibility of the results into account, this paper adopts the method of expert evaluation to set the weight, which is, gather experts’ reviews on the questions to be predicted and give them feedback after organizing, summarizing and collecting all the reviews, and then repeat the procedure until a consensus is reached. And during the weight-setting process, experts are not allowed to discuss with each other or make some linkages, but communicate with the investigators, and give their feedback and revision. Finally, the investigators collect the almost consistent views given by experts as the final result of the expert investigation.

A specialized weight-setting team of 10 members are invited to give quantitative assignment of the various interpersonal relationships in this paper. The formula is:

\[ M_j = \frac{1}{m_j} \sum_{i=1}^{m_j} C_{ij} \]

In which, \( M_j \) represents the arithmetical mean of the interpersonal relationships of the group members to the \( j \) \((j = 1, 2, \cdots, n)\), \( m_j \) represents the number of experts in assessing interpersonal relationships of \( j \), \( C_{ij} \) represents the score that the \( i \) \((i = 1, 2, \cdots, m)\) group member gives on the \( j \) interpersonal relationships.

The value of \( M_j \) varies from 0 to 1. The larger the value of \( M_j \) is, the greater the relative importance of the scheme is.

**Review threshold setting**

A case-by-case review system should be in place because different reviews have different impact on the interpersonal relationships of experts. For example, paper review and reward review differentiate greatly in the principle for setting avoidance on interpersonal relationships. Thus, in the actual reviewing process, the method of expert evaluation is applied to set the review threshold according to the varied requirements for evaluation.

A specialized threshold-setting team of 10 members are invited to give quantitative assessment, fully considering the affecting factors, such as the importance of the review, the project approval rate, the fitting degree of industrial policies and so on. The formula is:

In which, $T_j$ represents the arithmetical mean of the review threshold set by the group members to $j$ ($j = 1, 2, \cdots, n$), $t_j$ represents the number of experts in setting review threshold for $j$, $C_{ij}$ represents the score that the $i$ ($i = 1, 2, \cdots, m$) group member gives on $j$. The value of $T_j$ varies from 0 to 1. The larger the value of $T_j$ is, the more qualified relationship the review has.

Peer Review Method for Interpersonal relationships

After complicated interpersonal relationships of experts are extracted in different ways, different expert interpersonal relationships are given different weights. These relationship analyses are identified and quantified reasonably. At the same time, the review thresholds are set according to different requirements. The selection of assessment experts is based on the quantitative evaluation of interpersonal relationships and the different review thresholds. In the review, we analyse and identify effective interpersonal relationships, weigh the possible impact of them on the review, establish the calculation models of correlations.

In the review, in addition to those who are taken the initiative to ask to avoid by the reviewers, the others to be reviewed need to be compared in the relationship lists. If the value of the relationship is higher than the review threshold, it is necessary to perform the avoidance processing or weight the evaluation result. If the value of the relationship is lower than the review threshold, we can allow them to participate in the review, or weigh the evaluation result.

The overall process is shown in Figure 2:

![Figure 2. Peer review process for interpersonal relationships](image)

Empirical Research

In this section, in order to verify the feasibility of this idea, we will refine the interpersonal relationships of experts and apply to the actual reviews in the following examples. (In order to respect the experts' personal privacy, letters are used instead of the experts' actual names.)
By using the method mentioned above, we can get the information of the colleagues, instructors, classmates, students, and the co-authors of the expert Z. Then we can also refer to the weight value from the expert evaluation method and get the quantitative value of the expert Z’s interpersonal relationships by using simple calculation program designed by ourselves. The partial list is as follows:

<table>

Using the same method, the quantitative value of interpersonal relationships of the remaining experts (expert P, expert Y, expert L, expert W) in the evaluation group can be obtained.

In actual review, we first extract the information of the declarant, the technical director, and the corporation manager of a project, and compare it with the interpersonal relationships personnel of the experts. Then we select the experts according to the review threshold. Assuming that the panellists have set a review threshold to 0.2038, then select the people related to the expert with the expert relationship assignment greater than or equal to 0.2038 to form a list.

In the review, in addition to those who are taken the initiative to ask to avoid by the reviewers, the others to be reviewed need to be compared in the relationship lists. If the value of the relationship is higher than 0.2038, it is necessary to perform the avoidance processing, and that reviewer will have no qualification to review the project. If the value of the relationship is lower than 0.2038, we can allow them to participate in the review, however, it is also necessary to weigh the evaluation result according to the actual requirements of the review if they do have a relationship.

For example, in an annual review of Shandong Province that expert Z participate, the information of applicants including declarants of a certain project, technical directors and managers of the corporations is as follows:

YTB, ZRX, RGD, LZBin, LZBo, TYX, DQ, LJE, PSB, LMH, ZLJ, XYN, YCL, WY, WZG, ZX, QCR, LM, WYu, SDF, GHF, WXbo, WWH, MXP, PRJ.

There are 5 experts in the list of recommended members of the review: expert Z, expert P, expert Y, expert L, expert W.

In the expert Z relationship list, the personnel and the assignment of personnel relations are: LZBin 0.3.

In the expert P relationship list, the personnel and the assignment of personnel relations are: QCR 0.04.

In the expert Y relationship list, the personnel and the assignment of personnel relations are: WY 0.1677, WYu 0.0154.

In the expert L relationship list, the personnel and the assignment of personnel relations are: ZLJ 0.1.
In the expert M relationship list, the personnel and the assignment of personnel relations are: ZRX 0.0056, PSB 0.2056.

It’s easy to distinguish that experts whose relationship assignment are greater than the review threshold of 0.2038 include expert Z and expert W, and that means it is necessary to be judged by the evaluation committee or the management department whether they should be avoided or given the chance to participate in the review. However, the evaluation result should be weighed at last.

The scores of the project given by five experts (expert Z, expert P, expert Y, expert L, expert W) are: 90, 84, 79, 89 and 91.

The project final score got by using the original evaluation method is the average of scores from five experts, 86.6.

If we avoid the expert Z and expert W who own the relationship assignment over 0.2038, the scores given by the other experts are 84, 79, 89, the average of the project “Container terminal production management and control system V4.0” will be 84.

If we don’t avoid them and weigh the scores given by two experts (score/relationship assignment *0.2038), the final score will be: 61.14, 84, 79, 89, 90.2, and the average of the project will be 80.668.

In this way, we can make the score from subjective evaluation more objective, and be able to respond to the public questioning fairly and reasonably.

**Conclusion**

This improved comprehensive evaluation method weighs the possible impact of different interpersonal relationships on the assessment. During the appraisal process, it can analyse and identify the various relationships between the reviewer and the one to be reviewed, as well as quantify them reasonably according to different assessment requirements in order to reduce the subjective impact of interpersonal relationships. It not only considers the influence of the interpersonal relationships of the reviewers, but also reduces the subjective influence of interpersonal relationships by setting different weight. This idea may well have a positive impact on the effectiveness and justice of all kinds of scientific and technological advice and evaluation, promote the optimal allocation of scientific and technological resources and improve the management level of science and technology. This is a meaningful scientific evaluation conception as well as attempt. It fits actual requirements of the development of the current assessment and can be applied to a lot of areas.

This paper focuses on how to reduce the subjective influence of experts’ interpersonal relationships, and puts forward the innovative idea of weighting the evaluation results according to the close degree of interpersonal relationships, or just strictly avoiding them, according to the different relations, which makes the complex comprehensive evaluation more scientific and credible. This improved comprehensive evaluation method can be applied in many fields, and it is suitable for the comprehensive evaluation problem with both quantitative and qualitative evaluation opinions.

The science and technology project evaluation system based on interpersonal relationships is very conducive to scientific research management departments to select peer experts for different projects. Varieties of interpersonal relationships can be visualized in the management system, and the social relation between the commentator and the person reviewed is at a glance. Moreover, the quantitative value of different interpersonal relationships reduces the subjective impact of expert scoring, and thus contributes to a more fair and reasonable, more credible evaluation result.

However, there are a lot of things that need to be improved, such as how to set the weight value, to get rid of the subjectivity. How to set the threshold of the evaluation to be more credible, in the establishment of the network of experts’ guanxi, the problem of the name disambiguation is
more difficult to check, many hidden social guanxi cannot be measured, there are also guanxi
that can be quantified through various channels. The costs involved in a large scale
implementation of the proposed approach seem fairly substantial unless it is possible to
automatize a substantial part of the work. Except for large projects the costs may not be
outweighed by benefits that might be achieved through less cost intensive approaches. Further
research is needed to determine whether this review can be operable in a larger review. The
case presented suggests the involvement of strongly related experts can have a depressing effect
on review scores as well. Further assessments may provide insight in the extent that the apparent
problem is actually strongly prevalent in the Chinese context and/or whether it can be resolved
by the proposed approach.

Abstract
The aim of this study is to demonstrate that microblog communication networks in China present the small-world property based on the theory and method of Complex Network Analysis (CNA). This study selects Tencent Weibo to conduct empirical study, which is one of the most popular microblogs in China. An actual communication network of celebrity users on Tencent Weibo is constructed using the method of snowball sampling, then it’s proved to present the small-world property by calculating its clustering coefficient and average path distance which are the most important two parameters used for identifying a small-world network. The pivotal users of communication network are determined by calculating the node betweenness centrality of each node, which frequently act as the “opinion leaders” in the process of information dissemination. The pivotal relations between users in the communication network are determined by calculating the edge betweenness centrality of each edge, which usually originate from one of the pivotal nodes and may act as the “long-range edges” in the whole communication network. This study provides theoretical and practical foundation for related research on information dissemination on microblogs with the theory and method of complex network analysis.

Conference Topic
Social network analysis

Introduction
The earliest research on small-world phenomenon was published by Milgram (1967) who designed the famous “chain letters” experiment and found that any person in the United States usually could be contacted by any other person passing through six persons on average, which is popular known as the inference of “six degrees of separation”. Watts and Strogatz (1998) found that the small-world phenomenon exists in many biological, technological and social networks which lie between the extremes of completely regular and completely random. Newman and Watts (1999) put forward a small-world network model which displays a normal continuous phase of transition between regular networks and seldom networks in the limit of large system size. Barabási and Albert (1999) further proposed that many large networks have a common property that the vertex connectivities of them follow the scale-free power-law distribution.

The small-world phenomenon has been found to exist in such many disciplines as materials science (Shi and Guan 2016), engineering (Song et al. 2014), computer science (Eppstein et al. 2013), management (Chen and Jaw 2014; Opsahl et al. 2017), economics (Gallo 2012; Sheehan and Young 2015), business (Feyen 2015), psychology (De-Marcos et al. 2016; Sankowska and Siudak 2016) and social science (Seltzer and Smirnov 2015). In the discipline of Library and Information Science (LIS), Hung and Wang (2010) examined and characterized the small world phenomenon in the patent citations network by analyzing the data of radio frequency identification (RFID) patents. Zhu et al. (2013) found that the keyword co-occurrence network of the LIS discipline presented the small-world property based on the keyword data extracted from Scopus. Zhang et al. (2014) examined the evolution...
of small world network and its impact on patent productivity in China based on the patent co-authorship data from State Intellectual Property Office.

In particular, Watts and Strogatz (1998) put forward a random rewiring procedure for interpolating between a regular network and a random network without altering the number of nodes or edges in the graph. The random rewiring procedure is as follows: starts from a regular network of \( N \) nodes with each node connected to its \( K/2 \) nearest neighbors at both sides (\( K \) is an even number), then randomly rewires each of these edges with probability \( p \), and continue this process with self-loop or duplicate edges forbidden. There are \( pNK/2 \) long-range edges are introduced in this rewiring process which connect several non-adjacent nodes. For \( p=0 \), the original graph is a regular network; as \( p \) increases, the graph becomes increasingly disordered; until \( p=1 \), the graph finally changes into a random network. For intermediate values of \( p \), the graph is a small-world network (See Figure 1). This study uses the concept of “long-range edge” to explain the reason for small-world phenomenon of communication networks on microblogs in China.

![Figure 1. The transition from a regular network to a small-world network and finally to a random network using the random rewiring procedure (\( N=20 \) and \( K=4 \))](image)

Microblogs are among the most popular network platforms for information sharing, dissemination and acquisition based on user relationship, for they allow users to exchange small elements of content such as short sentences, individual images, or video links. Different versions of services and software with microblogging features have been developed. Among the most notable services are Twitter, Tumblr, FriendFeed, Plurk, Jaiku and identi.ca. Other leading social networking websites such as Facebook, MySpace, LinkedIn, Yahoo Pulse, Google Buzz, Google+ and XING also have their own microblogging feature, which are better known as “status updates”. Because foreign microblogging services such as Twitter, Facebook, Plurk and Google+ are censored in China, internet users face a different situation and use Chinese weibo services such as Sina Weibo and Tencent Weibo, which are also the most popular two microblogs in China. This study selects Tencent Weibo to conduct an empirical study on the small-world phenomenon of microblog communication networks in China.

**Data**

The empirical data of this study are collected from Tencent Weibo (http://t.qq.com.cn) on February 10, 2017. Tencent Weibo is one of the most popular microblogs in China whose slogan is “Your voice, echoes of the world”. Up to June, 2016, Tencent Weibo has approximately 540 million registered users and more than 100 million daily active users. On Tencent Weibo, several celebrity users have received more attention than a great many of
grassroots users, thus they take a more important role in the communication process of network information and public opinion. In our study, we select celebrity users with more than 6 million followers. We collect data using the snowball sampling method which is a kind of non-probability sampling method.

We randomly select a celebrity user who has more than 6 million followers, then look through his/her followed users, and record those users who have more than 6 million followers, thus we collect user information in the first round of sampling. We repeat the above process of sampling to each user of the first round, thus we collect user information in the second round of sampling. The celebrity user “Kaifu Li” (http://t.qq.com/kaifulee) is the starting point of this process of snowball sampling. We repeat the above process of sampling and finally collect information of 143 celebrity users in three round of sampling. The above 143 users come from Mainland China, Hong Kong and Taiwan and cover such broad areas as business circles, literature and art circles, sports circles and academic circles. It’s fair to say that we’ve got a representative sample of microblog users.

The “following” and “being followed” relationship between above 143 users can be signified in the form of 143×143 1-mode adjacency matrix $Z_{ij}$. The “following” relationship is a unidirectional one, thus the matrix rows signify the followers while the matrix columns signify the followed users, and the direction of edges derive from the followers to the followed users. For each one of above 143 users, if one user appears on another user’s list of followed users, then the value of corresponding matrix element is 1, otherwise the value is 0, and finally constructs a 143×143 binary adjacency matrix $Z_{ij}$. We present visually the adjacency matrix $Z_{ij}$ of this Microblog communication network using the drawing software NetDraw (see Figure 2).

Figure 2. The communication network of celebrity users on Tencent Weibo

The reason that user A follows user B can be summarized as follows: (1) user A is one of friends or acquaintances of user B in their actual social network, and the “following” relationship between user A and B is usually a bidirectional one in this case; (2) user B is a well-known figure in society whose words and deeds have extensive social influence; (3) user B is attracted by the worth and wit of what user A has to say, for example, the grassroots user “We Like to Tell Cold Jokes” has more than 18 million followers, and the “following”
relationship is usually a unidirectional one in the latter two cases. If user A follows user B, the direction of edge in their communication network is from A to B: A→B, while the direction of information dissemination is from B to A: B→A.

Methods

The information communication model of microblog is different from that of traditional media which has a linear propagation model (One to One), and it’s also different from that of network media which has a webbed propagation model (One to N), and it has a emerging circumnuclear propagation model (One to N to N) which allows information to disseminate in a geometrical progression in a short period of time. The information communicates through microblog depending on its users’ social networks which are sets of relationships between social actors. Each actor publishes information in his/her social network, so he/she is both sender and receiver of information, that is, each actor disseminates information through microblog depending on his/her own social network. Thus, we can conduct empirical study of information communication on microblogs with the theory and method of Complex Network Analysis (CNA) and Social Network Analysis (SNA).

Complex Network Analysis

The small-world network is defined as highly clustered like a regular network and yet with small average path length like a random network (Watts and Strogatz 1998). Therefore, the clustering coefficient $C$ and average path distance $L$ are the most important two parameters used for identifying a small-world network.

The clustering coefficient $C$ of a network

Suppose that node $i$ is connected to $k_i$ neighbors via $k_i$ edges. Then at most $k_i(k_i - 1)/2$ edges can exist between these $k_i$ nodes which occur when every neighbor of node $i$ is connected to every other neighbor of node $i$. The clustering coefficient $C_i$ of node $i$ is defined as the ratio of the actual number of edges $E_i$ between the $k_i$ nodes to the maximum possible number of edges $k_i(k_i - 1)/2$, that is, it can be expressed as:

$$C_i = \frac{2E_i}{k_i(k_i - 1)}$$

The clustering coefficient of the whole network is the average of the clustering coefficient of all nodes, that is, it can be expressed as:

$$C = \frac{1}{N} \sum_{i=1}^{N} C_i$$

The average path distance $L$ of a network

The distance $d(i, j)$ between the nodes $i$ and $j$ in a network is defined as the number of edges in the shortest path connecting node $i$ and node $j$. The average path distance $L$ is defined as the number of edges in the shortest path between two nodes averaged over all pairs of nodes which can be calculated with the following formula:

$$L = \frac{2}{N(N+1)} \sum_{i \neq j} d(i, j)$$

where $N$ signifies the number of nodes within a network, $i$ and $j$ signify the nodes in a network, and $d(i, j)$ signifies the distance between the nodes $i$ and $j$. 
Social Network Analysis

The concept of “betweenness centrality” was firstly put forward by Freeman (1979) who applied it to analyze the importance of individuals in a social network. The betweenness centrality measures to what extent a node or an edge can control other nodes or edges. A node possibly performs an important mediation function if it exists amid several pairs of nodes. Even if the degree of this node might be relatively low, it is still a significant node within the network. Therefore, this study uses betweenness centrality as a measure to determine pivotal nodes and edges.

The node betweenness centrality

The node betweenness centrality measures to what extent a node can control the information communication between other nodes in a network. A node with a high betweenness centrality has the capacity to facilitate or limit interaction between the nodes it connects, and thus it has the capacity to control (bridge) the information dissemination within a network (Hung and Wang, 2010). For a given node \( n_i \), the node betweenness centrality \( C_B(n_i) \) of node \( n_i \) can be calculated as:

\[
C_B(n_i) = \sum_{j<k} \frac{g_{jk}(n_i)}{g_{jk}}
\]

where \( g_{jk} \) is the number of geodesics connecting nodes \( j \) and \( k \), while \( g_{jk}(n_i) \) is the number of geodesics connecting nodes \( j \) and \( k \) which pass along the node \( n_i \). The node betweenness centrality \( C_B(n_i) \) of node \( n_i \) usually can be normalized as:

\[
C'_B(n_i) = \frac{2C_B(n_i)}{(N-1)(N-2)}
\]

where \( C'_B(n_i) \) signifies the normalized node betweenness centrality of node \( n_i \), \( N \) signifies the number of nodes within a network, \( (N-1)(N-2)/2 \) is the maximum possible value of node betweenness centrality, which is that of the star graph consisting of \( N \) nodes.

The edge betweenness centrality

The edge betweenness centrality measures the number of an edge occurring on the geodesics between two nodes. It measures to what extent an edge can control the information dissemination in a network. For a given edge \( l_i \), the edge betweenness centrality \( C_B(l_i) \) of edge \( l_i \) can be calculated as:

\[
C_B(l_i) = \sum_{j<k} \frac{g_{jk}(l_i)}{g_{jk}}
\]

where \( g_{jk} \) is the number of geodesics connecting nodes \( j \) and \( k \), while \( g_{jk}(l_i) \) is the number of geodesics connecting nodes \( j \) and \( k \) which pass along the edge \( l_i \).

Results

The total number of edges in the Microblog communication network is 2,114, so its average number of edges per node equals 2,114/143=14.78. We construct a seldom network with almost the same average number of edges per node \( (K=15) \) using the social network analysis software Ucinet 6.2, then compute the clustering coefficient and average path length of the actual communication network and constructed seldom network. Table 1 shows the average path length \( L \) and clustering coefficient \( C \) for the actual network compared to the random network with almost the same number of nodes \( (N=143) \) and average number of edges per node \( (K=15) \). The average path length \( L \) of the actual network is almost the same with that of the random network, but the clustering coefficient \( C \) of the actual network is much more than that of the random network, which shows that the actual network possesses obvious small-

The pivotal edges (relations) which influence the information communication within the whole network can be determined by computing the edge betweenness centrality of each edge. Table 3 shows the top 12 pivotal relations ranking with their edge betweenness centrality whose edge betweenness centrality are much more than most other relations in the communication network (>142). It can be found that the majority of 12 pivotal edges originate from one of above 10 pivotal nodes, that is, one of two vertices of the 16 pivotal edges is likely to be the above 10 pivotal nodes.

Discussion
This study constructs a communication network of celebrity users on Tencent Weibo using the method of snowball sampling, compares the clustering coefficient \( C \) and average path distance \( L \) of the actual communication network with the corresponding random network which are the most important two parameters used for identifying a small-world network, and finds that the communication network presents the small-world property for its clustering coefficient \( C \) is much more than that of the random network keeping their average path distance \( L \) nearly equal. The pivotal nodes and edges of the communication network are found by analyzing the betweenness centrality of each node and edge, which play an important role in the process of information communication in the whole network. These pivotal edges usually originate from one of the pivotal nodes and they may act as the long-range edges in the communication network, which significantly reduce the average path distance at the same time maintaining a high clustering coefficient, thus the whole network present the small-world property. To determine the pivotal nodes and edges contributes to guide public opinion and to deal with emergencies through microblogging platform. The pivotal nodes frequently act as the “opinion leaders” in the process of information dissemination, with the aid of “long-range edges” of the communication network, internet public opinions can rapidly diffuse among the whole communication network on microblogs.

Abstract
This paper aims to explore the international development of research on library and information science in China, including the four regions of Mainland China, Hong Kong, Taiwan, and Macau. We conducted a bibliometric analysis of publications written by Chinese authors in library and information science based on Social Science Citation Index between 1993 and 2014. The result shows that China’s SSCI papers in LIS are growing at a rapid speed. After 2008, the Mainland China surpassed Taiwan to become the largest region by the number of publications in LIS. WuHan University, Taiwan University, City University of Hong Kong are respectively the most productive institutions in Mainland China, Taiwan, Hong Kong. Ronald Rousseau is the most cooperative scholar with Chinese scholars who has made great contribution to promote the internationalization of Chinese library and information science. There is still a big gap on citation among Mainland China and Taiwan, Hong Kong.

Mapping and visualization
The application of informetrics on evaluation

Introduction
With its fast economic growth, Chinese government put plenty of money into the education to promote the internationalization of education in recent years. R&D expenditure in China has risen steadily over the years, with an annual growth rate of 23 % during the 2000s (Wang 2015). Therefore, China has exhibited an exponential growth with its scientific research output. China is one of the countries with a large number of scientific papers which are indexed by the Science Citation Index-Expanded database. But China’s scientific research output varies greatly across disciplines. Compared with the natural sciences, the social sciences in China still have a certain gap on internationalization. So many colleges in China ask their teachers of social sciences to publish more papers on internationalizing journals, especially those indexed by the Social Science Citation Index database.

The library and information science in China has experienced a fast development in this background. More and more Chinese students go to foreign LIS institutes for further studies. The cooperation and communication between Chinese and foreign institutes in LIS is becoming more and more frequent. In order to explore the internationalization and the research status of LIS in China, a bibliometric analysis base on SSCI has been made. Many studies use bibliometric tools to reveal the development situation of scientific production in a specific domain. Huang Youliang et al(2015) conduct a retrospective bibliometric analysis of articles about traditional Chinese medicine research. Sui Xiaoyun et al (2015) performed a bibliometric analysis of published research papers related to the Mekong River during 1991-2012. The study also made the comparative analysis of publications among three regions from China to understand the development of LIS in China, including Mainland China, Taiwan, Hong Kong and Macau.
Methods

Data source
The data of this study is from the online database of the Social Science Citation Index, SSCI, among Web of Science Core Collection. Articles from the four regions of China were identified by authors’ addresses. The search phrase used to search address for this study was “China or Hong Kong or Taiwan or Macau”. Then, web of science category was used to refine the research results focusing on the category of information science & library science. Publications that document types are Article and Review were selected for this study.

Time span
The time duration of most bibliometric articles is five, ten, fifteen or twenty years. This method of selecting is easy to understand, but to some degree it is a bit subjective. In this study, we determined the time span of research according to number of articles each year. Prior to 1992, there are fewer SSCI indexed articles written by Chinese authors in LIS each year, the maximum number of documents is 11. After that, the number of articles written by Chinese authors is steadily increasing each year. So the time span of this study was identified from 1993 to 2014. In total 3160 research articles written by Chinese authors published from 1993 to 2014 in LIS were considered for this analysis with 103 articles excluded before 1992. The first author and corresponding author are considered to have more contribution to papers. Therefore articles with first author’s address from China were selected for this study. There were 66 articles without first author address information from Web of Science that were identified by corresponding author addresses. In last 2655 articles with first author’s or corresponding author’s addresses from China were selected.

Data analysis
The documents records of 3160 articles with full bibliographic information were downloaded in plain text format from web of science. We made a java program to deal with these .txt files. We converted these txt files to Excel files by the java program and then performed the bibliometric analysis.

Results

Total number of articles
From 1993 to 2014, Chinese authors published 2655 papers in SSCI journals of LIS. Table 1 shows article number of four regions of China. Among these papers, 1205(45.4%) were from Mainland China, 982(37%) from Taiwan, 464(17.5) from Hong Kong, only 4(0.1%) from Macau. The Mainland China has become a major contributor in the field of international library and information science in China.

Distribution of publication yearly

According to SSCI there are 2655 articles written by Chinese authors during the period from 1993 to 2014 in LIS. Results of publication output by year are shown in Fig. 1. It is not difficult to find that the growth trends of publication in total and publication in Mainland China are similar. The 2002 is a dividing line. Before 2002, HK&MC is more than the number of documents in ML and TW. After that ML and TW increased over HK & MC, but in different way. Though from 2003 to 2008 TW is growing faster than ML, ML rises sharply after 2008 exceeding TW. On the whole, the number of publications in HK&MC is stable, and the growth is slow. TW maintains a steady growth rate after 2000. ML keeps a rapid growth rate after 2008 and the gap between ML and TW is gradually expanding since 2012.

Fig. 1 Output of articles published by authors from the Mainland China (ML), Hong Kong (HK) & Macau (MC), Taiwan (TW) by year during 1993-2014

Distribution of Journal

Through the analysis of the published journals, we can find out the preference of the Chinese authors in the SSCI journals of LIS. Table 2 to 4 list respectively the top 10 journals published by authors from Mainland China, Taiwan, Hong Kong and Macau. SCIENTOMETRICS is the largest number of published literature journals in Mainland China and Taiwan. The largest number of literature journals in Hong Kong and Macau is INFORMATION & MANAGEMENT. This shows that the Mainland China and Taiwan scholars in LIS are more concerned about the field of scientometrics. Hong Kong and Macau scholars are interested in information management. There are four journals that appear in all the three lists, JOURNAL OF THE ASSOCIATION FOR INFORMATION SCIENCE AND TECHNOLOGY, INFORMATION PROCESSING & MANAGEMENT, JOURNAL OF INFORMATION SCIENCE, INFORMATION & MANAGEMENT.

Most productive institutions

Table 5 shows respectively the top 5 institutions ranked by the number of published literature from Mainland China, Taiwan, Hong Kong and Macau. Wuhan University has an absolute leadership position in LIS in Mainland China with 148 articles. Wuhan University is
the first institution in Mainland China to carry out the education of library and information science, which has a wide range of influence at home and abroad in the field of library and information science. Chinese Academy of Sciences with 98 articles is in the second place in Mainland China. The following is Zhejiang University with 64 articles, Peking University with 62 articles and Tsinghua University with 49 articles. In Taiwan, National Taiwan University is the most productive university with 126 articles, City University of Hong Kong with 126 articles lead the list in Hong Kong and Macau territory. From the three top lists, the mainland universities are in a dominant position, WuHan University is the most productive institution in China.

Highly-cited papers

Highly cited articles are worth analyzing because of the potential association between high citation counts and high quality research. Thought the analysis of highly cited articles we can learn the general information about the issues on which Chinese scholars are focusing and doing research. Table 6 to 8 respectively present Top 5 highly cited papers from Mainland China, Taiwan, Hong Kong and Macau. The most cited article is from Taiwan which published in SCIENTOMETRICS in 2004 with 517 times. Highly cited papers in China are concentrated on INFORMATION & MANAGEMENT, SCIENTOMETRICS, INTERNATIONAL JOURNAL OF INFORMATION MANAGEMENT, INTERNATIONAL JOURNAL OF GEOGRAPHICAL INFORMATION SCIENCE. The total citations of this top five articles in Mainland China, Taiwan, Hong Kong & Macau are respectively 373, 1823 and 1131. This shows that the literatures from Taiwan have a high influence in the discipline of international LIS, followed by the Hong Kong. The citation frequency of literatures from Mainland China is low. Compared to Taiwan and Hong Kong, there is a large gap on citations of papers in Mainland China.

Coauthorship network

Coauthorship network is a very important form of social network. There are many studies conducted by researchers to reveal the development status and structure of disciplines. Erjia Yan et al. (2010) constructed the mapping library and information science in China from 2002 to 2007 by a coauthorship network analysis. There are many tools to construct and visualize the coauthorship network, such as VOSviewer (van Eck 2010, Waltman 2010), CiteSpace (Chen, 2004, 2006; Chen et al 2010), The Science of Science (Sci2, Sci2 team 2009). In this paper, we use the Sci2 to build the coauthorship network of Chinese authors indexed by SSCI in LIS. Sci2 is a new knowledge mapping tool designed by Katy Börner team from Indiana University. Sci2 is a modular toolset specifically designed for the study of Science. The tool allows users to create various bibliometric networks and maps based on Web of Science.

There are 4407 nodes (authors) and 9331 edges (coauthorship) among these authors in this data set. The average degree is 4.2, which means that the average of 4.2 authors in an article. There are 460 weakly connected components and 150 isolated nodes. The coauthorship network is not weakly connected. The largest connected component consists of 3261 nodes. All vertices and edges in a graph will be some problems, such as the display is not clear, the tag overlap. We extracted top 200 nodes by number of authored works from the coauthorship network. The top 200 authors collaborative network visualization results are shown in fig 2. The author with the largest number of collaborators (64) is Ronald Rousseau, who is the president of the international society for scientometrics and informetrics. The following is Huang Mu-hsuan (55) from Taiwan university. In the field of international library and information science, there are
two active groups in China, one is for the leadership of Ronald Rousseau, the other is for the leadership of Huang Mu-hsuan. Ronald Rousseau is very well-known foreign scholar in LIS of China, who has worked with many Chinese scholars and institutions, is committed to promoting the research of LIS in China and strengthening the relationship between China and the world in the field of library and information science.

Conclusion

This paper studies the international development of research on library and information science in China from 1993 to 2014, including the four regions of Mainland China, Hong Kong, Taiwan, and Macau. We have witnessed the growth of the Chinese literatures indexed by SSCI in LIS, especially the Mainland China, which has surpassed the Taiwan and Hong Kong regions. The Mainland China is the leader in the study of library and information science on the number of published literatures. However, the mainland scholars’ papers are cited less frequently, the international influence is low in LIS, and there is a certain gap between Taiwan and Hong Kong scholars. Therefore, the Chinese mainland scholars should continue to improve the quality and impact of papers. It is necessary to strengthen cooperation and exchanges with academic institutions from other countries and regions, thereby enhancing the overall quality of mainland scholars and promoting the internationalization of library and information science in China.

Abstract
Proceeding from results of an earlier pilot study usage and citation impact data from the 2013 annual volume of the Web of Science Core Collection (WoS) were collected and used to build indicators. Besides basic indicators on citation impact, usage counts and international collaboration, we applied the method of Characteristic Scores and Scales (CSS) to analyse the distributions of citations and usage counts to further test the relation between the usage and citation impact. The results could confirm and extend the results of the previous study to a larger set of subjects and countries. In addition, a new journal metric, the Journals Usage Index, is proposed to supplement journal impact measures by a usage based index.

Conference Topic
Usage data; The application of informetrics on evaluation; Indicators

Introduction
In a recently published pilot study, the authors investigated the relation and distributions of citations and usage counts for three countries with similar publication output and five selected fields in the sciences and social sciences as a pars pro toto exercise (Chi & Glänzel, 2017). The Web of Science Core Collection (WoS) daily-updated usage counts were analysed to measure the level of interest in a specific item. In order to do so, typical citation indicators have been calculated for their counterparts based on usage counts and compared with indicators of citation impact.

So-called usage statistics are provided by Clarivate Analytics (formerly Thomson Reuters) along with its Web of Science Core collection. According to Pringle (2015, p.1):

“This count measures the level of interest in a specific item on the Web of Science platform. The count reflects the number of times the article has met a user’s information needs as demonstrated by clicking links to a full-length article at the publisher’s website (via direct link or OpenURL) or by saving the metadata for later use.”

These counts may be an interesting supplement to citation indicators at practical any level of aggregation since unlike altmetrics indicators, which are devised to measure the impact on the general public, usage focusses again on communication among scholars (Pringle, 2015). The results showed that citations and usage counts in WoS correlate significantly. The application of Characteristic Scores and Scales (CSS) to the samples proved the usefulness and robustness of the method also in the context of usage distributions. In the present study, we aim at deepening the results of the pilots study by extending the dataset to a complete annual volume of the WoS, broadening their scope to disciplinary and journal analysis to gain reliable and consolidated new insights of mote general validity. We also propose a new journal indicator,
the journal usage index, based on usage counts alongside with the traditional journal impact measures. Although all indicators are calculated for the complete dataset, we present, because of space limitation, only a selection of subject fields, disciplines, journals and countries. Further data will be presented in an extended version of this study and are available from the authors on request.

Data sources and data processing

All indicators built in this project and calculated for this study are based on bibliographic items extracted from the Science Citation Index Expanded (SCIE), Social Sciences Citation Index (SSCI) and the Arts & Humanities Citation Index (A&HCI) of Clarivate Analytics WoS database. Only “citable items”, i.e., documents of the type article, letter and review have been taken into account. For this study the volume year 2013 was used with an observation period of three years, i.e., 2013–2015 for citation and usage data. At this point we have to mention that the WoS used for this study are not downloaded from the online version of the database but taken from custom datasets provided by Clarivate Analytics. Documents have been assigned to the 16 major fields and 74 subfields according to the modified Leuven-Budapest classification system (see Glänzel, Thijs & Chi, 2016).

Methods and Results

Usage-count based macro-level measures

Proceeding from the scenario of our previous study (Chi & Glänzel, 2017), we have first selected five major fields for the presentation and analysis of data in this paper as well. Later on, in the course of the study we will zoom in on subfields (disciplines) and finally on the journal level. We will present the selected fields, disciplines and journals as examples being part of broader research areas that cover research in the life sciences, natural sciences, mathematics and social sciences. We have processed data on all major fields, disciplines and journals. The data and results of which will be made available in the supplementary online material of a later extended version of the paper according to the policies and guidelines of the journals where the study will be published. However, we start the exercise with the highest hierarchical level to gain insight into the peculiarities of scholarly communication in different broad but still quite heterogeneous areas of scientific research. In the second part, the disciplinary analysis will also take the subject-specific peculiarities into account to extend the analysis to more homogeneous subjects.

The five selected major fields representing natural sciences, life sciences and social sciences, were selected to analyse the relations between usage and citation impact, also taking the effect of international collaboration into account. The fields are Chemistry, Mathematics and Neuroscience & Behavior; furthermore, we selected the diversified but focused topics of non-internal medicine specialties (Clinical and Experimental Medicine II in the Leuven-Budapest subject classification scheme – cf. Chi et al., 2015) and economic, political & legal studies within the social sciences (Social Sciences II in our classification scheme). Here we stress again that we only present selections of fields and countries in this study.

Table 1 gives the basic indicators for four of the five fields (neurosciences will be used later, in the context of journal indicators) and a selection of 15 out of the most active countries in all fields combined and the world reference standard. We use the following basic indicators: number of papers in 2013, the mean citation rate in a 3-year citation window (MCR), the share of uncited papers in the same window (c(0)), the mean citation rate of internationally co-authored papers (MCRint) along with the corresponding indicators based on the usage counts,
i.e., mean usage count (MUC), the share of papers with zero usage in the 3-year observation window \(u(0)\) and the mean usage count of internationally co-authored papers (MUCint).

![Scatter plots of MCR vs. MUR of countries with at least 100 papers in four fields.](image1)

**Figure 1.** Scatter plots of MCR vs. MUR of countries with at least 100 papers in four fields.

![Scatter plots of c(0) vs. u(0) of countries with at least 100 papers in four fields.](image2)

**Figure 2.** Scatter plots of c(0) vs. u(0) of countries with at least 100 papers in four fields.

However, before we have a closer look at the data shown in Table 1, we will analyse the more general trends based on all countries with at least 100 paper each in the fields under study. Figure 1 and Figure 2 show the correlations between MCR and MUR and between c(0) and u(0).
u(0). The relation between MCR and MUR is more influenced by subject than the relation
between uncited or unused papers. In Figure 1, papers in chemistry show a trend to have high
usage when they are highly cited. This trend is not that strong in mathematics, compared to
other fields. The low citation and usage data in the field may be a reason of this weak
correlation. By contrast, lowly cited and used papers are highly correlated with each other in
all the fields as shown in Figure 2. It reveals that “uninteresting” papers would not arise
attention from the community either in its citing or using behaviour.
In the first place we observe a generally higher usage than citation impact in Social sciences II,
where the factor for “translating” impact to usage amounts to 7.6 followed by chemistry with
5.6. In mathematics we find a more moderate situation: one citation “corresponds” to 3.4 usages
and clinical medicine II forms the low-end here with 1.9. The usage range between 1.9 and 7.6
already points to subject-specific communication patterns of scientists in different fields.

Internationally co-authored papers generally have higher citation and usage impact than all the papers. The large increases of citation and usage caused by international papers are specially obvious in the social sciences. Compared to usage data, citations have the larger differences between these two types of papers in all the four fields.

Inspired by the relational charts for the presentation of relative indicators (see Braun, Glänzel & Schubert, 1985; Schubert & Braun, 1986), we show the plot of the Relative Citation Rate (RCR, see Schubert & Braun, 1986) vs. Relative Usage Count (RUC). For simplicity we have just divided the countries’ indicator values by the corresponding field standard of the world total. The “relational charts”, where the neutral value of 1.0 is indicated by horizontal and vertical lines and the coincidence of relative usage and citation impact by a diagonal line, are illustrated in Figure 3 for the four selected fields and the 15 countries. In general, developed countries are located in the upper right quadrant whilst developing countries are presented in the lower left quadrant.

Besides the country specific features, such as the low values in both citation impact and usage for Brazil, South Africa, Iran and Poland contracted by high values of Switzerland, Denmark, Belgium, Australia and Singapore, we find quite interesting subject-specific details for some countries reflecting national preferences and capacities. Iran’s high impact and adequate usage in mathematics is striking, which is contrasted by low indicator values in this field. The same applies to the usage data of Germany and France. Denmark’s citation impact is not outstanding here, either. Instead, it has much better citation performance in clinical medicine and the social sciences. Singapore has remarkable performance in terms of both indicators in the most fields except for clinical fields.

Usage CSS

Characteristic Scores and Scales (CSS) are obtained from a recursive procedure of iteratively truncating a sample at its mean value, recalculating the mean of the truncated sample and continuing this procedure until it is stopped, when the pre-set number of thresholds is reached or no new scores can be obtained. We give only a short mathematical explanation here, while a more detailed and formalised description can be found in previous studies by the authors (e.g., Glänzel, 2007).

Let \( X \) denote the random variable represented by the sample. Putting \( b_0 := 0 \) as the very first characteristic score, we then obtain the subsequent scores as \( b_k := E(X|X \geq b_{k-1}) \) for all non-negative integer values \( k = 1, 2, \ldots \). Usually we stop the procedure at \( k = 3 \). We just mention in passing that for a Lomax/Waring distribution underlying the sample we obtain a very interesting property, particularly

\[
b_k = E(X|X \geq b_{k-1}) = a \cdot b_{k-1} + b_1 = N^{\alpha}(a^{k-1}) \text{ with } a = \alpha/(\alpha-1); \ k = 1, 2, 3,
\]

where \( \alpha \) is the “tail” parameter of the distribution. The probability of being in the intervals \([b_{k-1}, b_k)\) between two adjoining scores amounts to \([a^{-\alpha}]^{k-1}(1-a^{-\alpha})\). These intervals define the “performance” classes from “poor” (Class 1) to “outstanding” (Class 4).

Turning theory to practice, we proceed from a suited bibliometric sample or dataset. Note that the sample needs not necessarily be a random one. This could, for instance, be a set of papers published in a given discipline and the variable \( X \) stands for citation rates, or usage counts. If the tail parameter is in the neighbourhood of the value 3, we have \((1-a^{-\alpha}) = 0.7037\) for \( \alpha = 3.0 \) and obtain a theoretical distribution of objects over classes 1 through 4 roughly following a 70%–21%–6.5%–2.5% rule. This rule of thumb could be empirically confirmed in the literature (Glänzel, 2007; Albarrán & Ruiz-Castillo, 2011; Chi & Glänzel, 2017; Glänzel, Thijs & Debackere, 2018).

Taking into account the different standards of citation impact and (assumably) also of usage in the major research fields, we break down data into the more homogeneous discipline level since the calculation of the CSS scores and classes requires at least this level of granularity (cf. Glänzel, Thijs & Debackere, 2014). In order to illustrate the subject dependence of characteristic scores and the relative insensitivity of performance classes defined on them, we show first the \( b_k \) values for the WoS 2013 volume and twelve of the 74 subfields according to the Leuven-Budapest scheme in a three-year observation window based on both citation impact and usage counts in Table 2. The selected subfields comprise biosciences, internal and non-internal medicine, chemistry, physics, engineering, and the social sciences and one each from mathematics, geo- and space sciences and neurosciences. The number of papers assigned to these disciplines is sufficiently large as it ranges between roughly 15,000 and almost 60,000.

If we compare the scores of citation impact and usage counts in the same discipline, we find the same typical patterns as pointed to in the previous section. Here the two extremes are particle & nuclear physics with a factor close to the value 1, while in business, economics, planning both kinds of communication are separated by almost one order of magnitude. The steps from \( b_k \) to \( b_{k+1} \) are otherwise, both between metrics and across disciplines, roughly proportional. By contrast, the distribution of citations over the four classes that are defined by the \( b_k \) scores are strikingly insensitive to both the metric and the underlying discipline. This kind of robustness is in line with the observations published in the above-mentioned studies by Glänzel (2007) and Glänzel, Thijs & Debackere (2014).
Table 3 shows the corresponding class distributions for the same selection of disciplines as above. The conclusion drawn from these empirical distributions is in line with observations made by Albarrán and Ruiz-Castillo (2011) and Glänzel, Thijs & Debackere (2014). According to their observations, the share of poorly cited papers (Class 1) amounts to roughly 70%, the share of those assigned to Class 2 to about 21% and the share of papers in the upper two classes is 6%–7% and 2%–3% of all papers, respectively. Translating this model to usage, we could speak about a distribution of papers with poor, fair, remarkable and outstanding usage with similar properties (cf. Table 3). The most uncoordinated shares of four classes between citation and usage appear in physics and engineering disciplines. Even though the social sciences have the largest difference between the scores of two indicators, the shares of their publications in four classes keep stable.

The Journal Usage Index

At this point the question arises of whether appropriate journal indicators could be devised on the basis of usage counts. The first and most obvious journal metric that puts itself forward for defining a usage-count analogue, is, of course, the Impact Factors. Once we have a dataset based on one publication year but an observation window of three years, we define our usage indicator following this structure. In order to avoid confusion, we call the impact metric just Journal Impact Measure (JIM; cf. Glänzel & Moed, 2002). The analogous usage-based metric will be called Journal Usage Index (JUI).

Table 4. The ten journals ranking highest according to a 3-year journal impact measure (JIM) in 2013 and their Usage Index (UI). 210
The most obvious question is, of course, aimed at the correlatedness of the two measures. Intuitively, one would expect some but not too strong correlations since we have observed a different extent of correspondence between impact and usage already at the subject level. In order to analyse the correlation, we have first selected all journals assigned to three selected WoS subject categories, particularly, Neurosciences, Information Science & Library Science (LIS) and Inorganic & Nuclear Chemistry. As we have mentioned in the beginning of this section, we present the selection as examples and will make available data and results on more science fields, disciplines and journals in an extended version of the study.

Spearman’s rank correlation amounted to 0.584 for the neurosciences, 0.766 for LIS, and 0.732 for the chemistry discipline. This seems to be reasonable, but does not indicate a really strong correlation.

Table 4 shows the lists of top ten JIM journals in the three selected subject categories. In information science and inorganic chemistry the UIs of those journals are much more boosted from their JIMs than those in neurosciences. This finding reflects the subject-specific communication patterns of scientists in different fields mentioned in the usage-count based measures.

Finally, to deepen this results we decided to study another type of relationship (cf. Glänzel, 2010), namely by directly analysing the plot of the conditional expectation $E(\xi(t) | \zeta(t))$ against $\zeta(t)$, where $\xi$ represents the usage counts and $\zeta$ stands for the citation rates. In this context we mention, that this method has already successfully been applied to the correlation between citation impact and download statistics (Glänzel & Heeffer, 2014). Theoretically there are two extreme cases: The condition $E(\xi(t) | \zeta(t)) = const$ with $r = 0$ means uncorrelatedness. The other extreme is the identity, i.e., $\xi(t) = \zeta(t)$, which results in the trivial solution $E(\xi(t) | \zeta(t)) = \zeta(t)$. However, because of the properties of conditional expectations there exists always a function $f$, such that $E(\xi(t) | \zeta(t)) = f(\zeta(t))$.

![Figure 4. The plot of usage index vs. citation impact based on conditional means for journals with at most 100 citable publications for all fields combined (2013 with 3-year observation window) [Data sourced from Clarivate Analytics Web of Science Core Collection]](image)

We have applied this method to all journals (i.e., in all WoS categories) with at least 100 citable publications. This approach avoids the effect that many small journals affecting the regression and thus distorting the results. Figure 4 shows the plot of usage against impact, where journals
are now grouped if there impact values fall in the same intervals. Correlation is moderate and, on an average, two usages globally correspond to one citation.

Conclusions
We found a significant moderate correlation between citations and usage counts in WoS. The slope reveals interesting subject-specific details on the relationship between impact and usage: While in several fields impact and usage are of the same order of magnitude (e.g., physics disciplines, subfields of biosciences, mathematics and geosciences), usage exceeds citation impact in other disciplines by up to one order of magnitude (e.g., subfields of the social sciences and chemistry). The phenomenon of the social sciences does not strike us unexpectedly since citations in journal literature is less significant in these disciplines making here the application of bibliometrics problematic.

Furthermore, no causality should be assumed as there is no clear direction from usage to citations or vice versa. This is in line with earlier observations concerning the correlation between downloads and citations, no causality in one particular direction should be assumed (Glänzel & Heeffer, 2014). One should also keep in mind that downloads, usage and citations reflect different forms of communication: downloads and usage does not necessarily result in publishing, while citing journal literature and there is no evidence that citations induce interest and usage by colleagues. As mentioned by Wang et al. (2016), the “clicking and saving” WoS usage counts may not perfectly represent the usage data of “views and downloads” provided by publishers’ platforms. We will further study impact and usage patterns in relation to download statistics as of our pending future research task.

The application of CSS proved working in the context of usage counts as well as a robust profiling tools regarding the distributions over “performance classes”. It even keeps the robustness of usage and citation distributions in the fields which have large difference between two indicators, such as the social sciences. Basically, CSS properties are very similar in impact and usage keeping their subject-specific peculiarities and the “translation factor” between impact and usage we have already observed for the basic indicators.

Finally, the new indicator (the Journals Usage Index) may serve as an interesting supplement to journal citation measures. According to the expectation, there is a moderate correlation between the two type of metrics, where the disciplinary “translation factor” is kept but journal-specific patterns exhibit unexpectedly higher/lower usage counts resulting in some noticeable changes in the disciplinary ranking lists. The basic trend that could be observed was that the differences between two journal indicators are larger in the social sciences and basic sciences compared to life sciences.

Abstract
The evaluation of paper impact is one of the core contents in the informetric field, and citation analysis or Altmetrics are commonly employed to measure the influence of papers in academia. This study focuses on constructing a multi-dimensional evaluation system of paper impact with integrating academic and social influence of papers effectively. Such indicators as Relative Citation Ratio (RCR), H-index and Impact torque are used to evaluate correspondingly academic influence, while the social influence is assessed by Altmetrics. Finally, Fuzzy Analytic Hierarchy Process (FAHP) is employed to calculate the weights of each indicator. In current research, 50 highly cited papers in psychological field are selected as a case for verifying the introduced evaluating approach. The findings show that the novel evaluation method synthesizes the academic influence and social influence of the paper effectively. Comparing with traditional single indicator evaluation method, the new approach explains comprehensive impact of paper scientifically with integrating multi-dimensional indicators.

Conference Topic
The application of informetrics on evaluation

Introduction
In this highly competitive pursuit of scientific research achievement, evaluating the influence of papers is the most effective approach for assessing the contributions of researchers, which reflects the academic value of the papers and the degree of cognition of others. Traditionally, these judgments mainly depended on some defective indicators and peer review. With the rise of open access and the networking of scientific research communication promote the development of Altmetrics, which foster a new approach for the comprehensive evaluation of paper’s influence. At present, researchers have increasingly turned to numerical approaches and divided the evaluation of papers into two categories. One emphasizes the improved evaluation indicators based on the citation quantity of the paper, such as H-index (Schubert, 2009), Impact Torque (Wang & Ye, 2014), Mean Normalized Citation Score (Lundberg, 2007), Relative Citation Ratio (RCR) (Hutchins, Yuan, Anderson, & Santangelo, 2016) and Academic Trace (Ye & Leydesdorff, 2013), etc.; The other is to optimize Altmetrics, such as calculating on relativity of evaluation indicators and citations based on Altmetrics (Li, Thelwall, & Giustini, 2012), optimizing the evaluation system of influence (Bornmann, 2014b) and evaluating new types of academic achievements.

Through each of the quantitative methods mentioned above has strengths, their accompanying weaknesses are to measure the academic and social influence of papers separately. To fill in this gap, we construct a multi-dimensional evaluation system of paper impact with combining academic influence and social influence effectively, to adopt H-index, RCR and Impact Torque as the indicators of academic influence, meanwhile use partial indicators of Altmetrics as the indicator of social influence. With this purpose, the following two research questions are proposed:
(1) How to assess the academic influence and social influence of the paper, and how to combine them effectively?

(2) Is there a relationship between the academic influence and social influence of the paper? What is the relative importance between the H-index, RCR, Impact Torque and Altmetrics?

Related Work
Many alternative methods for evaluating the influence of paper has been proposed mainly based on the bibliometrics (Garfield & Merton, 1979; Hutchins et al., 2016; Leydesdorff & Opthof, 2011; Schubert, 2009). However, with the change of the mode of academic publishing and academic exchange, the evaluation indicators are becoming increasingly inefficient for on-side insight and the time lag. It cannot reflect the influence of papers objectively and comprehensively (MacRoberts & MacRoberts, 2013). In the new research environment, the rise of Altmetrics enriches the evaluation system, and divides the evaluation of the paper into two categories: based on citation analysis or Altmetrics.

Measuring the influence of papers based on citation analysis
Since Garfield firstly proposed to use the impact factor to evaluate the influence of journals, citation analysis has increasingly become a scientific field of study (Garfield & Merton, 1979). Moed further proposed a Relative Citation Rate used the average citation counts to all publications in the journals to quantify the impact of the paper group (Moed, Burger, Frankfort, & Van Raan, 1985). Hutchins improved this method and rename RCR to quantify the influence of a research article by making novel use of its co-citation network to field-normalize the number of citations it has received (Hutchins et al., 2016). Van Raan extended the indicators which used the field-specific normalization to replace the journal-specific normalization, and presented the Citations Per Publication/Field Citation Score (CPP/FCSm) indicators (Van Raan, 2006). Opthof and Leydesdorff argued this procedure only generates an effective indicator in the case of normal distributions, when giving the skewed distributions, one should average the observed versus expected values which are to be divided firstly for each publication (Opthof & Leydesdorff, 2010). And Egghe proposed to employ averages of ratios to replace ratios of averages for assessing the MNCS evaluation indicator (Egghe, 2012). Without changing the acronym of “MNCS,” one could define the “Median Normalized Citation Score,” this would relate the new crown indicator directly to the percentile approach (Leydesdorff & Opthof, 2011). On the other hand, Schubert used h papers which have been cited h times in cited literature as the H-indicator of the paper in order to reflect the direct and indirect influence of the papers (Schubert, 2009). Wang has recently employed a new indicator Impact Torque (M) to evaluate the impact of the paper on scholars, which is calculated by multiplying the number of authors who are affected by papers as the force A and the paper’s influence span time D (Wang & Ye, 2014).

Measuring the influence of papers based on Altmetrics
Although some of methods based on citation analysis have dramatically improved our theoretical understanding of papers’ evaluation, none have measured the social influence of the paper. Altmetrics offer new ways to measure the relevance of public and research output, which can be considered an interesting option for assessing the societal impact of papers (Piwowar, 2013). Its advantages and disadvantages have been explained by Bornmann, and he also discussed the definition of Altmetrics (Bornmann, 2014a). Furthermore, Bornmann (2014b) introduced Altmetric-based scientific evaluation system, which involves both academic influence and social influence. In order to validate the scientificalness of Altmetrics, Galligan and Dyas conducted an in-depth study on the data source and data
providing platform of Altmetric evaluation system (Galligan & Dyas-Correia, 2013). On the other hand, many comparative studies with citation analysis were proposed to demonstrate the usefulness of Altmetrics (Thelwall, Haustein, Lariviere, & Sugimoto, 2013). For instance, Zahedi randomly selected 20,000 articles in WOS and analysed the correlation between Mendeley's readership and the number of citations (Zahedi, Costas, & Wouters, 2014). Eysenbanch, Shuai, Pepe and Bollen explored the correlation between the number of citations and tweets, but there comes to no consistent conclusion from them due to the different data sources (Eysenbach, 2011; Shuai, Pepe, & Bollen, 2012). Finally, Ortega found a weak correlation between traditional bibliometric and Altmetrics indicators at the author level (Ortega, 2015).

In summary, the current evaluation system of the impact of papers mainly focuses on the development and improvement of single indicator, thus, the evaluation of the impact of papers is biased. Although some scholars have put forward the comprehensive evaluation of academic influence and social influence, they don’t construct an effective evaluation system to evaluate the comprehensive impact of papers. Based on the academic influence and social influence of paper, this study tends to construct the scientific evaluation system of paper’s influence by fuzzy analytic hierarchy process (FAHP) for uncovering comprehensive impact of papers with employing the RCR, H-index and Impact Torque to evaluate the academic influence, and utilizing Altmetrics to evaluate the social influence of paper.

Methodology and Data

Description of the Model

For evaluating the influence of papers, we should consider their academic influence and social influence synthetically (Rongyin.Z, Fengjiao.G, & Jie.T, 2016). But how to measure the academic influence and social influence effectively? Galligan pointed out that Altmetrics can better reflect the social value of papers and prove its relevance to the public (Galligan & Dyas-Correia, 2013). In terms of measuring academic influence, the citation counts of paper have been a direct indicator of the academic influence in previous studies. However, there is a time lag of publications, and RCR is a more effective citation measurement indicator which incorporates a customizable benchmarking feature that relates field- and time- normalized citations (Hutchins et al., 2016). Simultaneously, Schubert pointed out that the number of citations reflects the direct influence of papers, but ignores the indirect influence. So he came up with the H-index to measure the direct influence and indirect influence of papers (Schubert, 2009). Wang stated that the academic influence of papers is firstly reflected by the influence of the relevant scholars, and not limited to the citation counts (Wang & Ye, 2014).

After reviewing previous approaches, this study defines the influence of papers with the combination of academic and social influence, and selects RCR, Impact Torque and H-index as key indicators, which measure the direct influence, indirect influence and influence on the relevant scholars respectively. Social influence is measured by Altmetrics, such as Mendeley, Blog, CiteULike and other social indicators. A hierarchical multiple model will be built to evaluate the influence of papers (Figure 1). The weight of the indicators is determined by the FAHP which combined with the power method. Finally, paper’s influence is obtained by using the multi-objective linear weighting.
Academia Influence Indicator

We report here a comprehensive measurement of the academia influence, which select RCR, Impact Torque and H-index as key indicators. RCR puts the co-citation network of papers as a subject area (Figure 2), which provides a dynamic view for studying field. The analysis process is consisted of five steps:

1. Calculate the average number of citations per year. The formula is presented as follows:
   \[ Acr = \frac{\text{Citations}(p)}{\text{Age}(p)} \]
   Where Citations (p) is the total number of essays cited, and Age (p) is the number of years since the publication;
2. Generate the co-citation network of papers;
3. According to the quotation rate of periodicals in the common network, it is estimated that the anticipated number of citations in the field of paper. And \( Fcr \) is defined as:
   \[ Fcr = \frac{\sum jcr_i}{N} \]
   Where there are N papers in the total network and \( jcr_i \) is the reference rate of journals;
4. According to the linear relationship between Acr and Fcr, we can generate the expected number of citations per year (Ecr) in the area, where the paper belongs to. And the ratio of Acr to Ecr is the RCR of the paper.

Another indicator is Impact Torque which examine the influence scale of the paper and the effect of aging. The impact Torque \( M \) is defined as the product of the influence of scholar force \( A \) and influence span \( D \), its formula is shown as follows:
Where \( t_j \) is the time limit that the paper has been experiencing; \( c_j \) is the quoted number of the jth year; \( C \) is the total number of cited; and \( N \) is the total number of years the article has been published.

RCR and Impact Torque are adopted to measure the direct influence, meanwhile we use H-index to quantify the indirect influence. The specific mathematical expression is presented as follows:

Set \( TC \) as the a sequence of descending order of number of cited times \((1, 2, \ldots, r, \ldots, z)\) in order to express the order of the paper; And \( TC_r \) as the total number of paper \( r \) cited, then the following sequence is available:

\[
TC = (TC_1, \ TC_2, \ldots, TC_r, \ldots, TC_z)
\]

And \( TC_1 \geq TC_2 \geq \cdots TC_r \geq \cdots TC_z \). Thus, the mathematical meaning of \( h \) is:

\[
H = \max \{r; r \leq TC_r\}
\]

**Social Influence Indicator**

Studies have shown that Altmetrics can measure the social influence of the paper effectively, it has 15 indicators for the evaluation of papers, including Twitter, Facebook, Redditers, News, Blog, Mendeley, CiteULike, F1000, Google +, Pinterest, Q&A, Weibo, Peer review, Wikipedia and Policy documents. While there are too many invalid indicators with zero value, such as Pinterest, F1000, etc. In current research, we will remove those indicators, which have excessive null value, and choose CiteULike, Mendeley, Blog, Policy, Twitter, News, Facebook, Wikipedia as key factors to measure the social influence of the paper.

**Weight Calculation**

In current study, the weight of each indicator was determined by FAHP, which introduces fuzzy consistent matrix and does not need consistency test. At the same time, we use power method to calculate the ordering vector, reduce the number of iterations and increase the convergence rate to meet the requirements of the computational accuracy. Specific steps are shown as below:

- Constructing a finite relational matrix. Using the \([0.1 \sim 0.9]\) scale and establishing a priority judgment matrix \( F = (f_{ij})_{n \times n} \);
- Converting the precedence relation matrix to a fuzzy consistent matrix. \( R = (r_{ij})_{n \times n} \), \( r_{ij} = \frac{r_i - r_j}{2n} + 0.5 \), where \( r_i = \sum_{j=1}^{n} f_{ij}, i = 1, 2, \ldots n \).
- Calculating ordering vector by square root method;
- Using the power method to obtain a higher precision ordering vector. The complementary judgment matrix \( R = (r_{ij})_{n \times n} \) is transformed into a reciprocal judgment matrix \( E = (e_{ij})_{n \times n} \), where \( e_{ij} = r_{ij}/r_{jj} \). The sort vector \( W^{(0)} \) is taken as the initial vector \( V^{(0)} \) and iterated with the formula \( V^{(k+1)} = EY^{(k)}, V^{(k)} = \frac{V^{(k)}}{\|V^{(k)}\|_\infty}, k = 1, 2, \ldots \) If \( \|V^{(k+1)}\|_\infty - \|V^{(k)}\|_\infty < \varepsilon \), \( \varepsilon \) is the given error, then \( \|V^{(k+1)}\|_\infty \) is the maximum eigenvalue. The sort vector \( A \) is calculated as follows:

\[
A = \left[ \frac{V_{k+1,1}}{\sum_{i=1}^{n} V_{k+1,1}}, \ldots, \frac{V_{k+1,n}}{\sum_{i=1}^{n} V_{k+1,n}} \right]^T
\]

**Impact Calculation**
After obtaining the weights of each indicator by the FAHP, paper’s influence is calculated based on the multi-objective linear weighted calculation. The formula is shown as follows:

\[
\text{Impact} = \sum_{i=1}^{n} A_i \sum_{j=1}^{m} W_{ij} P_{ij}
\]

Where Impact is the evaluation of paper’s influence, \(A_i\) is the weight of the i-th indicator at criterion layer, \(W_{ij}\) is the weight of the j-th project hierarchy indicator under the i-th criterion, \(P_{ij}\) is the actual value of the jth project hierarchy under the i-th criterion.

Data collection and preprocessing

At present, the RCR is limited by paper PMID number, so current study chooses psychology papers as the analysis object. In addition, for calculating the paper Impact Torque, manual collecting data is need. Due to time limitation, only selected 50 psychology papers which are high cited are employed as sample.

As a case study, we select the Web of Science core set as the retrieval platform, psychology as the subject and the “ARTICLE” as document type, all publication and information about all citation report were downloaded and analysed. Sorting by the number of citations, top 500 literatures are selected as the preliminary sample and then exported to EndNote. After removing the papers without the DOI number, 440 papers are available. With retrieving the corresponding literatures in Altmetric.com according to the DOI, Altmetrics indicators and search results are obtained. The next step is to filter out the literatures without the PubMed, and 265 articles are left. Finally, sorting the literatures in descending order according to Alt Score, top 50 literatures are selected as a sample of our study. In addition, we retrieve the corresponding RCR value in the ICite website according to the PubMed number of literature. Finally, Z scores is used to standardize all the data.

Results

Weights

We invited one professor, two doctoral students and three master students in the field of information science of Wuhan University to formulate the initial priority relation matrix of the evaluation system, 3 reliable judgment matrices are obtained as follows:

The preferential relation matrix of the criterion layer: \(F_A = \begin{pmatrix} 0.5 & 0.7 \\ 0.3 & 0.5 \end{pmatrix} \)

The preferential relation matrix of the project hierarchy: \(F_{B_1} = \begin{pmatrix} 0.8 & 0.5 & 0.7 \\ 0.6 & 0.3 & 0.5 \end{pmatrix} \)

\[
F_{B_2} = \begin{pmatrix} 0.5 & 0.2 & 0.6 & 0.4 & 0.3 & 0.8 & 0.7 & 0.5 \\ 0.8 & 0.5 & 0.8 & 0.6 & 0.5 & 0.9 & 0.8 & 0.6 \\ 0.4 & 0.2 & 0.5 & 0.3 & 0.2 & 0.5 & 0.4 & 0.3 \\ 0.6 & 0.4 & 0.7 & 0.5 & 0.4 & 0.8 & 0.7 & 0.6 \\ 0.7 & 0.5 & 0.8 & 0.6 & 0.5 & 0.9 & 0.8 & 0.7 \\ 0.2 & 0.1 & 0.5 & 0.2 & 0.1 & 0.5 & 0.4 & 0.2 \\ 0.3 & 0.2 & 0.6 & 0.3 & 0.2 & 0.6 & 0.5 & 0.4 \\ 0.5 & 0.4 & 0.7 & 0.4 & 0.3 & 0.8 & 0.6 & 0.5 \end{pmatrix}
\]

In this paper, MATLAB is used to write FAHP process, the precision is set to 0.00001 and the maximum number of iterations is 1000 times. Then, the preferential relation matrix mentioned above is calculated as a parameter and input in program respectively to obtain the weight of indicators. These weights are calculated as follows:

\[
W_1 = W_{B_1}(W_{C_1}, W_{C_2}, W_{C_3})
\]

\[
= 0.6(0.2453, 0.4536, 0.3011),
\]
\[ W_2 = \mathcal{W}_{B_2}(W_{C_4}, W_{C_5}, W_{C_6}, W_{C_7}, W_{C_8}, W_{C_9}, W_{C_{10}}, W_{C_{11}}) = 0.4(0.1197, 0.1765, 0.0879, 0.1432, 0.1765, 0.0750, 0.0951, 0.1260) \]

**Papers’ Influence**

The influence of each sample was calculated by multi-objective linear weighting. In order to compare the consistency of our method with RCR, Impact Torque and H-index, the top 10 papers are selected as samples. Table 1 provides descriptive statistics of these papers’ influence, including the value and ranking of each indicator.

In this paper, the standardized values of the indicators were compared, and the figure 3 is arranged in descending order of Impact. We found that the ordering of the indicators of the sample not only shows a certain degree of relevance, such as the article of the high influence, its Impact Torque, RCR ranking also higher, but also shows a certain degree of independence. Therefore, we checked for significant relevance between each indicator through the Spearman coefficient of SPSS. Because that the social impact indicators are excessive, here we only selected Blog, Twitter and Mendeley for correlation analysis, the correlation coefficient is in Table 2

**Figure 3 The distribution of the indicators of papers’ influence**

With the correlation analysis of each indicator, we found that the influence of the dissertation has a strong correlation among RCR, M and H-index, and H-index is also associated with more indicators. However, we found less significant relevance within the academia influence indicator and social influence indicator of papers.

#### Discussion

**Compare with other evaluation methods**

This paper measures the academic influence and social influence of papers comprehensively by constructing a multi-dimensional influence evaluation model of papers. Comparing the evaluation results of our method with the Altmetric, RCR, H-index and Impact Torque of the top 10 articles, the evaluation of consistency between Altmetric.com and our method is 0.2, H-index is 0.5, RCR is 0.6, and Impact Torque is 0.8. In the comparison of consistency of evaluation results, Altmetric.com has the lowest consistency with our method while the academic influence indicator has a higher consistency, which could be due to the selection of partial Altmetric.com evaluation indicators. Figure 3 presents the distribution of each indicator, showing a general consistency with our method, which demonstrate that the new impact evaluation method of this paper takes into account the influence dimension reflected by the indicators synthetically. In general, new approach is more comprehensive and scientific than other evaluation methods.

**Assess the importance of each indicator**

The weights of each indicator in the evaluation system are obtained through the processing of FAHP. The results show that the weight of academic influence (0.6) in the evaluation method is higher than that of social influence (0.4), which may be due to the fact that the essence of papers is the academic achievement of the researcher. In the indicators of academic influence, the weight distribution is “RCR (0.4536)>Impact Torque (0.3011)>H-index (0.2453)”, which RCR overcomes the difference between discipline and time with the highest weight. Impact Torque evaluates the impact of the paper on the researchers from another angle, and its weight is slightly higher than H-index. As for the indicators of social influence, Twitter (0.1765), CiteULike (0.1765) and Blog (0.1432) have higher weights than others. Twitter is one of the top ten Internet access sites, while Blog is the first blog service provider, so both of them have...
a high weight of social impact. On the other hand, CiteULike is a document management tool, also reflects the academic influence of the paper to a certain extent, and therefore also has a high weight.

The independence and relevance of each indicator

In this paper, we compared each indicator to determine whether there were correlations between them, as shown in Table 2. We found a weak significant correlation between RCR and H-index (0.288), and no correlation was found between RCR and Impact Torque (0.177), which mainly because they measure the influence of different directions of paper. However, we found a moderate significant correlation between H-index and Impact Torque(0.585), which shows that H-index synthetically considers the direct influence and indirect influence of the paper. On the other hand, the correlation coefficients between Blog and Twitter, Blog and Mendeley, Mendeley and Twitter are 0.527, 0.347, 0.347 respectively, indicating that there is moderate significant correlation between social influence indicators. As the academic influence and social influence of the paper measuring the influence of the two dimensions, there is no significant correlation between the social influence indicator and the academic influence indicator. Therefore, in the evaluation system of paper influence, each indicator has a certain degree of relevance and independence, and can be used to measure academic influence and social influence of paper perfectly.

Conclusion

Current study constructs the multidimensional evaluation model of paper’s influence with extracting the effective indicators of measuring both academic influence and social influence of papers, and comparing the important degree and correlation between the academic influence and the social influence indicators. The new approach provides a novel evaluation perspective, which is not limited for using single indicator to reflect the influence of a paper, but integrating meaningful indicators to achieve multi-dimensional and multi-method combination. There are also several limitations in this study. For instance, fewer samples are employed in this paper. The further research mainly lies in the improvement of the indicators in this paper, as well as the expansion of the core indicators in the evaluation system, so as to form a unified evaluation method of paper influence.

Abstract
In this paper we present a novel methodology for identifying scholars with a Twitter account. By combining bibliometric data from Web of Science and Twitter users identified by Altmetric.com we have obtained the largest set of individual scholars matched with Twitter users made so far. Our methodology consists of a combination of matching algorithms, considering different linguistic elements of both author names and Twitter names; followed by a rule-based scoring system that weights the common occurrence of several elements related with the names, individual elements and activities of both Twitter users and scholars matched. Our results indicate that about 2% of the overall population of scholars in the Web of Science is active on Twitter. By domain we find a strong presence of researchers from the Social Sciences and the Humanities. Natural Sciences is the domain with the lowest level of scholars on Twitter. Researchers on Twitter also tend to be younger than those that are not on Twitter. As this is a bibliometric-based approach, it is important to highlight the reliance of the method on the number of publications produced and tweeted by the scholars, thus the share of scholars on Twitter ranges between 1% and 5% depending on their level of productivity. Further research is suggested in order to improve and expand the methodology.

Conference Topic
Altmetrics; Studies on the level of individual scientists

Introduction
Social media have become increasingly important as a tool for scholarly communication (Sugimoto et al., 2016). Academic social networking sites such as Mendeley, Academia.edu and ResearchGate are used by scientists to connect with peers, share (pre)prints and track the visibility of their work. Twitter is a popular microblogging platform in which diverse communities, such as journalists, students and scientists among others, interact and exchange information. Earlier research has studied discourses on Twitter in comparison to news discourses (Mondragon et al., 2017) and the use of Twitter amongst different scientific disciplines (Holmberg & Thelwall, 2014). A major drawback of these previous studies is their small scale. The majority of research on Twitter use amongst academics deals with 500 accounts or less (but see Hadgu & Jäschke, 2014). In general, there is a lack of identification methods that can be used to identify scientists on Twitter on a larger scale. Earlier work has used a variety of (labour intensive) methods to identify scientists on Twitter. The most commonly used method is based on selecting Twitter accounts manually (Veletsianos, 2012; Lulic & Kovic, 2012; Holmberg & Thelwall, 2014; Haustein et al., 2014; Hwong et al., 2016), often starting from an established set of scientists through snowball sampling (identifying for instance all scientists that follow or are followed by the established set of scientists). A second method is self-identification through survey research (Rowlands et al., 2011; Van Noorden, 2014; Collins, Shiffman, Rock, 2016). In this method, that potentially can be used to collect a larger group of scientists active on Twitter, researchers send out surveys to a group of scientists asking them, amongst others to identify their social media accounts. However, such method is always limited by response rate as well as the need to identify contact information for scientists before being able to contact them. A third method
is by identifying scientists through (conference) hashtags or Twitter accounts (Ross et al., 2011; Hadgu & Jäschke, 2014; Veletsianos & Kimmons, 2016). Hadgu and Jäschke (2014) have been especially successful by combining accounts of various conferences to obtain a large sample of Twitter accounts affiliated with computer science conferences. A fourth method is the use of lists compiled by Twitter users (Sharma et al., 2012). This approach has resulted in the largest set of scientists on Twitter to date compiled by Ke, Ahn and Sugimoto (2016). This study collected Twitter accounts of lists where the list as well as the Twitter biography contained a scientist title (e.g. psychologist, economist, PhD, researcher, etc.). They were able to collect 45,867 Twitter accounts of (self-identified) scientists. A fifth strand of research on Twitter users originates in computer science analyses on the demography of Twitter. Such studies involve far less manual labor and often work with very large datasets extracted from the Twitter API. These studies use metadata of Twitter accounts (such as the Twitter biography and location) as well as tweets and the network of followers and following to identify geographical location, age, gender and occupation of users (Mislove et al., 2011; Sloan et al., 2013; Sloan et al., 2015). This approach is successful in obtaining information about the demographics of Twitter, but is not able to identify individual scientists. The inclusion in lists and the presence of scientists titles in the Twitter biography section, as developed by Ke, Ahn and Sugimoto (2016) is a viable strategy, however this approach favours more established scientists who are included in Twitter lists far more often than junior scientists.

In this paper we take a different approach by creating a match between two universes of individuals: the set of authors recorded in the Web of Science database and the Twitter accounts recorded by Altmetric.com. Altmetric.com has developed a database of all tweets (and their related metadata) that include a (link to) a DOI (mostly related to scientific journal articles), which gives us a population of 2.6 million Twitter accounts, many of them being very likely related to scholars. Our aim is to identify all those Twitter accounts that belong to individuals among the 22 million disambiguated authors recorded in the Web of Science with at least a publication after the year 2005. We think this approach is more viable than the approaches described above for a number of reasons. First, drawing on these two datasets makes it possible to match scholars (determined by their authorship of publications covered in the Web of Science) and Twitter handles in a systematic manner, involving far less manual labour. Second, when we identify the Twitter account of an author, we can immediately connect this to other data (such as institution, field of activity, publication profile, citation profile, collaborations, etc.) related to the scientific author. Third, while it relies partly on self-identification (the author has to be on Twitter using—to some extent—her own real name and has to have tweeted a paper recorded in Altmetric.com) it uses a variety of factors to determine whether an account can be ascribed to a particular scholar, thus going beyond the mere identification of the Twitter user as a scholar in the Twitter biographical section. Fourth, we aim at validating the linkages between scholars and Twitter accounts based on a gold standard of valid set of scholars with Twitter accounts, for this using the self-reported Twitter accounts of researchers recorded in the public ORCID registry (https://orcid.org/).

Methodology

Data sources

The two data sources used for this matching are the Web of Science (WoS) database, and the Altmetric.com database. We use the author-name disambiguation algorithm developed by Caron & Van Eck (2014) and we work with a set of 22,642,206 disambiguated author names. From the Altmetric.com database we extracted all distinct Twitter accounts that have tweeted
at least a paper recorded in Altmetric.com until April 2016 (i.e. 2,622,116 distinct Twitter handles).

Matching author-Twitter names

In order to match the two different data sets – WoS disambiguated authors and Twitter user accounts – we started with some normalisation and cleaning of the data in order to harmonize the characters from both sources. In WoS, Roman characters are always used. However, in Twitter, scholars can (and often do) also use other character sets. There is, as such, a bias toward this Roman character set inherent in the matching (although automatic transliteration of other character sets could be a future strand of research).

Moreover, accents and diacritics are also generally elided in the WoS database while not in Twitter. This has been compensated by applying specific matching strategies for specific accents. For instance, umlauts in German are often not merely removed, but rewritten with an added e, so that for instance ü becomes ue. In our matching we have accounted for both û, u and ue in these cases. We have attempted to apply such flexible matching to all frequent diacritics and spelling variations. Another frequent example is allowing hyphens to match whitespace. These are often used interchangeably in double last names, and so we consider them interchangeable.

The data from the Twitter side has issues of its own too. We use two data fields recorded in the Altmetric.com database: the handle (or username), and the “full name” as the users have entered it in their Twitter account. Twitter makes no distinction between first and last name. In fact, sometimes users do not actually enter their real name in this field at all. However, we are not interested in these cases as we aim at researcher that quite clearly disclose their identity in their Twitter accounts. Still, when they provide their actual name, it can come in various guises. They can provide any combination of first name, initials, last name, maiden name, title and sometimes even institution, and these can occur in almost any order. By looking at the source data, we have tried to catch as many of these as possible within what we might call “format templates”. So if we find a name that is formatted “X.X. Xxx” (where X is any alphabetical character) we assume that the first two characters are initials and the last three are the last name. If the name is formatted “ XX Xxx” it will be the same, yet if the second X is in lowercase (“Xx Xxx”) it will be considered a first name and last name. And so on. Another complication to this name field is that it is limited by Twitter to twenty characters. Of course, full names can easily exceed this, and it is hard to predict how users deal with this cut-off. In any case, it is sure to increase the number of incomplete names.

Matching of the Twitter account with the author name can also be done based on the name from the handle. Handles on Twitter have a maximum length of fifteen characters and can include only a combination of alphanumeric characters and underscores (_). Of course, the absence of a whitespace character as well as other characters that might appear in a name (like dots and dashes) makes this field less reliable than the full name field. On the other hand, the restrictions can also help. In the case of many Chinese and Japanese researchers, for instance, the full name field contains their name in their own character set, whereas in their Twitter username they have been forced to use the Romanized version. Like with the full name, we use “format templates” here. We here assumed underscores to function as dividers between first and last names, or initials and last name, and we also took into account the sequence of upper- and lowercase characters (so that the username “XxxYyy” can be divided into first name “Xxx” and last name “Yyy”).
Based on these extraction processes and attempts to make matching as flexible as possible, the two data sets are finally connected and pairs of authors and Twitter users have been created.

Scoring the matches

Based on the previous matching approach, a total database with 503,599,561 pairs of author names and Twitter accounts has been created. The following step is to determine which of those pairs are correct. In order to do so, a scoring method based on different rules has been developed in order to select the most likely correct pairs of authors and Twitter accounts. This rule approach is inspired by a similar approach for author-name disambiguation developed by Caron & van Eck (2014). Several data elements that can happen both in Twitter data and in WoS data have been collected in order to weight the pairs. Different rules have been applied in order to score the occurrence of the different elements, and a final score by summing the different rule-based scores has been provided for each author-Twitter account pair. Table 1 presents a summary of the rules and their scores.

Table 1. Summary of the criteria and scores for the different elements matched.

</table>

$^1$ We penalize when an author uses her first name in her papers but uses a different one (or none) in the Twitter name.
As presented in table 1, there are a total of 14 rules, one of them with a negative score. The rules can be organized in four main groups.

1) **Rules based on the matching of the names of the authors and the Twitter names** (rules 0 to 4). These rules are based on a relative clear identification of both the authors and the Twitter users, and their matching. Rule [0] refers the general matching of authors and Twitter information done in the previous step. Thus, all potential matches get, in principle, a score of 1, although later on this can be changed with the negative rule.

2) **Rules based on the matching of individual-related information of the authors and the Twitter users** (rules 5 to 8). These rules are based on the matching of different elements (mostly institutional and geographical) provided both by the authors in their papers (e.g. affiliations, countries, e-mails) and the Twitter users (URLs, Twitter name and Twitter handle, geographical information provided in the Twitter profiles, biographical description in Twitter, sometimes including their city, country or also academic institution). In these rules, different scores are established depending on the frequency of the different elements in WoS. Thus, the higher the number of scholars that are linked to the same entity in WoS, the lower the score that will be attribute to that match.

3) **Rules based on the matching of activity-related information** (rules from 9 to 12). Here the rules are based on the publications, fields and journals of the authors and the publications tweeted by the Twitter account. The rationale is that the more a Twitter account (sharing a minimum name similarity with a given author) has tweeted the same papers of the author (i.e. ‘self-tweeting’ activity), papers from the same micro-fields, and/or from the same journals of activity of the author, the higher the chances that the author and the Twitter account correspond to the same person. Additionally, if a Twitter account has been

---

2 Micro-topics are defined as the fields obtained in the publication-level classification developed by (Waltman & Van Eck, 2012)
mentioned (by another Twitter user) together with a paper of the author with which it has been matched, it is very likely that the Twitter account corresponds to the author, in a sort of co-tweeted event (e.g., somebody in Twitter has tweeted a link to a paper and the handle of the author in the same tweet\(^3\)).

These rules have the highest scores. Activity rules are expectedly more accurate in the identification and discrimination of the correct matches as they provide information on more specific patterns of the relationship between the scholar and the Twitter account.

There is also an additional rule [13] that assesses the commonness of the matching. If an author is only matched to one Twitter account, the matching is weighted more positively than when the author is matched to numerous different Twitter accounts.

Based on the previous rules, there is also an additional rule, labelled as the ‘preferred rule’. It is not a scoring rule but a selection one. After performing the scoring of pairs of matched based on rules 0-13, each author (when matched to several Twitter accounts) is only assigned to the Twitter account with which it has the highest score. In case of ties (i.e. when an author is matched to several accounts with the same score) the author is kept linked to all of them. This rule is expected to reduce the noise caused by matches of authors with very similar names and activity profiles, working in the same institute, field, etc., which may cause that they get high scores in their combination with different Twitter accounts. It is a rule to increase the precision of the matching procedure.

**Gold standard, validation of the matching and final selection of author–Twitter handle pairs**

In order to determine the threshold of the score for the final selection of the most adequate matches, we have performed precision-recall analysis using a database of self-reported linkages of authors with their Twitter accounts. This ‘gold standard’ is based on the public ORCID data from years 2015 and 2016 (Paglione et al, 2015; Haak et al, 2016).

From these databases we found a total of 768 of different individuals that are also authors in the database of disambiguated scholars and have reported a Twitter account in their public ORCID profile. We further selected those individuals with a Twitter account in Altmetric.com (i.e. researchers that have tweeted at least one paper) finding a total of 631 different individuals. This means that about 82% of the scholars with a Twitter account in the gold standard are recorded (at least once) in the Altmetric.com database, thus suggesting the potential relevance of this method in order to be able to identify scholars\(^4\). Of the 631 we further discarded 4 scholars as they had their last publication before the year 2005. A total of 627 individuals were finally considered in the analysis. Based on the pairs of author names and Twitter names and in the scoring of the matches as described in table 1 we estimated the precision/recall values for those researchers in the gold standard. The results of such analysis are presented in Table 2. Table 2 presents the overall results of the number of scholars that have been paired with a Twitter account with a given score value (from \(\geq 3\) to \(\geq 6\)), together with the precision/recall values based on the gold standard.

</table>

\(^3\) See an example here: [https://Twitter.com/wmijnhardt/status/781245999545212930](https://Twitter.com/wmijnhardt/status/781245999545212930)

\(^4\) Somehow it supports the idea that scholars that are on Twitter tend, at some point, to tweet or re-tweet a scientific publication, thus entering into the realm of altmetric sources (Haustein, Bowman & Costas, 2016).
As it can be seen in Table 2, precision increases with higher scores, while recall decreases. Basically, with scores higher than 5 we reach values of precision higher than 95%, but values of recall below 80%. Regarding recall, with a score low as 2 we get a value of 92%. In the discussion of recall it is important to keep in mind that not all the author-Twitter account recorded in ORCID are valid matches, for examples, there are Twitter accounts reported that are institutional or collective (e.g. labs, teams, departments, etc.). Therefore, the values of recall reported here have to be regarded as relatively conservative.

In this paper, in order to make a selection with a relative balance between precision and recall, and considering that precision is something to be preferred over recall (it is reasonable to argue that is best to have correct matches over more but noisy ones) a minimum value of 4 has been chosen as a good compromise. As a result, more than 385,000 individual scholars have been linked to a Twitter account. This number of scholars found in Twitter is the largest so far compared to any of the previous studies. Even if we would have selected a minimum score of 6, we would have obtained a set of almost 135,000 scholars on Twitter (i.e. almost three times more than in the largest study of identification of scholars on Twitter so far, cf. Ke, Ahn & Sugimoto, 2016).

**Analysis of the presence of scientists on Twitter**

In this section a general analysis on the presence of scholars with a Twitter account is presented. For this analysis we have focused on distinguishing those scholars that have a Twitter account as identified with the methodology explained above in contrast to those without a Twitter account. Only individuals with an article, review and letter and in the period 1980-2015 and with at least a publication after 2005 have been considered in the analysis (a total of 17,332,510 disambiguated scholars). A total of 334,856 (2%) of them have been matched with a Twitter account with a score of 4 or higher.

In Figure 1 the share of researchers that have a Twitter account controlling by production is presented. As it can be seen the share of scholars on Twitter increases with the number of publications, ranging between 1% and 5%. It could be argued that this is a sign that more research active scholars are also more likely to be active on social media. However, considering that some of the scoring rules (i.e. activity rules – 9,10 and 12) are dependent on the number of publications of the authors, the outcomes of the analysis could also indicate that researchers with more output are more likely to be linked to their Twitter account in our methodology.

In Figure 2 the share of scholars with a Twitter account by scientific domain is presented. In order to classify scholars into major scientific domains the same approach as used by Larivière & Costas (2016) has been employed here. Thus, individuals are assigned to their main domain of activity based on their number of publications, and in case of ties (i.e. a scholar linked to several domains with exactly the same number of publications) a random assignation is applied. Results show how scholars with Twitter accounts are prominent in disciplines such as ‘Social and Behavioral Sciences’ (above 5%) as well as ‘Law, Arts and
Humanities’ (almost 4%). The shares in the ‘Medical and Life Sciences’ (about 2%) as well as in the ‘Natural Sciences’ (just above 1%) are much lower.

Figure 1. Overall number of scholars and percentage of them with a Twitter account, controlling by production

![Graph showing the overall number of scholars and percentage of them with a Twitter account, controlling by production.](image)

Figure 2. Percentage of scholars with a Twitter account by main domain of activity

![Bar chart showing the percentage of scholars with a Twitter account by main domain of activity.](image)

In Figure 3 an analysis on the age of the scholars is presented. In this case, age is determined by the year of first publication of the scholars. This year has been proven to be the best overall
proxy of the academic age of scholars (Costas, Nane, & Larivière, 2015). Controlling for the number of publications we find that scientists with a Twitter account tend to be on average younger than those without a Twitter account. Not surprisingly, scholars with a lower number of publications tend to be younger overall than those with more publications, although the pattern of younger scholars on Twitter is observed for all groups of productivity.

Figure 3. Average Year of first publication (YFP) of scholars with a Twitter account vs. those without a Twitter account, controlling by the number of publications

Conclusions and further research
In this paper we present a novel methodology for identifying scholars with a Twitter account. By combining bibliometric data from WoS and Twitter accounts from Altmetric.com we have obtained the largest matching of individual scholars with Twitter users made so far. Our methodology consists of a combination of matching algorithms, considering different linguistic elements of both author names and Twitter names; followed by a rule-based scoring system that weights the common occurrence of several elements related with the names, individual elements and activities of both Twitter accounts and scholars matched. The methodology developed presents interesting advantages with respect to previous approaches:
- It is a systematic approach that can be applied to large sets of researchers. It relies on the role of scholars are publishing authors and is not dependent on aspects such as the biographical descriptions of the Twitter users or their presence in lists (cf. Ke, Ahn & Sugimoto, 2016).
- It is subject of validation by external gold standard, in this case a gold standard based on data provided by ORCID has been employed, but the analysis of other golden sets would be also possible.
Once a Twitter account of an author is identified, it is possible to link this with additional bibliometric data (e.g. affiliations, scientific domain, citation impact, collaboration patterns, etc.) related to the scientific author. It is of course also possible to extract data from the Twitter handle, thus being able to incorporate information on the online activity of the scholar (e.g. followers, followees, (re)tweeting activity, hashtags, etc.). This opens a unique possibility to exhaustive studies on the activities that scholars are performing in social media as well as in their publications.

The main limitation of this approach is its reliance on WoS (see also Ke, Ahn & Sugimoto, 2016) and Altmetric.com, which means it can only be used to identify scientists that publish in journals included in WoS. This means we would fail to identify a larger amount of humanities and social science scholars active on Twitter but not active in WoS. Similarly, scholars who are on Twitter but not tweeting scientific outputs (or tweeting outputs not properly tracked by Altmetric.com) would also be excluded. Also, activities in social media platforms different than Twitter are not considered in this analysis (e.g. the Chinese Weibo).

In any case, results show positive values in terms of precision and recall suggesting a strong validity of this methodology. More than 385,000 scholars can be linked to a Twitter account. In general, our results indicate a presence scholars on Twitter between 1% and 5% in the overall population of scholars in the WoS. The numbers of scholars on Twitter vary by levels of productivity, thus researchers with higher levels of production have also a stronger presence on Twitter, this very likely also caused by the reliance of the method on the number of publications of scholars. By disciplines we find a strong presence of researchers from the Social Sciences and the Humanities. Natural Sciences is the scientific domain with the lowest level of scholars on Twitter. Researchers on Twitter tend to be younger than those that are not on Twitter. These results align with those reported by Ke, Ahn & Sugimoto (2016) who also reported a higher presence of Social Sciences and Historians on Twitter, and lower levels of Life and Natural Sciences as well as Mathematicians. The high level of Humanist scholars is remarkable, considering that previous studies found that the Humanities is not one of the strongest scientific domains in altmetrics (Costas, Zahedi, & Wouters, 2015) as well as the fact that publications of scholars in this domain are least likely to be covered in the WoS.

The approach presented here also opens new and diverse venues of further research:

- Improvement of the matching and scoring algorithms. An important element that will need to be explore in the future is how to improve the matching methodology. For example, how to better match names in other non-Roman alphabets, the better parsing of Twitter names, a better matching and scoring the pairs of authors and Twitter users, etc. All these are relevant research aspects that will need more attention in the future. Additionally, the creation and evaluation of additional gold standards (i.e. validated lists of authors and their Twitter and other social media accounts) will be a necessary step in order to validate future approaches of identification of scholars on social media.

- Incorporation of other databases. Including other bibliometric databases (e.g. Scopus, Google Scholar, Microsoft Academic) would increase the population of publications and scholars. Also, the inclusion of other altmetric data sources (e.g. PlumX Analytics) as well as working with social media platforms directly (as done in Ke, Ahn & Sugimoto, 2016) would increase the possibilities to identify scholars on social media platforms.

- Demography of scholars on Twitter. Based on the current research, further analysis should focus on more deeply studying the demography of scholars on Twitter. Thus, considering the combination of both bibliometric and Twitter data it will be possible to analyse the countries of the scholars on Twitter, their gender or their subdisciplines, among other perspectives (e.g. age, collaboration, mobility, etc.).
- Moreover, the combination of bibliometric and altmetric information opens a clear path to study of the relationship between bibliometric performance and Twitter and social media activity. Thus, questions related with the impact (citation and altmetric) of those scholars on Twitter compared to those who are not on Twitter will be key future questions.
- Similarly the analysis of the activities and interactions of scholars on Twitter will be an excellent method to better determine and contextualize the interactions that scholars are maintaining with other societal stakeholders, as suggested by Robinson-Garcia, van Leeuwen, & Rafols (2017).

It can be conclude that this approach represents as a qualitative first step towards a large identification of the science-Twitter universe in a systematic way combining both bibliometric and altmetric sources. A combination of our approach with the list approach (as in Ke, Ahn & Sugimoto, 2016) as well as an analysis of the biographies of the followers and followings of the identified scholars might help to counter the limitations of the current approach, opening the path to a more complete perspective of the true engagement of scholars on social media platforms.

Abstract
This article studied the usability of altmetrics in the academic evaluation based on the data from Altmetric.com. This study was carried out in five steps. Firstly we sorted out all the related studies to make exhaustive understanding of the existing methods and conclusions for evaluating the usability of altmetrics. Secondly, the evaluation method was proposed and the dataset was constructed, which consisted of 18 altmetrics indicators of papers from 10 disciplines and published in recent 10 years. Thirdly, for every indicator we studied the distribution of coverage and mean count over time to analyze the indicators’ accumulation characteristics and focus on early literature. In the fourth part, the value of every indicator and the redundancy among values were studied. The approaches included correlation analysis between altmetrics indicators and citation, correlation analysis with each other among altmetrics indicators, and PCA among all indicators. In the last, we analyzed some factors that may affect the usability of altmetrics, such as discipline, JIF, country, language and so on.

The conclusions of this article are as follows. Some altmetrics indicators just pay attention to newly published papers, while other indicators could have wider coverage. This situation causes different data accumulation process. It’s common to find redundancies among indicators in value. The value reflected by altmetrics is various and not limited to academic value. Besides, the application of altmetrics in academic evaluation must consider discipline, JIF, language, country and so on.

Conference Topic
Altmetrics

Keywords Altmetrics, Social Media, Online Academic Communication, Academic Evaluation

Background
Peer review and citation analysis are the two main methods for academic evaluation. Peer review is a qualitative evaluation method which may be affected by the professors’ knowledge area, academic vision, or even academic morals (Cole, Cole & Rubin, 1977). As a quantitative evaluation method, citation analysis could avoid the problems above, but as it only relay on the citation relationship among papers, it has other shortages such as evaluation delay (Buschman & Michalek, 2013), measure limitation (MacRoberts & MacRoberts, 2010), and participations limitation for non-academic circles. Under the development of social media and open access, the academic communication form is constantly changing, with online academic communication becoming more and more important, and activities such as reads, download, use and collect should also be considered. So is the form of academic achievements. Besides papers, there are the blogs, presentations, software and so on. Peer review and citation analysis could no longer satisfy the needs of academic evaluation in new environment. Thus, many researches have tried to introduce some new indicators for the supplement of the existing evaluation system.

Altmetrics, short of alternative metrics, was put forward in 2010 by Jason Priem. It is the most well-known new form of metrics with great development in both theory and practice in the past several years. It has many advantages compared to traditional bibliometric (Piwowar & Priem, 2013). Indicators of different types are included to reflect actions like mention,
collection, recommendation and usage. The timeliness of many indicators is better than citations, while the forms of achievements they could measure are diverse. Nevertheless, altmetrics also have many shortcomings. Haustein (2016) summarized three main shortages as heterogeneity, data quality and dependencies. The data from websites makes it hard for altmetrics indicators to be as rigorous as citation. Many attentions achievements got from social media are the reflections of popularity or visibility on the Internet without deep understanding of their content. There are still many achievements in lack of uniform identify, which influence the accuracy and coverage of indicator data. All these problems are obstacles for the spread and usability of altmetrics. The usability of altmetrics indicators are concerned by many researchers, data providers and users. Only by having clear understanding of the indicators’ usability on academic evaluation, could altmetrics achieve wide acceptation and better development in the future.

In this paper, we studied the usability of altmetrics indicators in academic evaluation from different perspectives based on the data provided by Altmetric.com, in order to make objective suggestion for its usage and to perfect theoretical system.

State of research

Coverage of indicators

Coverage of an indicator means the percentage of academic work with at least count. It could reflect the probability of one piece of work to be used on the particular platform. Compared to citation, many altmetrics indicators are of short history, and are lack in unified standards or constraint as well. They don't have the ability to pay enough attention on large proportion of papers. As a result, the coverage of most altmetrics indicators is low. Among all the indicators, mendeley has the highest coverage. Hammarfelt (2014) found that mendeley has coverage of 61% on humanities-oriented papers followed by tweeters, but the coverage of many other indicators like mentioned in blogs or Facebooks is very low. Haustein, Peters and Bar-Ilan et al. (2014) found the coverage of mendeley is almost four times higher than that of citeulike, even though they are all readership of online communication platform.

For papers published in different years, the coverage they got from altmetrics indicators is different. Generally, most indicators have higher coverage on newly published papers than the old ones. Wang, Fang and Sun (2016) found the usage data to be more active on newly published papers. Cronin and Sugimoto (2014) found the mention on Twitter of hot papers spread like virus and can get to the peek in a very short time. The coverage of indicators on papers from different disciplines is also different. For papers from Art & Humanities and Life Science & Biomedicine, they could get more attention from altmetrics indicators than that from other disciplines (Costas, Zahedi & Wouters, 2015), (Holmberg & Thelwall, 2014).

Ability of reflecting papers’ impact

Many researchers doubt the value of altmetrics that it is just regarded as the popularity on social media. The related work could be summarized into three parts: correlation analysis between altmetrics and citation, predication of citation using altmetrics, and the motivation analysis of data growth of altmetrics.

A lot of studies about correlation analysis have been done based on different dataset with the similar results that mendeley is moderately correlated with citation, while mentions on social media like tweeters shows no correlation with citation, such as (Mohammadi & Thelwall, 2014), (Peters, Kraker & Lex et al., 2016), (Rosenkrantz, Ayoola & Singh et al., 2017) and (Song, 2014). Thelwall and Fairclough (2015) used mendeley to calculate JIF, and found that the JIF variants tend to be more stable, proving the value of mendeley. Altmetrics indicators could pay attention to papers more timely than citation does. If one altmetrics
indicator can be used to predict the future citation, this indicator could be regarded as a reliable metric (Thelwall, 2014). Thus some researches have been done in this way, like (Peoples, Midway & Sackett et al., 2016) on tweeters, (Shema, Bar-Ilan & Thelwall, 2014) on academic blog and (Schlögl, Gorraiz & Gumpenberger et al., 2014) on readership. Analyzing the motivation behind data increase is a method learned from text mining. Thelwall, Tsou and Weingart et al. (2013) and Na (2015) analyzed the content of tweets and found that most tweets echoed paper title or a brief summary, believing that tweets show no in-depth critical discussion of paper but they could help discover interesting researches. Jamali and Sangari (2015) found that bloggers tend to use papers to support their argument and believes that science blogs could be used to reflect papers’ value.

*Influence factors on usability*

Maflahi and Thelwall (2016) investigated the influence of time on mendeley based on papers from LIS journals, and found mendeley needs a long time to accumulate. Some researches about coverage also considered the influence of paper age or disciplines.

There are other factors like JIF, language, country, OA or not and so on. Alhoori, Ray and Kanan et al. (2015) found higher correlation with citation on papers from OA journals than that from non-OA journals. Wang, Mao and Xu (2014) found longer attention from usage data indicators on papers from OA journals. Mounce (2013) found the OA publications being able to gain more citations, and altmetrics could be used as supportive filtering system for OA in the future. There exist many advantages for developed countries in using altmetrics indicators because of the unbalanced development of social media and online communication (Moed, 2015). Many papers from developing countries are written in non-English language, or have no DOI, which are restricted from getting enough attention from international academic circles (Alperin, 2015).

*Integration of altmetrics indicatos*

Different altmetrics indicator could reflect different kind of impact. In order to establish a suitable index system and to adopt a reasonable evaluation method, multiple altmetrics indicators should be integrated. The analysis of similarities and differences between indicators was discussed in many studies.

Correlation analysis and PCA are the main methods for discovering the redundancy in value validity of indicators. Bollen, Sompel and Hagberg (2009) used PCA to analyze 39 possible factors of scholarly impact, finding that scholarly impact is multi-dimensional and cannot be measured by any single factor. Liu and Song (2016) studied data from PLOS ALM and found that correlation exist commonly among indicators, especially for usage data and online readerships. Some studies are done about indicators normalization. Bornmann believes that normalization must be done on indicators before altmetrics data to be used for measuring papers’ impact (Bornmann, 2014). Bornmann and Haunschild (2016) proposed one way to normalize tweeters by calculating normalized Twitter percentiles on journal level, and this method could be considered to be used for other indicators with low coverage. Haunschild and Bornmann (2016) used mean count on disciplines as denominator to normalize mendeley readership. Some studies are done in theoretical way. Haustein, Bowman and Costas (2015) proposed a combined altmetrics usage framework of 3 levels. Wang, Fang and Wang (2015) proposed a continuous, dynamic and comprehensive article-level evaluation system by using the indicators in different time and with different weight.
Methodology and data set

Methodology

The primary investigation contents of this paper include four main parts. Firstly we study the distribution of coverage and mean count over time for every indicator, analysing their accumulation characteristics and focusing on earlier published papers. Secondly, we study the value of indicators by correlation analysis with citation. Thirdly, correlation analysis is used to study the redundancy in value among indicators, and PCA is used to explain indicators from different dimensions. The possible affecting factors on usability are analysed then. At last, we discuss the integrated use of all indicators based on the empirical studies above.

Data set

We obtained citation data from Web of Science and altmetrics data from Altmetric.com in November 2016. We firstly choose ten disciplines from WOS and get all the journal articles published between 2006 and 2016 in those disciplines. The ten disciplines are Ecology, Biochemistry & Molecular Biology, Oncology, Neuroscience, Nursing, Geochemistry & Geophysics, Information Science & Library Science, Artificial Intelligence, Philosophy, and Educational Research. They covered five research domains of WOS. The whole number of articles is 1776187. For every article, DOI is used to collect altmetrics data from Altmetric API. Finally, we got 394678 papers with altmetrics data of 20 indicators as the main object for analyzation.

Altmetric.com provides an integrated score (Altmetric Attention Score, in the following text, we will use “Score” instead) for every paper by calculating all indicators with different
weight. As seen in table 1, mendeley, tweeters and accounts have higher coverage than other indicators. The coverage of Pinners, linkedin and book_reviews is very low, so we don’t analyse them in the following part.

The rows with dark shading are the indicators with zero weight for Altmetric Attention Score. When grasping data from Altmetric API, if one paper’s Score is zero, nothing would return but “null”. In other studies like (Haustein, Costas & Larivière, 2015), the coverage of mendeley is around 60-80%, but based on our dataset it is only 21.74%. This happens because when grasping data from Altmetric API, many papers got zero in Score while their mendeley readership is not zero, so “null” returned and the mendeley readership of that paper is not observed. The same happens to connotea and citeulike.

**Procedures**

**Distribution of coverage and mean count over time**

We analyzed the coverage distribution of Score over time and disciplines in Figure 1 to show the overall coverage trend for indicators. We find that for all papers of any discipline, the coverage increases over time, especially after the year of 2011. The coverage on papers published earlier than 2011 is quite low, but larger than zero. This phenomenon indicates that altmetrics indicators not only pay attention on newly published papers, but also on old ones.

Papers from the research domain of Life Sciences & Biomedicine have higher coverage. This kind of distribution over disciplines is suitable for most indicators except for some with obvious aptness on particular discipline. The platform of rh only evaluates and recommends papers of Life Sciences & Biomedicine. As the platform of quora, Stack & Flow is the website discussing IT problems.

![Figure 1. The coverage distribution of Altmetric Attention Score over time and disciplines](image)

In order to analyze their trend and connection, We calculate the coverage and mean count of every indicator over time in Figure 2. For most indicators, their coverage starts to increase after 2010. Some platforms start to grow or prosper since 2010, so the papers published after 2010 would receive more attention. The coverage of rh, wikipedia, policies keep decreasing from 2006. Their platforms have already been mature, so they would focus on the literature that has been recognized by the academia and the society. Different from coverage, the mean count of indicators show three main trends, including increasing, decreasing and keeping stable, in Figure 2.

Comparing the trend of coverage and mean count for every indicator, we could analyse their attention to newly or earlier published papers. Some indicators perform continuously while some others just pay attention to newly published papers. For example, mendeley has the increasing coverage, while mean count decreasing over time, which means that the newly published papers could get attention there but still need time to accumulate. Connotea and citeulike from online communication platform, feeds and peer_review from academic websites show the same trend. But wikipedia, rh and policies show a decrease in both coverage and mean count, which means that old papers that have been tested are more easily to get attention on those platforms. For indicators from social media, mainstream media and
usage data, their coverage and mean count keep increasing, for the reason that newly published papers could attract attention but this kind of attention doesn’t last long.

Figure 2. Indicators’ coverage and mean count on papers of different published year

Value of every indicator

Correlation analysis is the most commonly used method in proving indicators’ value. Researchers believe that correlation existing between altmetrics and citation could prove the indicators’ ability to reflect papers’ impact. Our study use Spearman Correlation to analyse the relation between every altmetrics indicator and citation. The result is shown in Figure 3. We found that indicators from the same type of platforms tend to have similar correlation coefficient. Most indicators from online communication platform and academic websites show low to medium correlation with citation. Mendeley has the highest coefficient of 0.66. But other indicators like social media mention or usage type have no correlation with citation.

Figure 3. Correlation between altmetrics indicators and citation

In order to make comprehensive understanding of the correlation between altmetrics and citation, we analysed the distinctions of correlation based on papers of different disciplines and different ages.
Figure 4 shows the changes of the correlation coefficient over time. As citations need at least 3 years to accumulate, we used papers published before 2013 for analysis. The correlation of mendeley with citation reduced after the year of 2010, which means that for papers newly published, mendeley has the space to increase and mendeley could reflect the value of earlier published papers to some extent. The same phenomenon was observed from citeulike, connotea and wikipedia. For rh and feeds, their correlation with citation keep increasing till 2012, after which it begins to fall, indicating that these indicators need time to increase but their ability of discovering old papers is not as strong as citation. Other indicators like tweeters and accounts keep increasing till 2013, proving their weak ability of reflecting the value for newly published papers.

For papers from different disciplines, the correlation between altmetrics indicators and citation shows no obvious distinction, except for citeulike which has lower correlation in Natural Science, and rh which has much higher correlation in Life Sciences & Biomedicine.

**Redundancy of indicators’ value**

We found low to medium correlation existing commonly between altmetrics indicators. Indicators from same type platforms have similar meaning of data, which makes them easily to have correlation with each other.
Accounts has correlation with many indicators, especially those from social media platform. It has high correlation with tweeters, and low correlation with feeds, msm, fbwalls and gplus. Mendeley is another indicator which has correlation with many indicators. Those indicators are citeulike, rh, feeds, msm, accounts and gplus, most of which are from online communication platform and academic websites. Besides, low correlation exists between many other indicators as shown in Figure 5.

For indicators from platform of same type: mendeley, connotea and citeulike, all of which are from online communication platform, have low correlation with each other; tweeters and fbwalls have low correlation, while other indicators from social media show no correlation. For indicators from different type of platform: most indicators from online communication platform have correlation with that from academic websites; indicators of usage have correlation with most indicators from social media platform and mainstream media; msm has correlation with many indicators from social media platform.

In order to find the reason behind redundancy, we use PCA (Principal Component Analysis) to analyze the indicators from different dimensions. Citation is included for comparison. The first two components could explain 70% of the variance, while the following components keep score around 1, indicating that they also represent information of different dimensions and cannot be ignored. All the indicators variances on principal component are shown in coordinate in Figure 6.

Based on the variance of every indicator on components, we could summarize the two components as follows: PC1 means timeliness of indicator, and the negative direction means indicator could reach the top just after a short time; PC2 means the aspect of value indicators could reflect, and the positive direction means the indicator tends to reflect the academic value of papers, while the negative direction means the indicator tends to reflect the social value.

According to Figure 6, we could see three obvious groups of indicators. The first group includes z9, mendeley and citeulike, which tend to reflect the academic value of papers and need a period of time to accumulate. Besides the three, other indicators like rh, connote show the similar character with lower degree. The second group includes accounts and tweeters, tending to reflect the social value of papers timely, and fbwalls, msm, rdts and gplus have the same character but lower degree. The third group is around the origin point, with the meaning of no obvious tendency to both PCs. Their character may be explained in other dimensions. PCA could just give rough explain on character tendency.

![Figure 6. The distribution of altmetrics indicators on Principal Components](image-url)
Analysis of influence factors on usability of altmetrics

We assume that the journal impact factor is one of the factors. The total number of journals having at least one paper with Score is 1900, and the top 10 (sorted by the whole number of papers with Score) of them are all from Life Sciences & Biomedicine. We use JIF, 5JIF and NE as quantitative indicators to represent journal impact, which are published in July 2016. 5JIF refers to the mean JIF of recent five years. NE, short of Normalized Eigen factor, is released as a supplement for JCR for cross-field comparison. The NE of one journal is 2, which means this journal impact is twice than the average impact of journals from the same discipline. We found more than 71.57% of papers is with NE larger than 1, and the correlation coefficient of NE and Score is 0.173 on these papers. On the remaining part, the coefficient is 0. We could get the point that altmetrics pay more attention to papers from journals of high impact.

In order to study the influence on every single altmetrics indicator, we did correlation analysis between altmetrics indicators and the three journal impact indicators, including citation. We got the result that for indicators like accounts and msm, the correlation with JIF and 5JIF is higher than that with citation, indicating that the indicators with short accumulation period would be more easily affected by journal impact. Comparatively, indicators like mendeley, Wikipedia, citeulike and policies which have long accumulation period would be more easily affected by citation than by journal impact.

Figure 7. Correlation between altmetrics indicators with journal impact indicators

Altmetrics indicators have prejudice against non-English papers. English is the main language used in online communication platform, as well as the social media and academic websites. In order to make a easy communication with others in the international academic circle, researchers tend to use English to write papers. For all papers got from WOS, 34 types of language are used, and the percentage of English papers is 97.67%. For papers with Score, 10 types of language are used, and the percentage of English papers is 99.73%.

The prejudice also exists in papers from developing countries, mainly because of the insufficient use of DOI and the non-English language used. We firstly analyze the DOI distribution all over the world to have a glimpse of DOI popularity for different areas. We found that for countries from North America, Europe, Oceania and East Asia, DOI is more widely used than that of Africa, South America and Middle Asia. Then we use the first author’s nation to represent the papers’ source country, to analyze the coverage of altmetrics all over the world. The result is shown in Figure 8. The top 10 countries with highest percentage are Switzerland, USA, UK, Denmark, Ireland, Austria, Netherlands, Sweden, Italy and Germany, all of which are from developed areas. For some countries with low percentage, most papers are written in non-English languages and have quite low DOI popularity. For example, 63.81% of all papers from Russia are written in Russian and only 10.44% papers have DOI.
We also assume that collaboration on author level and country level would have an influence on the usability of altmetrics. 73.79% of papers with Score are written by multiple authors, while the percentage of all papers from WOS is 56.02%. With the data of country that we collect from authors’ address, we found that 26.92% of papers with Score are internationally collaborated, while the percentage for all papers from WOS is 18.45%. This shows that multiple authors collaborated papers and internationally collaborated papers could both get more attention from altmetrics. Analyzing on papers of different published year shows that the percentage gap of international collaboration between all papers and papers with Score is reducing over time. Few differences have shown for different indicators.

![Figure 8. The percentage of papers with Altmetric Attention Score all over the world](image)

**Discussion**

The coverage and mean count of most altmetrics indicators change over time. Indicators from online communication platform and academic websites need time to accumulate. Earlier published papers could also get attention from these indicators. Indicators from social media, mainstream media tend to pay attention to newly published papers. Some indicators from platforms that have got enough development tend to pay attention to papers that have been tested by time. For different indicators, the moment they pay attention to and the time to accumulate are different.

For the correlation with citation, mendeley has medium coefficient, other indicators from online communication platform and academic websites have low coefficient, while the coefficient for indicators from social media, mainstream media and usage data is around zero. By correlation analysis among all indicators, we found redundancy exist commonly in value for indicators from same type platforms and different type platforms. Mendeley and accounts are the two indicators that have most commonly correlation with other indicators. By doing PCA, we conclude two main components, timeliness and value impact, to explain indicators. But as other components having high percentage on variance, we don’t regard the PCA having the good result as usual, believing that some information would miss if doing so. This conclusion supports the diversity of indicators.

We found factors like disciplines, JIF, languages and DOI popularity could influence indicators’ usability. For example, papers from Life Sciences and Biomedical Sciences could get more attention from many indicators, in-time indicators such as tweeters would suffer from the impact of source journal, and non-English papers or papers from undeveloped areas would get less attention they deserved. For the effect of OA, we did not get the chance to analysis because of the dataset we got (all the papers are from non-OA journals).

The differences in accumulation rate, the attention for earlier published papers, the redundancy and diversity in value, make it hard to integrate use of indicators. All these
problems must be considered, as well as the better performance of indicators on English papers, papers from developed areas, and papers from Life Sciences & Biomedicine. The normalization for indicators which is one of essential parts (Bornmann, 2014) is just at the exploring period, with mendeley and tweeters being the researching objects and normalization over time and disciplines being the main method. Many things need to be done before a universal framework proposed. The integrated use of indicators needs guides in theory as well as supports from practice.

Conclusions

In this article, we studied the usability of altmetrics indicators on academic evaluation from many perspectives. The study was carried out from the count level to the value level of indicators, with the method of comparative analysis, correlation analysis and PCA. By analyzing the distribution of coverage and mean count over time, we studied the accumulation character for every indicator and their attention to earlier published papers. By analyzing correlation between citation and indicator, and among indicators, we studied the value and the redundancy on value for every indicator. By doing PCA for indicators, we explained the indicators on different dimensions, and have better understanding on the diversity and aptness of indicators. We also analyzed possible factors that may make influence on the usability. At last, we discussed the integrated use of indicators, and found the research of usability and universal framework still has a long way to go.

Abstract
Science and technology are becoming more and more closely linked today and the research on the relationship between them has become a hot topic. In this paper, we are trying to investigate the relationship between science and technology at micro-level. A new carbon nanomaterial - graphene is taken as an example, and publications and patents are used as data sources for the representation of science and technology. Citation networks of publications and patents are constructed, on which a knowledge meme discovery algorithm is used, in order to identify scientific knowledge memes and technological knowledge memes that play a key role in the evolution of scientific and technological knowledge. We also track the diffusion and co-occurrence of knowledge memes, which could provide guidance for promoting scientific and technological innovation and making research policy.

Conference Topic
Citation and co-citation analysis; Patent analysis

Introduction
The relationships between science and technology are complex, and a number of endeavours have been undertaken to reveal the connection and interaction between science and technology in recent years (Meyer, 2001; Van Looy et al., 2003; Boyack and Klavans, 2008; Narin and Noma, 2005; Zhao and Guan, 2012, 2013; Huang et al., 2015). Some researchers find science and technology are becoming more and more closely linked today (Meyer et al., 2010). However, the relationships are often different in different fields and at different phases of a technological “life cycle” (Brooks, 1994).

Publications are the main channel for documentation of scientific findings, and patents reflect the development of new technologies. Bibliometric methods based on paper and patent analysis are the main methods to study the relationships between science and technology. These methods are often based on the citation of papers and patents (Chen and Hicks, 2004; Narin and Noma, 2005; Yeh et al., 2013; Huang et al., 2015), or the relationship between the inventors of the patent and the authors of the paper (Meyer, 2006; Wang and Guan, 2010). This “science-technology relationship” research based on these methods mostly reveal the quantitative characteristics of the relationship, however, the research on the interrelated topics between science and technology is still relatively rare.

Graphene - a new type of carbon nanomaterials is taken as an exemplary research field in this study. It has attracted the attention of a large number of researchers and has been widely used to modify various polymers in recent years (Novoselov et al., 2005; Geim and Novoselov, 2007). The potential applications in lithium-ion batteries, solar cells, sensors and supercapacitors have been extensively studied and have great application prospects (Wu et al., 2010). Over the past few years, graphene/polymer nanocomposites have made encouraging progress in basic research and product application development, but from basic research to extensive application there is still a long and complex process. With the “Material Genome Project” proposed, how
to accelerate the process of research and application of materials to promote the integration of science and technology has become the common needs of countries around the world. Therefore, the development of effective methods to explore the relationship between science and technology, and promote their integration is a key issue. Although this paper focuses on the field of graphene, the related methods can be extended to other fields.

In this paper, we are going to investigate the relationship between science and technology at micro-level, in which “knowledge memes” are identified and tracked. Dawkins introduced the term “meme” (Dawkins, 1976) for the entities such as words, ideas in cultural evolution that are similar as genes. Memes are the cultural equivalent of genes that spread across human culture by means of imitation (Kuhn et al., 2014). Here we use also use “meme” to refer to the knowledge that plays an important role in shaping the evolution of science and technology. Based on the knowledge memes, this study offers a further description of knowledge diffusion path and knowledge innovation, with the help of meme co-occurrence networks.

The rest of this paper is organized as follows: Section 2 reviews related work; Section 3 introduces the proposed method including how to identify knowledge memes and build knowledge meme networks; Section 4 presents the results of the proposed method; then we conclude in Section 5.

Related Work

The study of the relationship between science and technology can be traced back to the study of Price in the 1960s (Price, 1965). He believed that science and technology had their unique knowledge accumulation structure. When the paradigm is broken, knowledge may flow from science to technology or flow from technology to science. Bibliometric methods based on publication and patent analysis are the main methods of studying the relationship between science and technology. Commonly used data comes from USPTO, EPO and other patent offices and Derwent Innovation Index (DII) database for patent data and Web of Science (WoS) for publication data. The main methods can be divided into three categories: patent’s paper citation analysis, paper’s patent citation analysis, “inventor - author linkage” analysis.

One approach of exploring science-technology relationships consists of taking into account citations to scientific papers found in patents, which reveals the promotion of basic science research to technological innovation. Patent citations, particularly the citations to non-patent references (NPRs) (Verbeek et al., 2002), are regarded as the most popular indicator to track the linkage between science and technology (Chen and Hicks, 2004). Narin and Noma (Narin and Noma, 2005) analysed the citation relationship between patents and papers in the field of bioscience, and concluded that patents and papers were highly correlated, and high-tech was closely related to science. Meyer (Meyer, 2001) used patent’s paper citation information to analyse the relationship between nanoscience and nanotechnology. The linkage established through the reference field of patents or publications, however, are doubtful, mainly because of different citation behaviours and different citation motivations among authors, inventors and patent examiners (Meyer, 2006). The above studies use citations to papers in patents for analysis, observing only one aspect of the interaction.

The citation of patents in academic papers also contains the relationship between basic research and technological innovation. Glanzel and Meyer (Glanzel and Meyer, 2003) analysed the similarities and differences of different disciplines based on the citation of patents in SCI papers, and found that the chemical field had cited more patents than other disciplines, and the patents
on chemistry, medicine and medicine were cited more frequently. Some scholars combined the patent’s paper citation analysis with paper’s patent citation analysis to reveal the two-way interaction between science and technology (Huang et al., 2015).

Furthermore, some studies quantified the interaction between science and technology through inventor-author linkages (Meyer, 2006; Wang and Guan, 2010) by tracking the patent inventors published research papers or researchers invented patents. Alternative approaches concerned about how to explore joint publications between academia and industry (Van Looy et al., 2003, 2006). Similarly, Zhao and Guan (Zhao and Guan, 2012, 2013) qualified and evaluated the associations between scientific activity and technological output in the case of innovation system.

Most of the researches have analysed the quantitative characteristics of the relationship between science and technology, but the research on the interrelated topics between science and technology is still rare. In the development of science and technology, a key knowledge element may play the role of “knowledge meme”, which determines the evolution and mutation of specific domain knowledge. The identification and research of knowledge memes may shed light on the understanding of the development of the research field. Recent research on memes is interested in meme diffusion in social media, such as blog space and Twitter (Ratkiewicz et al., 2011). The issue of competition among memes with limited attention also draws researchers’ attention (Weng et al., 2012). In science, the spread of a knowledge meme can be tracked via citations. Kuhn et al. (Kuhn et al., 2014) proposed a method based on citation networks to extract scientific memes in the scientific literature. They also give a definition: A scientific meme is a short unit of text in a publication that is replicated in citing publications.

In this paper, we follow the definition of Kuhn et al., and also extend it to technological meme: A technological meme is a short unit of text in a patent that is replicated in citing patents. The identification of knowledge memes could help us to understand the evolution and interaction of science and technology more deeply from the micro level. Furthermore, the exploration and the recombination of knowledge memes, could promote the development and innovation of science and technology.

Materials and Methods

Dataset
The study exploits a patent database of graphene research field from Derwent Innovations Index (DII). The patents that have “graphene” in title, keyword or abstract are included in the patent database. Publication data related to graphene is derived from Web of Science (WoS) based on the same search strategy and stored in the publication database. The data covers the period 2010-2015 and there are totally 15,818 patents and 71,008 publications.

Building paper and patent citation networks
The inheritance of knowledge by citation processes reflects the evolution of knowledge. When paper cites the previous papers, the part of knowledge that is similar has been retained. The most relevant and most valuable knowledge has been inherited, which becomes the knowledge memes. Thus, the citation relationship provides an advantageous resource for the discovery of knowledge memes.

The main storage medium of scientific knowledge is papers. The citation relationships between papers show the communications of vertical inheritance and horizontal association of scientific
literatures. They reflect the trajectory of scientific development and the inheritance of knowledge. Similarly, the main storage medium of technological knowledge is patents, and there are also citation relationships between patents.

In this paper, we use the citation relationships to build paper citation network and patent citation network. The nodes in the network are papers (or patents), and the links between them represent the citation relationships.

**Identifying knowledge memes**

The identification of scientific knowledge memes and technological knowledge memes can help to discover what knowledge memes play a key role in the evolution and mutation of domain knowledge and predict the future development trend of the field.

Words or phrases that often occur in the literature can be considered as important memes, but many frequent words such as “method” are of little significance to a field. Kuhn et al. proposed a scientific memes identification algorithm based on the citation network, mainly using the frequency of occurrence and the degree to which they propagated along the citation graph. A meme that is often appear in publications that cite meme-carrying publications but rarely appear in publications that do not cite a publication that already contains the meme (Kuhn et al., 2014), has a higher score. $P_m$ is defined as the propagation score:

$$P_m = \frac{d_{\rightarrow m}}{d_{\rightarrow m}}$$  \hspace{1cm} (1)

where $d_{\rightarrow m}$ is the number of publications that contain meme $m$ and cite at least a publication that contains $m$; $d_{\rightarrow m}$ is the number of publications that cite at least a publication that contains $m$; $d_{\rightarrow m}$ is the number of publications that contain meme $m$ but did not cite any publications that contain $m$; $d_{\rightarrow m}$ is the number of publications that did not cite any publications contain $m$.

The method also considers the frequency of the meme $m$, using $f_m$ to represent the proportion of the publications that contain $m$. Finally, the score of meme $m$ is defined as:

$$M_m = f_m P_m$$  \hspace{1cm} (2)

The propagation score, as defined in Eq. (1), could be improved by adding a small amount of controlled noise $\delta$, which we will try in the future work.

The words in titles and keywords after removing stop words are used as candidates for memes. Based on this method, this paper extents it to the paper and patent citation networks, discovering scientific knowledge memes and technological knowledge memes at the same time, and further investigating the relationships between science and technology.

**Constructing knowledge meme co-occurrence network**

On the basis of the identification of knowledge memes, we construct a knowledge network, which is a network with knowledge memes as nodes and the co-occurrence relationships among memes as edges. The weight of the edge is the number of times two memes appear together. Based on the knowledge meme network, the community discovery algorithm (Blondel et al., 2008) is used to identify closely related meme subgroups. The knowledge memes in a community have a close relationship, the recombination of which may reveal possible hidden knowledge innovation.
Results

Scientific memes and technological memes

All the words in the title and keywords after removing the stop words of the papers and patents are considered as potential memes. After building the paper citation network and patent citation network, we use Eq. 2 to compute the scores of the memes. A higher score indicates the word or phrase is more likely to be a meme in the research field. Table 1 and 2 show the top 10 scientific memes and technological memes in the year 2010, 2012 and 2014. The annual data used for the calculation of memes is the cumulative data from 2010 to the current year.

It could be seen from table 1 that the scientific knowledge memes such as Metamaterial, Nanocomposite, OLED and Laser have been the common memes in graphene research field and have been playing an important role in the development of the field. As time goes by and the progress of technology, knowledge memes are also evolving. The identification of these memes is of great importance in understanding the evolution of the field.

From table 2, we could see that the technological memes are more about the preparation of materials and the research of process performance. Polymer, Composite, Substrate, Film, Electrode, OLED, etc. have always been the knowledge memes in graphene technological field. In 2014, the focus of technological research is still similar with that of a few years ago, there is no obvious evolution in the topics.

Relationships between graphene science and technology based on knowledge memes

With the help of the identification of scientific knowledge memes and technological knowledge memes, we could investigate the relationships between graphene science and technology from the view of knowledge memes as follows:

**Differences:** Graphene scientific research is mainly carried out from three aspects: the preparation of graphene, graphene applications, and graphene composites. The range of applications is wide, in particular, including batteries, superconductors, semiconductors, capacitors, carbon nanotubes, Lasers, cell imaging, etc. Graphene technology is mainly focused on the preparation of graphene and part of graphene applications, such as the preparation of graphene composites, films, electrodes, lasers, which is more concentrated.

**Similarities:** The preparation of graphene is the focus of both science and technology, and in the applications, the battery, laser, composite materials are also important common concerns. In these aspects, the interaction between science and technology is frequent and it could be easy to apply the findings of basic research to application. In other aspects, there needs more efforts to promote the two-way interactions.

**Development Trends:** Although there are some differences in the research topics between graphene science and technology, the relationship between them is becoming more and more close. The boundary is becoming more and more blur, showing convergence trend.

Some researchers found that the time between the publication of a journal article and the patent application citing the article was relatively short (Carpenter et al., 1980). In Fig.1, we plot the time spans between the publication year of patents and the average publication year of the cited papers in the field of graphene. We obtain similar results: the time span is showing a shrinking trend. This may indicate that the knowledge flow and the transformation from basic research to application is becoming quicker.

![Figure 1. Publication year of the patents vs. publication year of the cited papers (the numbers in the figure are the average publication years of the papers, and the numbers on the right are the time spans between the publication year of the patents and the average publication year of the cited papers).](image)

We also examine the similarity between the titles of patents and papers in order to identify a consensus in the use of terms between science and technology. The titles of patent and paper are represented as two vectors: \( \mathbf{A} \) and \( \mathbf{B} \). \( \mathbf{A} \) and \( \mathbf{B} \) have the same dimension (the combination of terms in the titles of patents and papers), and the components of the vectors are 1 if the titles
of the patent or the paper have the corresponding words. Then, the similarity between two vectors $\mathbf{A}$ and $\mathbf{B}$ is computed using cosine similarity:

$$
similarity(\mathbf{A}, \mathbf{B}) = \frac{\mathbf{A} \cdot \mathbf{B}}{\|\mathbf{A}\| \|\mathbf{B}\|} = \frac{\sum_{i=1}^n A_i B_i}{\sqrt{\sum_{i=1}^n A_i^2} \sqrt{\sum_{i=1}^n B_i^2}} \tag{3}
$$

where $A_i$ and $B_i$ are components of vector $\mathbf{A}$ and $\mathbf{B}$ respectively.

In a certain year, the similarity between the title of a patent and the aggregated titles of its cited papers is computed using cosine similarity, and then the topic similarity is averaged using the number of patents in that year. Fig. 2 plots the topic similarity between patents and the cited papers in subsequent years. In general, the average similarity is increasing from the year 2010 to 2015, although not very obvious.

![Figure 2. Topic similarity between patents and the cited papers (the numbers in the figure are the average similarities per year).](image)

**Knowledge meme diffusion path on citation networks**

Based on the identification of knowledge memes, we could track the meme diffusion path on citation networks. For example, in Fig. 3(a), which is the patent citation network with memes, we could see: a. the key patents that play an important role in the knowledge meme diffusion; b. the diffusion path of knowledge memes. Some patents play as the basis of other patents, such as patent “US7071258-B1”, the title of which is “Nano-scaled graphene plate material used for composite material, comprises nanometer-scaled plate(s) comprising sheet(s) of graphite plane, and length, width and thickness of nanometer scaled plates are specified”. The memes it contains are “composite”, “graphite”, “comprise” and “material”. It provides the basic knowledge about nano-scale graphene material which is useful for other patents. Meanwhile, some patents, for example, patent “US7790242-B1” (Electrostatic deposition of graphene on substrate involves applying voltage across graphite sample secured to positive electrode and substrate placed over a second electrode, so as to transfer graphene from graphite sample to the substrate), inherits the knowledge from many other patents, the memes of which are “involve”, “oled” and “graphite”. Different patents belong to different levels in the development of technology.

Similarly, scientific knowledge meme diffusion path could also be tracked as seen from Fig. 3(b). For example, we mark two papers that on the diffusion path of the meme “OLED”, paper (DOI: 10.1021/nn1015874: “Organic Photovoltaic Devices Using Highly Flexible Reduced Graphene...
Oxide Films as Transparent Electrodes”) and paper (DOI: 10.1002/pola.23802: “Thermosensitive Graphene Nanocomposites Formed Using Pyrene-Terminal Polymers Made by RAFT Polymerization”). The paper (DOI: 10.1002/pola.23802) contains memes “oled”, “nanoco” and “nanocomposite”, and inherits the knowledge from many other papers.

Figure 3. Knowledge meme diffusion (a) on the patent citation network in 2010 (nodes are patents with memes) (b) on the paper citation network in 2010 (nodes are papers with memes). Different colors indicate different clusters of patents identified by community detection algorithm.

Knowledge innovation based on meme co-occurrence networks

In this section, knowledge meme networks are built based on the co-occurrence of memes, from which we could get insight into the knowledge memes that are always appear together, and explore possible knowledge innovation based on the recombination of knowledge memes.

Fig.4 shows an example of technological knowledge meme co-occurrence networks in the year 2010 and 2012. “Graphene” is ignored as it almost occurs with all the other memes, and affects the results. In 2010, the memes are basically formed a large group and closely related, which is mainly about the preparation of materials. In 2012, using community detection algorithm, there are three groups. The memes contained in each group are: dioxide, oxide, titanium, involve, fiber, saturate, oled, laser, graphite, prepare; layer, film, memory, device, semiconductor, form, transistor, substrate, carbide, solar, electrode, silicon; composite, carbon nanotube, battery, lithium, carbon, material, nanotube, resin, phosphate, comprise.

Figure 4. Technological knowledge meme co-occurrence networks in 2010 (a) and 2012 (b).
Fig. 5 is the scientific knowledge meme co-occurrence networks in the year 2010 and 2012. In 2010, there are several memes closely related, e.g. oled, nanoparticle, nanocomposite and nanoco. In 2012, we could see the structure is very different from that of patent network. The three groups are: nanocomposite, nanoco; graphene, quantum well, molecular beam, nanoribbon, isotope-separation, hydrogen-peroxide detection, nanopore, nanoparticle, diffusion dynamics, superconductor, silicon, nanofluid, single dirac cone, metamaterial, organic conductor, graphene quantum dot, graphyne, oled, single-layer mos2; q-switch, mode-lock, fiber laser, saturable absorber, laser.

![Figure 5. Scientific knowledge meme co-occurrence networks in 2010 (a) and 2012 (b).](image)

The memes that are in one group that have not linked together, may have the chance of recombination to give rise to knowledge innovation. In the future work, we would like to apply link prediction algorithm to predict potential links between knowledge memes.

Conclusions
In this paper, the knowledge meme identification algorithm is used to identify the scientific and technological knowledge memes, and the knowledge meme network is constructed, which is applied to the graphene field to investigate the relationship between science and technology and track the diffusion of memes. The results reveal the similarities, differences and development trend between science and technology in the graphene field, and the related research can be extended to other fields and provide guidance for making science and technology policy and promoting technology innovation.

This study is a first attempt to investigate the relationship between science and technology in the view of knowledge memes at micro-level. There are also some limitations of this study. Firstly, the relationship between science and technology is not fully explored, in order to solve this, we are building citation networks between papers and patents to fully link science and technology. Secondly, based on the knowledge meme networks, we will try to use link prediction algorithms to study the recombination of memes, model the association trend between scientific and technological memes, making efforts to accelerate the transformation of science to technology and the promotion of technology to science.

Abstract
Science is a dynamic system. Its cognitive structure is subject to permanent changes. Any particular structural change, such as new research trends and emerging topics, can be detected in cognitive maps. In this paper, we attempt to identify new research trends and topic transition by detecting both changing structure and anomalous events in the course of mapping the structure of journal-based clustering. We form one community for each journal cluster, with nodes representing journals and edges representing the citation links among journals. To measure the significance of changes in the dynamic journal clusters, a community similarity measurement is required. However, the existing similarity algorithms neglect the shift of the internal structure in networks and graphs, which determines that these algorithms cannot be directly applied to journal clusters. We propose a novel community-similarity algorithm, which considers both the shifts of vertices and the shifts of communities’ layered structure. Communities’ layered structure categorizes nodes into different groups, depending on their influence on the community. We apply the novel algorithm on the temporal journal data set, and identify two types of anomalous events. Both the visualizations of the journal clusters and the text annotations demonstrate that the identified events correspond to new emerging trends in scientific fields.

Conference Topic
Knowledge discovery and data mining, Scientometrics

Introduction
Mapping of science has played an important role in the field of library and information science. It helps improve the subject delineation and identify the emerging and converging fields (Janssens, Zhang & De Moor, 2009). However, science is a dynamic system. New research topics emerge, others might disappear and increasing inter- and cross-disciplinarity also affects structure and relationships of the concerned disciplines. Not all of those can be predicted or follow linear evolitional paths. Breakthroughs, delayed recognition, cross-fertilization may lead to unexpected changed in the network of scholarly communication. Finally, a critical mass of research results and literature is needed to make changes visible (Glanzel & Thijs, 2012). These can be regarded as anomalous events that occur in the development of science mapping.

Journal clustering can uncover such changes and provide insights into the emergence of new research topics (Liu, Glanzel & De Moor, 2012; Glenisson, Glanzel & Janssens, 2005). Previous studies have proven that journal clustering can be employed as a good reference for journal categorization (Liu, Yu & Janssens, 2010). It is also efficient to be applied to detect new trends in different scientific fields. Thus in this paper, we adopt the temporal journal data set from Clarivate Analytics Web of Science Core Collection, and attempt to detect anomalous events that occurred in scientific mapping.

We analyze the temporal journal data set based on their citation relations. Dynamic journal networks are constructed, with node representing journals and edges representing the direct citations among journals. Journal clusters can be obtained by partitioning the journal networks. Particular, journal clusters can be regarded as communities. Thus, to detect the anomalous
events in journal clusters, a notion of community similarity is required to measure the significance of changes in the evolution of these temporal journal clusters. Several studies have focused on algorithms that measure the similarity of two graphs or networks. Without loss of generality, we do not distinguish networks from graphs in this paper. Similarly to community detection, graph similarity algorithms are able to track temporal networks (Palla, Barabasi & Vicsek, 2007), to monitor the evolution of networks (Koutra, Vogelstein & Faloutsos, 2013), notably to track the changes over time and to detect anomalies (Noble & Cook, 2003) and events (Caceres, Berger-Wolf & Grossman, 2011). Multiple graph similarity algorithms have been proposed by both Bunke (2007) and Papadimitriou (2010). However, the existing algorithms ignore the structural shift of communities. Thus, the existing algorithms are not suited to identify communities with largely changing structure. For instance, the shift of the core journals in one journal cluster indicates that potential topic transition may have occurred. Therefore, approaches that are more convincing are needed to identify the shift of such structure.

This paper presents a novel community similarity algorithm by considering both the shift of communities' vertex set and the changes in communities' structure. Communities' structure determines the way in which individuals in communities are organized. It categorizes nodes into different groups, depending on their influence in the community. It is expected that the change of communities' structure should also affect community similarity. As the structure of communities proposed in this paper reflects the organization of individuals, without loss of generality, in the present study we refer such structure as the layered structure.

As the structure of communities categorizes nodes into different groups based on their influence, the shift of communities' structure can be measured by the shift of all nodes' influence. Thus, two kinds of weights are defined in our algorithm to measure the influence of nodes and the shift of the nodes' influence, respectively. The first one is the importance weight. It emphasizes that the core nodes could have stronger effect on the similarity of communities than on that of ordinary nodes. For instance, the overlapping of the core nodes could more strengthen the similarity of two journal clusters than that of the ordinary nodes with the same amount. The second one is the persistence weight. It proposes that the shift of nodes' status will weaken the similarity of two communities. For instance, if the core journals in one journal cluster degenerate to be ordinary in the next period, the similarity of the two journal clusters will be weakened.

We apply the novel algorithm to the journal data set from Web of Science Core Collection (WoS) database, aiming at tracking the changes in journal clusters and identifying anomalous events in science mapping.

The contribution of this paper is two-fold. First, we present a new community similarity algorithm, which takes not only the shift of the vertices, but also the shift of community structure into consideration. It is able to identify the transition of community structure in a better way, and is consistent to the intuition. Second, we apply the novel algorithm to a publication set. By calculating the similarity between each pair of two consecutive scientific data set, we are able to detect anomalous events in scientific mapping. Experiments show that there are two types of events in scientific mapping. The first one is related to a structural change in the journal clusters, while the vertex set remains relatively stable. It indicates that the research topics of the journal clusters may have changed. The second type reflects a situation, where the structure of journal clusters remains stable, though their vertex set considerably changes. This indicates that the new journals appearing in the set do not affect the structure of the journal clusters.
Related works

The evolution of scientific mapping

Literature about the evolution of scientific mapping includes, for instance, the evolutionary analysis of bioinformatics (Janssens, Zhang & De Moor, 2007; Janssens, Glanzel & De Moor, 2007), medical knowledge (Mina, Ramlogan & Tampubolon, 2007) and Health Research (Fiordelli, Diviani & Schulz, 2013).

Among these articles, we find three main approaches. The first category analyzes the lexical analysis of the scientific data set to detect emerging trends and bursts (Mane & Borner, 2004; Chen, 2006). Mane (2004) focused on identifying mapping topics and topic bursts in the Proceedings of the National Academy of Sciences (PNAS). They conducted Kleinberg's burst detection algorithm (Kleinberg, 2003), co-word occurrence analysis and graph layout techniques to generate maps that support the identification of major research topics and trends.

The second approach analyzes the evolution based on network theory using citation links. Boyack (2009) mapped the structure and evolution of chemistry research over a 30 year time frame. They analyzed the maps of 14 journal clusters in the field of chemistry research and visualized the knowledge flows among these journal clusters. They found that Biochemistry and Bioengineering are moving steadily into Chemistry territory, and are having a large influence on the general knowledge base.

Finally, a third approach makes an advantage of both methods by combining the two approaches. The so-called hybrid approach is a combination of citation-based and lexical analysis. This method was applied to track the evolution of research fields (Janssens, Glanzel & De Moor, 2007) and to detect and label emerging topics (Glanzel & Thijs, 2012).

In this paper, we conduct the citation analysis to depict the evolution of scientific mapping and detect scientific events. The major difference between our approach and the previous results is that we also consider the above-mentioned structural shift in journal clusters. The structure of journal clusters categorizes each journal of the cluster into distinct groups based on its influence. When the structure of a journal cluster changes, it indicates that a topic shift is likely to occur in the journal cluster. Thus, it is expected that the structural changes within journal clusters correspond to anomalous events in scientific mapping.

Graph similarity

Two types of graph similarity problems can be distinguished: (1) with known node correspondence; (2) with unknown node correspondence.

For the first type, various kinds of algorithms have already been proposed. Papadimitriou (2010) propose 5 similarity measurements for web graphs. Among them, the best two are the Signature Similarity, which is based on the SimHash algorithm, and the Vertex/Edge Overlap similarity. Bunke (2007) proposed techniques that were used to track sudden changes in communications networks for performance monitoring.

For the second category, the most widely used algorithms include: $\lambda$-distance (Bunke, Dickinson & Kraetzl, 2007; Peabody, 2002; Wilson & Zhu, 2008), which is based on the spectral method; algebraic connectivity method (Fiedler, 1973) and various algorithms based on graph kernels (Kang, Tong & Sun, 2012).

There are two major differences between the existing graph similarity algorithms and the novel approach in this paper. First, the existing algorithms usually ignore the shift of the layered structure of graphs. Second, communities do not necessarily possess sub-modularity structures, compared to graphs and networks. Therefore, the existing algorithms could not directly be applied to communities and a more specific method is required.
Methodology

In order to overcome the above-mentioned issue, we propose a new community similarity algorithm. We first present the basic idea of this community similarity algorithm. One key point in the algorithm is to measure the influence of nodes in communities, the shift of which is able to reflect the change in the communities’ layered structure. In this paper, the $k$-shell decomposition method is adopted to measure the nodes' influence. Then we introduce the algorithm itself.

The basic idea of the novel community similarity algorithm

The algorithm assumes that community similarity is affected by both the changes in their vertex set and changes in their structure. Intuitively, one assumes that communities are organized with certain structures, such as the flat structure and the hierarchical structure. The structure categorizes nodes into different classes, which reflect the influence of nodes. Thus, any change of a communities' structure can be measured by the changes of all nodes' influence.

For one node, $u$, belonging to two communities, $C_1$ and $C_2$, the following properties should hold in an effective community similarity algorithm:

1). If $u$ is influential in both $C_1$ and $C_2$, it will strengthen the similarity of $C_1$ and $C_2$.

2). If $u$ is influential in one community, but not so in another community, it will weaken the similarity of $C_1$ and $C_2$.

3). If $u$ is not influential in both communities, its influence on the community similarity is weak.

These properties show that community similarity is affected by two factors. The first one is the influence of nodes. Influential nodes are expected to be more crucial in community similarity measurement. For instance, when measuring the changes of one social group, the shift of group leaders should be more decisive. Thus, an importance weight is determined to measure the influence of nodes in the community. The second point is the change of the nodes' influence. The fact that a node is influential in one community but becomes an ordinary one in another community will weaken their similarity. Thus, a persistence weight will be defined to measure the change of a node's influence.

The Measurement of nodes' status

Both the importance weight and the persistence weight depend on the influence of nodes on communities. We adopt the $k$-shell decomposition method (Dorogovtsev, Goltsev & Mendes, 2006) to measure the influence of nodes. As proposed by Lu (2016), the $k$-shell decomposition method could identify the coreness of nodes, which is an effective indicator for the nodes' influence power.

The $k$-shell decomposition method is carried out as follows. First one removes all nodes with degree $k = 1$ from the network, and assigns the integer $k_s = 1$ to them. This procedure is repeated iteratively until only nodes with degree $k \geq 2$ are left in the network. Subsequently, one removes all nodes with degree $k = 2$ and assigns the integer $k_s = 2$ to them. Again, this procedure is repeated iteratively until only nodes with degree $k \geq 3$ are left in the network, and so on. This routine is applied until all nodes have been assigned to one of the $k$-shells.

Figure 1 shows an example of the community structure obtained by the $k$-shell decomposition method. In Figure 1, nodes in this community are categorized into three classes. Nodes with $k_s = 3$ are the most influential, and belong to the 'upper' class. These nodes are densely connected. Nodes with $k_s = 1$ are the least influential, and belong to the 'lower' class. They are usually located at the periphery of the community. The rest of the nodes belong to the 'middle' class.
Unfortunately, the $k$-shell decomposition method can only be applied to unweighted networks. To solve this problem, a modified $k$-shell decomposition method for weighted networks (Garas, Schweitzer & Havlin, 2012) is adopted. In particular, the weighted $k$-shell decomposition method applies the same pruning routine as the $k$-shell decomposition method above, but is based on an alternative measure for the node degree. This measure considers both the degree of a node and the weights of its links, and assigns a weighted degree, $k'$ to each node. The weighted degree of a node $i$ is defined as:

$$k'_i = [k_i^\alpha (\sum w_{ij})^\beta]^{\frac{1}{\alpha + \beta}}$$

where $k_i$ stands for the degree of node $i$, and $\sum w_{ij}$ stands for the sum of node $i$’s link weights. For simplicity, both $\alpha$ and $\beta$ are put 1, so that the weighted degree of a node $i$ can be written as:

$$k'_i = \sqrt{k_i \sum w_{ij}}$$

It is obvious that if the weights of all edges are 1 in the networks, the weighted degree reduces to the classical degree.

![Figure 1. The structure of a community obtained by $k$-shell decomposition method](image)

The structure based community similarity algorithm

We adopt the $k$-shell decomposition method to measure the influence of nodes. We conduct experiments on various networks and find that the number of nodes with certain $k$-shell value decreases exponentially as the $k$-shell value increases. Based on this fact, we assume that the importance weight of one node should also increase exponentially with its $k$-shell value. Thus, given the influence of the node $i$ in both communities, which are denoted as $k_{i1}$ and $k_{i2}$, the importance weight of node $i$ is defined as:

$$\text{weight}_i = 2^{(k_{i1} + k_{i2})/2 - 1}$$

which indicates that one node has large importance weight when it is influential in both two communities.

The persistence weight of one node is defined as:

$$\text{weight}_p = e^{-\tau(k_{i1} - k_{i2})/2}$$

where $\tau$ is the coefficient that determines the influence of the shift of a node's status. It shows that when the influence of one node remains unchanged in two communities, the persistence weight of the node is 1. The persistence weight of one node will considerably decrease, when the influence of the node in two communities largely differs.

For two communities $C_1$ and $C_2$, we denote $O(C_1, C_2) = C_1 \cap C_2$ and $F(C_1, C_2) = C_1 \cup C_2$. For each node $i$ in the set $O(C_1, C_2)$, the influence of the node in the two communities are denoted by $k_{i1}$ and $k_{i2}$, respectively. Thus, the overall weight of node $i$ is defined as:

$$2^{(k_{i1} + k_{i2})/2 - 1} \times e^{-\tau(k_{i1} - k_{i2})/2}$$
Thus, the overall similarity of two communities is defined as:

\[ \text{sim}(C_1, C_2) = \frac{\sum_{i \in \partial(C_1, C_2)} 2^{(k_{i1} + k_{i2})/2} - 1 \times e^{-\tau(k_{i1} - k_{i2})/2}}{\sum_{i \in \partial(C_1, C_2)} 2^{(k_{i1} + k_{i2})/2} - 1} \]

where the denominator is a normalization term, ensuring that the similarity of two communities takes values in the interval [0,1].

The publication data set

In this section, we briefly describe the journal set from the Clarivate Analytics Web of Science Core Collection (WoS) database, and how we use the journal data set to depict the evolution of subjects and detect the anomalous events in the cognitive mapping of science.

Data Sources and Data Processing

We apply the novel algorithm on the scientific data set from Clarivate Analytics. The original journal data contains tens of millions of so-called citable papers from 1992 to 2011 (i.e., papers of document type article, letter, note and review) indexed in the WoS database. We subdivide the dataset into four distinct periods, with each five years forming a single period. For each period, citations received by these papers have been determined for a variable citation window, which is consistent with the time interval of the period. By aggregating the citations among papers to the citations among journals, we obtain four journal networks, with nodes representing journals and edges representing the citations among journals. In particular, the number of both journals and citations in each journal network are given in Table 1.

Reference Labels of Journals

To evaluate the effectiveness of the novel algorithm in detecting anomalous events in scientific mapping, we refer to the 23 categorizations of Essential Science Indicators (ESI). For each ESI field, we first extract both the set of journals that belong to the field and the cross-citations among these journals. Thus in each period, we obtain one community for each ESI category, and apply our new algorithm to monitor the evolution of each ESI category. In particular, for each ESI field, we obtain three similarity values in the four consecutive periods. By identifying the striking similarity values, we aim at identifying the anomalous events in the evolution of the 22 standard ESI fields.

Subject classification scheme by journal clustering

Most existing subject classification schemes, including the ESI categorizations, are based on longstanding practice (Zhang, Janssens & Liang, 2009) and are drawn up by human experts. Due to their purpose, which requires robustness and stability, these cognitive classification schemes usually remain unchanged for years. However, cognitive clustering of the document space can help improve subject classification by taking recent structural development into account (Zhang, Janssens & Liang, 2009). In this study, we follow this approach by developing and applying out new method.
Thus, we apply clustering algorithms to the four journal networks to obtain journal clusters, which could reflect subject classification and its changes over time. In particular, the spectral clustering algorithm (Von, 2007) is adopted. In this paper, we assume that the subject classification remains unchanged in a short period, and obtain 60 communities in each period. Similarly, we apply our new algorithm to these communities, and try to identify the anomalous events in these subject classifications.

Experiments on the ESI subject classification

In this section, we apply our algorithm to the 22 standard ESI fields in the four periods, aiming to detect the anomalous events indicated the two types of changes that we have discussed in the previous sections.

(a) Period 1997-2001                  (b) Period 2002-2006                  (c) Period 2007-2011

Figure 4. The word clouds for the 20th ESI field (Data sourced from Clarivate Analytics Web of Science Core Collection)

We first apply the algorithm to obtain the community similarity values among consecutive communities for each ESI field. Then we determine the average similarity value and the
standard deviation of these similarity values. We denote the average similarity values by $\mu$ and the standard deviation of the similarity values by $\sigma$. Then the lower and upper limits of the normal similarity values correspond to $\mu \pm 3\sigma$. Using this method, we are able to define the threshold (lower control limit), below which the corresponding event is considered anomalous. In particular, the average similarity value is 0.86, the standard deviation is 0.0855, and the threshold amounts to 0.6035.

Figure 2 depicts the community similarities between consecutive communities for each ESI field. For the majority of subject fields, the community similarities lie in the interval [0.7,0.9]. Only three cases are under the threshold curve. The first case stands for the similarity between the first and the second periods for the 2nd ESI field. The remaining two cases stand for the two similarity values obtained in the last three periods for the 20th ESI field.

As shown in Figure 2, an anomalous event occurs in the 2nd period for this ESI field. To illustrate this, we present the word clouds of in both time slides. As shown in Figure 3, the 2nd ESI field in the 1st period focuses on the classical philosophy and history philosophy. Meanwhile, in the 2nd period, it focuses on different sub-disciplines of philosophy, including ethics, logic and phenomenology. Furthermore, Figure 3(a) indicates that America and Europe play a significant role in these topics of philosophy. By contrast, Figure 3(b) indicates that researches from Canada and UK in philosophy are more influential in philosophy in the second period. In turn, continental Europe’s influence on the research of philosophy has decreased in the 2nd period.

The 20th ESI category is concerned with ‘Plant & Animal Science’. As shown in Figure 2, anomalous events occur in the 3rd and 4th period. Thus, we present the word clouds of the three communities for this ESI field in Figure 4. Figure 4(a) and Figure 4(c) show that both communities focus on ‘entomology, biology, plant, physiology’. By contrast, Figure 4(b) shows that this community focuses more on ‘pathology, molecular, plantarum, and phytopathology’. This reveals that in the 3rd period researchers are more specialized on the research of treatment of plant disease. However, this specialization seems not to be persistent and disappears in the 4th period.

These two cases show that the new algorithm is efficient in identifying anomalous events in scientific mapping, and the identified events indicate topic transitions within each ESI field.

**Subject classification based on journal clustering: An experiment**

We adopt journal clustering techniques to obtain a subject classification scheme, and apply our new algorithm to analyze the evolution of the subject classification scheme in this section.

![Figure 5. Comparison of community similarities measured by both the new algorithm and the vertex overlapping strategy (Data sourced from Clarivate Analytics Web of Science Core Collection)](image-url)
Experimental results

We apply both the vertex overlapping strategy and the novel algorithm to calculate the similarities of journal clusters from adjacent periods. The comparison between the two strategies is plotted in Figure 5. The x-axis stands for the similarity of each pair of journal clusters obtained by the vertex overlapping strategy, the y-axis stands for the similarity of journal clusters obtained by our new algorithm, and the red line stands for the plot $y = x$.

Figure 5 shows that for most pairs of communities, the two similarity values are located around the plot $y = x$. This indicates that the similarities remain unchanged for the vertex overlapping strategy as well as our new algorithm. However, there are some exceptions. Four cases are marked, as their similarities obtained by the vertex overlapping strategy and our algorithm distinctly differ. The visualization, terms and core journals of communities for these four cases are presented in the following sections.

Case studies

For case ‘A’ and ‘B’, the structural similarities obtained by our new algorithm are much larger than that obtained by the vertex overlapping strategy. This indicates that the vertex sets in these communities considerably changes. By contrast, the structure of the community remains stable. In particular, for case ‘A’, the similarity obtained by our algorithm amounts to 0.60, while the similarity obtained by the vertex overlapping of 0.15 is much smaller than that obtained by our algorithm. For case ‘B’, the similarity obtained by our algorithm is 0.40, which is also much larger than that obtained by the vertex overlapping strategy.

We present both the terms and the most influential journals, particularly the core journals, of the two communities in Table 2 and Table 3, respectively. It can be seen that the core journals in these two communities are identical, and these are actually concerned with philology. One of the core journals is, for instance, ‘American Journal of Philology’, which was founded in 1880 and has achieved worldwide recognition as a forum for international exchange among classicists and philologists by publishing original research in classical literature, philology, linguistics, history, society, religion, philosophy, and cultural and material studies. In addition, the terms of both communities in case ‘A’ are ‘philology, classical, historical, roman’, which is consistent with the core journals. Furthermore, the word cloud figures for the two communities in case ‘A’ are also given in Figure 6 to provide more detailed information.
In case ‘B’, though the majority of nodes have changed, the set of core nodes remain stable. Thus, the similarity of the two communities based on the new algorithm is larger than the classical vertex overlapping strategy. Specifically, the two communities in case ‘B’ are concerned with ‘biblical, catholic, Jewish, fiction’. In addition, their core journals are identical, as well.

In cases ‘C’ and ‘D’, the similarities obtained by the vertex overlapping are much larger than that obtained by the novel algorithm. This indicates that although the vertex set of the communities remain relatively stable, the internal structure of these communities changes significantly. A potential topic shift has occurred in these communities.

As shown in Figure 5, the two communities in case ‘C’ share 35% of their vertices, while their structural similarity is 0.14, which is much smaller than that obtained by the vertex overlapping strategy. This indicates that the layered structure of these two communities considerably differs. According to Table 2, though the two communities in case ‘C’ concerned with zoology, they focus on different sub-disciplines. The first community could be characterized as being focused on ecology and biology, while the second community is concerned with animals, such as entomology, insects, and invertebrate. Furthermore, the core journals of the two communities also differ, as shown in Table 3. In addition, the word cloud figures for the two communities in case ‘C’ are given in Figure 7.

Similarly, in case ‘D’, the 1st community focuses on the library and information science. However, the 2nd community focuses on law and criminology. The core journals of the two communities in Table 3 are different, which deepens this conclusion.

Conclusions

In this paper, a novel community similarity algorithm is proposed to detect structural changes and topic shifts in science mapping. This concerns changes of vertices and the communities’ layered structure. This makes it possible to detect communities with vertices remaining stable but structure changed. These kinds of events in scientific mapping indicate that a topic shift took place in the corresponding research fields (Glanzel & Thijs, 2012).

We applied our new algorithm to the journal data set. Our experiments indicate that the novel algorithm is able to identify meaningful changes in scientific mapping. We found that the internal structure of the majority of journal clusters remained stable over time. This indicates that most of the research subjects keep their research topics unchanged. Beyond that fundamental observation, we could identify several journal clusters with changes in their journal constitution but with stable internal structure. This indicates that although journals focusing on the corresponding research subjects considerably change, the topic of the journal cluster remains unchanged. We also found several journal clusters stable members but with changes in their internal structure. This indicates that a topic shift took place in the corresponding research subjects. The textual analysis of these journal clusters demonstrates that the identified events are meaningful.

The aim of this study was to introduce a new method for topic identification and monitoring and to show its validity and usefulness. In later studies, we will apply our new algorithm to analyze the evolution of concrete research fields. The identification of topic shifts and structural changes has the potential to improve techniques for the monitoring of evolutionary patterns of research fields and the detection of emerging topics.

Abstract
This study presents a preliminary comparison of networks of international collaboration and mobility. Using affiliation data from scientific publications, we analyse the structural differences in the two networks and the role of countries. The results show that researchers collaborate internationally to a much higher degree than they become internationally mobile. The number of countries involved in the networks is three times higher in collaboration than in mobility, and the average degree demonstrates that mobility networks form tight structures with fewer links than collaboration networks. The role of countries differs between the collaboration and mobility network, predominately reflecting income level. Limitations and future research are described to further understand the dynamics of collaboration and mobility networks.

Conference Topic
Scholarly Communication; scientific mobility; collaboration; network analysis

Introduction
There is a popular saying: “Science knows no borders”. Indeed, scientists often move and collaborate internationally, accessing “multiple learning environments”, usually producing higher-impact research, and increasing their prestige (Gazni, et al. 2012; Glänzel 2001; Chinchilla et al. 2012). There are many well-documented reasons why researchers collaborate (e.g., Beaver 2001; Sonnenwald, 2007). Previous studies focus on the factors driving collaboration between countries, such as their relative size, their geographical, historical, linguistic, and thematic proximity, or their socio-economic characteristics (Zitt et al. 2000; Adams 2014).

Mobility has been advocated as key to increasing the efficiency and effectiveness of research (OECD 2008, 2010; Scellato et al., 2015). While some studies focused on the economic and development impact caused by mobility (Gibson & McKenzie 2012), few have utilized bibliometric measures to understand scientific mobility (Moed & Halevi, 2014; Sugimoto, Robinson-Garcia, & Costas, 2016). Furthermore, no study to-date has compared, at a global scale, the differences in the scientific networks created through collaboration and mobility. This is necessary to understand whether mobility provides a novel or a duplicative lens on the network created through scientific collaboration.

We present here, using collaboration and mobility data drawn from contemporary bibliometric data (2008-2015), the comparative network statistics and ranking for more than 200 countries considering socioeconomic indicators and grouping according to scientific and technological
capacities. These data can inform the understanding of and relationship between indicators of international collaboration and mobility.

Data and Methods
Data were retrieved from Web of Science database for the period 2008-2015, considering only authors that have at least two publications and for whom this period represents the date of first publication. A total of 3,521,797 individual’s authors were identified using a large-scale disambiguation algorithm developed by Caron and van Eck (2014). We consider all document types for the analysis. The nation-to-nation links were collected based on 14,097,939 publications. Country affiliations were extracted and cleaned, resulting in 213 unique countries. Collaboration linkages are measured considering all authors of each paper and their connections to countries. Mobility includes both migration (i.e., change from one affiliation to another) and co-affiliation (having multiple affiliations on the same publication or on two or more publications in a given year). Income level group was added as a proxy of wealth intensity of countries (World Bank 2016) and the Scientific and Technological Capacity Index—which measures expenditure in R&D, number of researchers, number of institutions, patents--(Wagner et al., 2001) was used as a proxy for the scientific capacities of countries.

For each group, we created and analyzed the subset of documents and researchers by calculating: the total number of publications per country and the number of publications with international collaboration. We use these two indicators as input to the international collaboration network. We build the international mobility network using the total number of active researchers per country and the number of active researchers linked to countries. We used integer counting, attributing a count of “1” to each occurrence of authorship or affiliation from a country.

Once we obtained the co-occurrence frequencies, we generated symmetric matrices using Pajek 64 4.10 (Batagelj & Mrvar, 1997) to derive statistical properties and structure of the networks. We explore the position and role of countries within each group using classical measures of network analysis. Closeness is calculated as the reciprocal of the sum of the shortest path between the nodes to other nodes (Freeman, 1978). Betweenness for a node is defined as the fraction of shortest paths among the whole network that pass through the node (Freeman, 1977). Density determines the degree of cohesion that exists among the nodes, revealing whether the network has a thick or thin consistency (Wasserman & Faust, 1999). The average degree measures the spread of influence across the networks (Hanneman & Riddle, 2006). Diameter measures the longest distance between a pair of countries, (i.e., how many steps from any node are necessary to reach any other node in the network (De Nooy et al., 2011)). The clustering coefficient indicates the proportion between the number of links in the neighborhood of a node and the number of links possible in the entire network (Watts & Strogatz, 1998; Barábasi, 2002). Assortativity is a property that reflects the tendency of nodes to connect to other nodes to a similar degree by means of measuring the Pearson correlation coefficient of degree between pairs of linked nodes (Newman, 2002).

For the visualization network, the proportions of collaborations and co-affiliations among countries were used as a pair of inclusion indexes (share of county j in the total co-authorships/co-affiliations of i or Affinity Index AFI (i,j), and its counterpart AFI (j,i) to characterize asymmetrical relationships between two countries (Zitt et al., 2000). AFI is a measure of the amount of collaboration or co-affiliations between a given country A and another country B, compared to the total collaboration or co-affiliation of the country A and country B. To position the countries (nodes) we applied the Kamada-Kawai algorithm (1989),
characterized by its ability to assign coordinates to the vertexes while adjusting the distances to a maximum with respect to theoretical distances. Lines indicate the relations among actors, with the color (on a scale of grey tones) indicating the intensity of the connection. The colors of countries refer to geographical regions.

Results
Each network, summarized in Table 1, has 212 countries, one less than the original 213 because South Sudan is isolated in the collaboration network and Tuvalu is isolated in mobility. Differences in the number of edges, the density, and the average degree of each network suggests significant differences in their structural cohesion. The collaboration network has a higher density than the mobility network. Nodes in the collaboration network have three times the average degree than nodes in the mobility network. In comparison, the average shortest distance varies only slightly, indicating that the two networks are cohesively connected, where countries could reach each other in an average of less than two steps. However, considering their diameter, a distinctive feature appears: the collaboration network has a diameter of two, meaning that it is tightly linked with short distances between any pair of nodes; however, in the mobility network the diameter is twice as large, suggesting that the two networks are structurally different. The clustering coefficient is high in both networks demonstrating that countries form tightly knit groups, but the coefficient is slightly higher in collaboration than in mobility, indicating that two countries who have common neighbors would be slightly more likely to collaborate than have mobile researchers in common. However, considering that there are more than 2.5 times as many links in collaboration as in the mobility network; the mobility network has apparently formed tighter structures with fewer links. The negative values of assortativity indicate that countries with a large degree tend to connect with countries with a small degree in both networks.

The rank of countries in collaboration and mobility networks
Figures 1-4 show the position of countries in closeness (left), betweenness (center) and clustering coefficient (right) for each network: with collaboration in the left panel and mobility in the right. We show four groups of countries according to their scientific and technological capacities where the colors of lines represent the income levels of countries: high (green), upper-middle (blue), lower middle (orange) and low-income (red). The interpretation of ranking labels goes as follows: Australia (3) (5) means that it ranks in the third position in the collaboration network and in the fifth position in the mobility network.
In the group of scientifically advanced countries (Figure 1), a country’s position is relatively stable across the two networks, suggesting that there exists a relatively similar ability to attract collaboration and mobility partners. The most striking situation is in Russia (upper-middle income) ranked relatively low in closeness and betweenness, whereas it has the second highest clustering coefficient in the mobility network; this suggests that Russia is not located in a central position, instead forming a tight group of partners, especially in mobility. While France, Germany, Denmark, Finland, and Ireland have more capacities to reach other countries and act as bridges especially in the mobility network, Canada, Taiwan, and Iceland show a more important role in the collaboration network.

Figure 2. Closeness, betweenness and clustering coefficient for scientifically proficient countries
The positions of scientifically proficient countries fluctuate more than those of advanced countries (Figure 2). India ranks higher in closeness and betweenness in the mobility network than in the collaboration network, but their group of partners in collaboration is more cohesive than in mobility. That means that the country acts as a key bridge in the mobility network, but its mobility neighbors do not form tightly group around it. A similar situation appears in Slovenia and Croatia, whereas Estonia, Bulgaria, and Cuba have roles that are more important in international collaboration than in mobility.

In the group of developing countries (Figure 3), Mexico and Chile rank highly in closeness and betweenness, but their slight drop between collaboration and mobility demonstrates that they can build and facilitate more connections in collaboration than in mobility. Turkey shows the opposite pattern, being more important in mobility. These three countries show the lowest cohesion with their partners in comparison with the rest of the group. Iran’s, Pakistan’s, and Armenia’s closeness and betweenness rank in mobility suggests than they have most important roles in linking researchers through mobility than collaboration. A striking case is Turkmenistan, which ranks at a top position by cluster coefficient and in the lowest position in closeness and betweenness, suggesting that while it does not act as a bridge in the network, it does forms a tight collaboration relationship with its partner compared to other countries in its group. Overall, developing countries are less stable between networks that advanced and proficient countries.

Countries classified as lagging are the most numerous (80 countries) and for visualization, we only show the top 30 in each indicator, explaining the lack of correspondence among the appearance of countries (Figure 4). The only high-income country appearing in this sample (among the six marked as lagging) is Saudi Arabia, which has an important role in closeness and betweenness, especially in the mobility network, whereas Malaysia leads in these two indicators in both networks. However, neither Malaysia nor Saudi Arabia establishes a tight
relationship with their partners in comparison with the rest of lagging countries. In general, many countries’ position changes dramatically, indicating that their positions and roles differ between the networks.

Figure 4. Closeness, betweenness and clustering coefficient for scientifically lagging countries

Both the collaboration and mobility networks demonstrate the importance of geographical proximity in the topology of the network (Figure 6). Historical and political linkages are also apparent—for example, the links between countries and colonies as well as linkages in former Soviet countries. Language also matters, as demonstrated by the connections between Spain and Latin American countries. The two networks the most advanced countries occupy the center, but the change in the position of some Asiatic countries such as India, Taiwan, Singapore, Malaysia or the position of South Africa, Nigeria, Kenya in the two networks reveal significant differences in partnership preferences but also in policies that promote the intensification and expansion of international scientific networks.
Figure 5. Network of international collaboration
Figure 6. Network of mobility
Discussion and Conclusion
This study presents a preliminary comparison of the diversity and complexity in establishing international relationships in terms of collaborative papers and the flow of mobile researchers. The results show that researchers establish more international relationships through collaboration than mobility. To a certain extent, networks show a high level of local clustering and a small average number of steps between actors, which fits with the model of the small world defined by Watts and Strogatz (1998) and the results of Wagner (2005).

However, the mobility network forms tighter structures with fewer links than the collaboration network, making this a distinctive feature between the two networks, despite the diameter of collaboration network is tighter than in mobility network. A country’s position in collaboration and mobility is not always consistent in both networks, revealing that positions and roles of countries in terms of capacities to be accessible to other nodes (closeness), in transferring knowledge (betweenness), or to be cohesive with their neighbours (clustering) may differ. Where stability between the networks exists, it is mostly associated with high-income countries, while upper-middle, lower middle, and low-income countries are more likely to change positions. Unlike countries in the scientifically advanced group that function as hub nodes, the role of lagging countries is unstable in both networks. However, the stability of a small subset of countries as bridge nodes, such as India, Malaysia, Turkey and South Korea, builds stronger connections in the mobility network. We also confirm the important role of Kenya and Nigeria, as noted in previous studies relating to collaboration networks (Adams et al., 2014). Although leading research economies tend to attract more researchers in terms of collaborative papers and mobility, the results suggest that there are complex patterns of knowledge circulation. The representation of the two networks also displays interesting drivers that reveal affinities between different economies based on linguistic, historical, as well as political and cultural linkages.

Further analysis is needed to overcome some of the limitations of this study and respond to other important questions related to the capacities and influences of countries in networking science. For example, the analysis of co-affiliations in Web of Science has an inflationary effect on the traditional measurements of collaboration based on affiliations creating some overlaps when we are comparing collaboration and mobility. There is a major general limitation of collaboration analysis based on author affiliations and further analysis should be done to minimize this effect (Hottenrott and Lawson, 2017). We intend to complement our analysis with a time component, allowing us to analyze some key points: authors’ choices regarding institution address selection from publication data and the evolving relationships for exploring how these more fine-grained temporal networks compare to the entire network presented here. We will explore different approaches to community detection in networks to identify the core and groups of vertices having the highest probability of holding a great deal of influence over the organization of the periphery of the network. We plan to analyze not just mobility, but also leadership, including changes in the positions that authors occupy in the bylines of co-authorship, their impact, the institutional reputation of destinations, and the capacity to develop or reinforce thematic research into their institutions and countries. In addition, the analysis of other factors that would influence the mobility and collaboration of researchers such as cultural, linguistic and geographical proximities will be analyzed. Overall, this analysis presents an introduction to what is possible through comparison of international collaboration and mobility networks, and serves as a foundation for future analysis.

Abstract
Intelligent service is the inevitable trend of ubiquitous network development. Situation Fusion Knowledge Discovery in Database(KDD) technology can further provides the intelligent service of ubiquitous network. In this paper, based on the characteristics of general structure of ubiquitous network, the method of Situation Fusion KDD technology is proposed for the problem of ubiquitous network information demand and drift of network element supply. By improving the information description and mining algorithm, the process of Situation Fusion KDD technology, such as situation role acquisition, situation role behaviour analysis, front-end application information mining and situation requirement knowledge discovery, is discussed in this paper. According to the functions which are involved in the ubiquitous network intelligence service of situation analysis including data organization, pattern discovery, resource aggregation and intelligent push, the application method of the Situation Fusion KDD is analyzed and the realization path of the intelligent service in the ubiquitous network is provided finally in this paper.

Keywords
Situation fusion; Knowledge discovery in database; Ubiquitous network; Intelligent service

Conference Topic
Knowledge discovery and data mining

Introduction
The information and demand are ubiquitous in the ubiquitous network where the information carrier forms, data sources, data structures, information content, quality standards, data exchange formats, etc. have become very complex. How to provide timely and accurate information and knowledge facing the network users’ complex demand with dramatic changes of roles is the main problem of ubiquitous network to solve. This paper argues that Situation Fusion Knowledge Discovery in Database(KDD) technology is the key to solving this problem. In this paper, according to the characteristics of user demand in the ubiquitous network, the KDD technology was used to study the principle of Situation Fusion KDD and explore the innovation mode of ubiquitous network intelligent service, thus solving the problem of information acquisition precision and service performance in the ubiquitous network.

Issues on Ubiquitous Network Intelligent Service
Ubiquitous network is the whole space-time interconnecting network based on the application support services as the main feature. Compare with the traditional information network, the same point are their four major constituent elements: human, material, capital and information. Their difference is that the ubiquitous network is the new network phenomenon where the above four elements deeply integrate to a certain stage, which is the consequence due to the highly developed traditional
information network in the application and service level. In this way, the role demand, the follow-up of application and service, the realization of value and data flow together constitute a new form of space-time ubiquitous network with “point to point” barrier-free real-time interactive experience.

In the ubiquitous network, there are two kinds of changes in the four elements of human, material, capital and information. One is the changes of the elements themselves, namely, the changes of “human” in network roles, the changes of “material” in the intelligent perception, application and service forms, the changes of “capital” in value realization dimensions and the changes of “information” in the data transmission access types. The other is the changes between elements, that is, the four elements have the phenomenon of the conversion of main body and object and the phenomenon of supply drift.

In the ubiquitous network, the benefits of intelligent service are the free conversion of the main body and object, the more extensive source of information, the surge in the amount of data, high value of information correlation and the value-added effects of information processing. The new form of space-time ubiquitous network has also led to the migration from the individualized customization needs to the various roles’ situation needs as well as the phenomenon of the network elements supply drift. The traditional intelligent service technology and method can solve the information demand problems with the small change of the network elements, but it is difficult to play the role of the transformation among network roles and the elements supply drift, which is a new topic in the ubiquitous network intelligent service. Due to the relative stability of the situation in the ubiquitous network, it is very important to explore the application of principle and method of Situation Fusion KDD in intelligent service mode.

**Situation Fusion Knowledge Discovery in Database**

According to the definition of the International Telecommunication Union, the ubiquitous network is divided into five layers: the sensing layer, the access layer, the next generation network layer, the middleware layer and the application layer. Among them, the next generation network layer, middleware layer and application layer are the key points of technology research and application support in the ubiquitous network. The next generation network layer provides ubiquitous communication; the middleware layer provides ubiquitous resource integration; the application layer provides ubiquitous situation services.

It can be found that the ubiquitous network architecture has been reflected the design idea from the user-oriented service mode to the situation-oriented service mode.

It is clear that traditional user fusion knowledge discovery method is difficult to adapt to the new paradigm and new requirements of the ubiquitous intelligent service. To this end, the further study for the situation demand is needed to enhance the function and application of Situation Fusion KDD based on the traditional KDD techniques and methods.

**Principle of Situation Fusion KDD**

The main function of traditional KDD is to extract information and knowledge and provide decision support service from massive data for users’ individual needs. In order to solve the problem of transitional drift of information demand caused by excessive conversion of user roles in the ubiquitous network, it needs to be improved in the user-oriented aspect and the new mode, Situation Fusion KDD, is thus needed.

The basic principle of Situation Fusion KDD is to change the data description way from the traditional way of describing the users as objects into describing the situations as objects so as to improve the mode and algorithm of KDD to achieve the intelligent service function for the situation and meet the information and knowledge needs of situation users in order to provide decision-making advisory services.
Functions of Situation Fusion KDD
The purpose of Situation Fusion KDD is to discover implied and valuable knowledge from situation information and predict the future trends and behaviour of situation users, thus providing advanced, situation-based decision support. Situation Fusion KDD should have five functions, including role behaviour prediction, situation correlation analysis, situation role clustering, situation resource classification, sequence pattern discovery and so on.

Predict the behaviour trend of situation groups
Predict various situation user groups that are interested in all aspects of information in the future and predict their behaviour patterns.

Situation correlation analysis
Automatically classify the seemingly irrelevant but frequently accessed data according to different situation to find potential associations between situation users.

Situation role clustering
The relevant information is recommended to the situation group based on the user group characteristics of different situations or the data accessed by the situation user.

Situation classification
Find the situation information and situation access mode which can access to the front-end application to obtain the situation profile features. Classify situations by those features and form the situation information resource system as the basic data using Situation Fusion KDD technology to predict potential situation roles and provide situation information service.

Situation sequence pattern discovery
Forecast the user situation access mode and carry out intelligent information services facing the situation to ensure the stable access of the front-end situation application information and knowledge.

Process of Situation Fusion KDD

Get situation access information
Ubiquitous network situation information is divided into website-side access information and mobile-side access information. At present, as the rapid spread of mobile Internet and the surge in the number of mobile users, the feature of “ubiquitous” is reflecting more and more significantly in the mobile Internet. Therefore, the situation information collection should be carried out from both the website side and the mobile side. Crawl the front-end application information through the ubiquitous network agent and use the knowledge base filtering technology to filter out the disturbing or low correlation front-end situation application information and data. Then extract the theme, keywords, paragraphs, special logos and other important front-end application data, thus gaining valuable information that is useful for the analysis of situation role access behaviour.

Analyze behaviour of situation roles
Generate situation role multi-dimensional tags and attribute characteristics through behaviour analysis tools. Situation role multi-dimensional tags represent different situation types and related characteristics accessed by situation roles; situation role attribute characteristics are
established based on the situation role multi-dimensional tags and deeply excavated according to the different situation probability level. Then, the situation role attribute characteristics are obtained and should be discovered for clustering so as to generate the situation role groups. On this basis, the construction of the initial situation needs pattern is completed.

Dig out front-end application information
Combined with situation information, use the analysis engine tool to analyze front-end application content for processes such as text-cutting, clustering, knowledge processing.

Situation demand knowledge discovery
According to the situation demand, dig out the information and knowledge of the role users in the situation area to complete the dynamic updating of the situation knowledge base and the dynamic updating of the situation mode.

Ubiquitous Network Intelligent Service
Ubiquitous network intelligent service use Situation Fusion KDD technology to study situation behaviour and situation definition taking the situation roles as objects for offering high-quality intelligent service to the situation users. According to the situations of various carriers themselves, ubiquitous network intelligent service system not only has the function of providing intelligent service for situation users, but has self-learning, self-adapting and self-organizing functions to meet the information and knowledge needs of situation roles users.

Advantages of Ubiquitous network intelligent service
The traditional intelligent information service system can meet the different depth of the needs of different levels of users, but there exist shortcomings such as single channel and single access information because of the single user domain and professional and other limits. Ubiquitous network intelligent service use Situation Fusion KDD methods to more deeply discover the potential situation needs in a relatively stable situation type, providing multi-faceted situation information and situation knowledge services. At the same time, regardless of the drift of user individual needs and the changes of user individual roles, the service quality and efficiency will be higher only pushing specific information and services for the situation needs. Therefore, comparing with the intelligent information service system which takes the network users as objects, the network intelligent service which takes the situation roles as objects has more depth in level, more extensive breadth, more accurate quality, higher service, more viscosity in media.

Features of Ubiquitous Network Intelligent Service
Ubiquitous network intelligent service system uses the data mining, artificial intelligence and other technical means to carry out situation fusion knowledge mining and intelligent service based on the characteristics of situation roles and information of situation requirements in the ubiquitous network ecosystem, with the following six characteristics.

Cross-border excavation
According to the same situation, the system aggregates cross-domain data and analyzes data and then discovers deeper level psychological needs of situation roles through collaborative processing.
**Multidimensional fusion**
In the dimensions including demand dimension, information dimension, method dimension, carrier dimension and role dimension, the data fusion should be completed based on the same situation to form the stable data resource which is more conducive to the stable application of knowledge discovery tools.

**Cobweb interactivity**
The intelligent service system and the dialogue of situation roles have all-round ubiquitous characteristic. In the same situation role, whether managers, consultants or network users can all engage in dialogue and interaction with the system in the form of full media and spider response regardless of time, space and fixed identity. The system automatically collects information and accurately presents to the user to meet the needs of different situation role users for the users in different situations.

**Perceived enhancement**
The system uses a variety of situation-aware technologies and augmented reality technology to provide visual information services.

**Dynamic experience**
Situation information needs positioning, situation information organization, knowledge mining, information transmission, service space, service form and user experience and other forms are open, multi-dimensional and real-time dynamic.

**Predictive accuracy**
Based on the Situation Fusion KDD service system, due to the deep excavation of stable situations, learning and service, the situation definition analysis and identification prediction are more accurate and the intelligent services are more active.

**Ways of Ubiquitous Network Intelligent Service**

**Situation perception and situation data acquisition**
The collection of the situation role characteristics and situation demand information in the ubiquitous network can be carried out through situation perception and collaborative acquisition. The situation supply and demand information source is formed through intelligent access, intelligent analysis and information aggregation.

**Situation data organization**
Integrate the situation needs and role characteristics to build situation data resource self-organization mechanism and form the situation supply and demand resource pool. At the same time, integrate information resources and form dynamically updated data resources and knowledge resource system to complete the intelligent service data collection.

**Situation needs and service pattern discovery**
The main function of the situation demand service mode use the Situation Fusion KDD technique to analyze the characteristics of the situation roles, and to find the potential knowledge rules and the situation demand pattern.
By using the correlation analysis and sequence pattern analysis technique, the correlation and regression characteristics of situation supply and demand information are analyzed and the knowledge requirement rule and situation service mode are formed.
Situation resource and technology aggregation

Combined with artificial intelligence, DSS and ES, use Agent theory, heuristic and other intelligent decision-making algorithms to integrate situation data, situation modes, reasoning technology and other resources to form human-computer interaction ubiquitous intelligent service environment for the base of intelligent situation resources of knowledge decision service.

Ubiquitous network intelligent service

The system analyzes and processes the collected information by analyzing the user situation roles and mining the information of the situation role information demand and then provides the service for different situation roles according to different situation, transferring from user information transmission to situation knowledge service. Ubiquitous network intelligent service mainly includes intelligent retrieval service, intelligent recommendation service and intelligent consulting service. The intelligent retrieval service intelligently sorts out the information and knowledge in the unified situation category and initiatively provides the intelligent retrieval service oriented to the situation roles. Intelligent recommendation service is the highlight of the system, the use of situation requirements and role characteristics data helps to initiatively recommend the situation needs information and knowledge and strengthen the situation users’ experience. Intelligent consulting service offers other users the consultation of the same situation based on the same service case of user information and knowledge needs in the situation domain, thus, the matched problem is more accurate and service efficiency and quality are higher than before.

Concluding Remarks

In short, the ubiquitous network intelligent service is oriented towards situation needs. The traditional service mode is user-oriented. Although it also has intelligent retrieval service, intelligent recommendation service and intelligent consulting service and other service forms, it cannot solve the individualized service’s poor quality caused by the drift of user demand and network element supply in the ubiquitous network environment. Ubiquitous network intelligent service changes the user-oriented service into the situation-oriented service and changes the individualized service into the role-oriented services, highlighting the situation of the service to adapt to the new requirements of intelligent services in the ubiquitous network, thus, improving the efficiency and quality of intelligent services. Ubiquitous network intelligent service takes situation requirements, role characteristics, knowledge resources, network facilities and application platform as the organic information resource system to organize and process to separate the users from the resource system and more highlight the analysis and service of the situation roles, meeting the different needs of information and knowledge due to the users’ changing roles. This paper analyzes the principle of Situation Fusion KDD and applies the technology to the construction of ubiquitous network intelligent service system. It is a preliminary attempt to generalize the ubiquitous network intelligent service theory and implementation method in order to get more in-depth research and discussion.

Abstract
It is well known that the Journal Impact Factor (JIF), originally intended as an indicator of impact of individual journals, should not be used as an unconditional standard of evaluation for individual researchers and individual research papers since the amount of citations of papers within any given journal has a highly skewed distribution such that the average number of citations are no longer typical. In this work, for each given journal, we ask the question that if one paper is not typical then a group of how many papers together can be typical. Typical means that the group average is close to the JIF while the standard deviation of average of the group generated by a Bootstrap process is much smaller than the standard deviation of single papers. According to this size, we proposed a definition of the minimum representative size of each journal. In addition, we found that this minimum representative size of most journals is significantly less than the corresponding journal size while for a few exceptions, this becomes comparable to the journal size or even bigger.

Conference Topic
Impact Factor, Journal-level indicators, Research Evaluation

Introduction
Evaluating the performance of scientists is important in promotion and grant applications, and a considerable amount of metrics have been proposed based on various assumptions (Bar-Ilan, 2008, Bornmann et al., 2012, Mingers & Leydesdorff, 2015, Waltman, 2016). As the most easily accessible metric, journal-level metrics (Glänzel & Moed, 2002), and more specifically, the Journal Impact Factor (JIF) (Garfield, 1955, 1999), of a journal in which their paper is published is used in the routine evaluation of individual scientists (or their work). The effectiveness of JIF in evaluating individual scientists and individual papers has been highly criticized in recent years (DORA, 2013, Hicks et al., 2015), with its main weakness being using an arithmetic mean to represent a highly skewed citation distribution (Seglen, 1992, 1997, Kurmis, 2003, Leydesdorff & Opthof, 2010, Factor, 2011, Bornmann & Mutz, 2011, Leydesdorff & Bornmann, 2011a,b, Mutz & Daniel, 2012) that highly overlaps among most journals (Larivière et al., 2016, Callaway, 2016, Mingers & Yang, 2017). Some journals have decided to not provide JIF on their journal webpage, or have chosen to provide a broader range of metrics (Callaway, 2016). We should note that, while metrics may facilitate performance of such an evaluation, peer review and in-person discussion remains the most reliable although much less feasible, method of evaluating scientists. With that being said, metrics do provide some convenience in comparing a set of papers or scientists in terms of, for example, journals or institutes. More specifically, it has been shown that, on average, journals with a higher JIF generally have higher impact papers than those with lower JIFs (Milojević et al., 2016). Of course, in much of this line of work, especially (Milojević et al., 2016), it is assumed that the number of received citation of a paper is a good proxy for the impact of the paper and we also take this assumption.

The principal reason JIF is not suitable for application to individual papers is the frequently highly skewed distribution of the amount of received citations for papers of each journal and to represent a highly skewed distribution function it requires moments at all orders, not only the mean, which is the first order moment. However, providing each journal such a set of
indicators of all orders of moments will then become overly complex. Therefore, one question that should be addressed is how to define a less complex indicator for journals that yields practical application not only to journals, but also to individual papers. There are such indicators proposed in the literature, such as the Integrated Impact Indicator and Percentile Rank (Bornmann et al., 2013, NSB, 2014).

Here, we decided to take an alternative approach to this question. From statistics (Wasserman, 2004), we know that given a set of data, we might calculate a series of K-sample averages μ(K) from the data. It means to take K values from the data with putting back and then to calculate the average of these K values. For example, the usual mean corresponds to 1-sample average. We also know that while μ(K) stays the same, μ(K) = μ (1), often the standard deviation Δ(K) decreases with K (Wasserman, 2004). For instance, if the data set follows a normal, distribution then Δ (K) ~ Δ(1)/K. This suggests that instead of looking at the reliability of using JIF on individual papers of the journal, we may look into how to reliably use JIF on a set of papers from the journal. If citation numbers of papers from a journal fluctuate extremely largely such that Δ(K) and higher order moments are very huge, then naturally, it will require a very large K to make Δ(K) to be sufficiently small. It is even possible that such K is required to be larger than the number of papers of the journal P, K > P. On the other hand, if papers from a journal have more or less the same number of received citations, then such required value of K might be very small. Thus, by looking at how large K is required to make Δ(K) sufficiently small we provide a consistency indicator of journals and it is a single number instead of all orders of moments.

When we ask the question of reliability of applying JIF or certain journal indicator θ to individual papers, we wish the probability that a paper with larger value of θ receives more citations than a paper with smaller θ is sufficiently high,

\[ Pr \left( c_{p(\theta_1)} > c_{p(\theta_2)} | \theta_1 > \theta_2 \right) \sim 1 \]  

(1)

Here p(θ_1) refers to one paper with indicator value θ_1 and is the received citations of that paper. When this θ refers to JIF, clearly it is not possible to guarantee the above condition. In fact, if we assume the number of received citations follows Gaussian distribution, denoted by N (x; μ, δ) then this probability can be calculated based on JIF and standard deviation via

\[ Pr \left( c_{p(\theta_1)} > c_{p(\theta_2)} | \theta_1 > \theta_2 \right) = \int_{-\infty}^{\infty} dx_2 \int_{x_2}^{\infty} dx_1 N_1 (x_1; \mu_1, \delta_1) N_2 (x_2; \mu_2, \delta_2) \]

, thus one needs not only the mean μ_2 but also the variation δ_2. Thus in this case, θ needs to include both μ and δ. When the normal distribution assumption is not valid, we then need even more information, which in principle requires all orders of moments but not only the first two, to determine the distribution function.

In this work, instead of using all orders of moments as indicators, we want to still use only JIF. For a journal, we ask the question of how large K is large enough to make Δ(K) sufficiently small so that JIF (μ(1), thus also μ(K) since μ(K) = μ(1)) become a good indicator of these K-sample from the journal. This is to ask what are the values of sufficiently large K that the following expression is more or less true,

\[ Pr \left( c_{p(\theta_1)} (K_1) > c_{p(\theta_2)} (K_2) | \theta_1 > \theta_2 \right) \sim 1 \]

(2)

which means that instead of individual papers, whether or not a set of K_1 papers with indicator value θ_1 from journal 1 can often have large received citations than another set of K_2 papers.
with indicator value $\theta_2$ from journal 2. $c_{p(\theta)}(K)$ means the received citation of a set of K papers with indicator $\theta$. This relies on the fact that $\Delta(K)$, variation of the K-sample, decreases with K so that the overlapping between $c_{p(\theta_1)}(K_1)$ and $c_{p(\theta_2)}(K_2)$ becomes very small.

In the method section, we will verify that it is a fact and also propose an explicit definition of criteria of `$\Delta(K)$ is sufficiently small'. Then, we report values of such K for a set of journals in the results section. We find that for some journals this K is very large. In this case, our calculation suggests that JIF is not representative for individual papers of the journal but it is valid to evaluate a set of K papers from that journal as a whole. Sometimes this K is even comparable to the size of the journal P, $K \sim P$. In this case, our calculation suggests that JIF probably not representative for the whole journal. For others, we find this K is much smaller than N, $1 \sim K \ll P$. In this case, our calculation suggests that JIF is reasonable to be regarded as indicators of a set of K papers from the journal. In applying this K to evaluating journals, first we need to perform the above comparison between 1, K and P to know better about the journal and then if one really insist on ranking journals, we would like to suggest the following: ignore those journals that $K \sim P$; and then for the other journals, order them according to JIF; at last for those with close values of JIF, the ones with smaller K should be favored, since keeping a very consistent impact of papers published in a journal by itself is a merit.

Our current work can easily be extended to studies on other journal-level metrics. In fact, whenever we worry about the reliability of representing a set of numbers using its average, no matter whether the underlying distribution is Gaussian or not, we can always try to calculate this large enough size K of the set. When the set has very consistent data then such K will be small and when it is highly fluctuating then K will be large. Furthermore, when K is close to the size of the set then it will be questionable to represent the whole set with its average. Therefore, the value of this K can be used to estimate whether or not the size of the data is large enough if one wants to evaluate the set by its average.

**Definition of $\kappa$**

Given a series of journals $\{j = 1, 2, \ldots, N\}$ and the citations for individual papers $\{c_{i,j}\}$, $p = 1, 2, \ldots, P_j$ in these journals during a fixed citing time window, the average citation per paper for an individual journal can be calculated as follows:

$$C^j = \langle c_{i,j}^j \rangle_p \quad (3)$$

The variance of $C_j$ of this set of N journals is as follows:

$$\delta_{1, \ldots, N} = \left\langle \left\langle C^j \right\rangle_j^2 \right\rangle_j - \left\langle \left\langle C^j \right\rangle_j \right\rangle_j^2 \quad (4)$$

This equation represents the variance in impact among the chosen N journals. If we do a bootstrap sampling with size K with replacement (every sample is put back to the set immediately after being sampled) and generate such K-sample L times for each journal, then we can get the variance of the average citation of the K samples as follows:

$$\Delta^j(K) = \left\langle \left( \frac{x^j_1 + x^j_2 + \cdots + x^j_K}{K} \right)_L^2 \right\rangle_L - \left( \left\langle \left( \frac{x^j_1 + x^j_2 + \cdots + x^j_K}{K} \right)_L \right\rangle_L \right)^2 \quad (5)$$
which represents the variance of impact within the \( K \) samples extracted from journal \( j \). We note that this sampling process and calculation of variance is similar to the concept of stability interval of the Laiden Ranking (Waltman et al., 2012).

\( \kappa_j \) is defined as the minimum \( K \) subjects to \( \Delta^j(K) \leq \delta \), that is demonstrated as follows:

\[
\kappa_j = \arg\min_K \Delta^j(K) \leq \delta_{1,\ldots,N}. \tag{6}
\]

The right hand side is just one choice of sufficiently small variation. Here we take it to be the variation among the chosen \( N \) journals. The depends on the choice of these \( N \) journals. It can be defined differently. Considering the meaning of \( \Delta(K) \) and \( \delta(1,...,N) \), the definition of \( \kappa \) is straightforward: the smallest size of papers ensuring that the variance of average impact within a journal is less than or equal to the variance between the chosen \( N \) journals. The above definition can also be explained in Fig. 1. Consider the case that two journals are chosen, \( N = 2 \) and two journals having largely overlapped distributions of number of received citations of their papers. Even when \( \mu_1 > \mu_2 \), it is hard to say that papers from one journal are of better impact than the other since \( \Delta^1(1) \sim \delta_{(12)} \), thus \( \Delta^2(1) \sim \delta_{(12)} \), thus \( \Delta^1, \Delta^2 \ll \delta_{(12)} \).

In this way, the overlapping between random variables \( c_{p(\theta_1)}(K_1) \) and \( c_{p(\theta_2)}(K_2) \) is very small so that Eq. 2 holds.

Next we confirm from empirical tests, although it can also be shown theoretically, that the bootstrap technique in statistics guarantees that for large enough \( L \), the \( K \)-sample variance \( \Delta^j(K) \) decreases with larger \( K \) for a distribution function with finite variance or for any set of empirical data with large variance that \( \Delta^j(K) \) remains finite (Wasserman, 2004). This can be verified in Fig. 2. Using real data from a set of journals, we verify that \( \Delta^j(K) \) indeed decreases with \( K \) as shown in Fig. 2. Since as shown in Fig. 2 \( \Delta(K) \) is very close to \( K/\Delta \), our definition of \( \kappa_j \) can be regarded as a conversion to \( \Delta^j \) as in \( \kappa_j^j = \frac{\Delta^j}{\delta} \).

![Figure 1: Definition of \( \kappa \) for two journals initially have largely overlapped distribution.](image)

(a) Originally two journals have largely overlapped distributions such that \( \Delta^1, \Delta^2 \ll \delta_{(12)} \).

(b) After taking \( \kappa_1 \) (\( \kappa_2 \)) samples from journal 1 (2), the resulting distribution functions
are well separated such that $\Delta^1 (\kappa_1), \Delta^2 (\kappa_2) \ll \delta_{(12)}$. (c) We can take $\kappa_{1,2} = 1$ for two journals whose distributions are already well separated such that $\Delta^1 (1), \Delta^2 (1) \ll \delta_{(12)}$.

The fact that our definition of $\kappa_j$ can be regarded as a conversion directly from $\Delta^j$, the standard variation of journal $j$, without involving bootstrapping at all makes tectonically the bootstrap procedure irrelevant to our discussion. However, logically the bootstrap procedure is still necessary since it tells us that we may now regard the $K$-sample average as a mean to evaluate the $K$ papers from the journal $j$ as a whole and consider average and variation of various choice of $K$ papers. Furthermore, in pure theoretical consideration, this bootstrap procedure is also necessary since, in theory, we might need to discuss average and variance of various $K$ samples from a heavy-tail distribution function, such as a power-law function, of citation counts, in which case, $\Delta (K) = \frac{\Delta}{K}$ might not hold anymore.

From the definition of $\kappa$, we can see that $\kappa$ is both determined by the selected journals and the citation distribution of each journal. A significant variance in the numbers of received citations of the selected journals results in a large $\Delta$, thus $\kappa$ will be small and the journals with papers yielding higher consistency in the numbers of received citations will have smaller $\kappa$.

Figure 2: Empirical results verify that $\Delta(K)$ decreases with $K$. Here the horizontal line corresponds to the value of group $\delta$. We can also see that $\Delta(K)$ is very close to $\Delta/K$. Here we use $L = 4000$.

3. Results

3.1. Data

We extracted papers published in 2010 and their corresponding citation count between 2010 and 2012 of 25 journals from Web of Science. The journals selected are both multidisciplinary and subject-specific in scope, and cover a wide range of average citations per paper. Names and other information of selected journals can be found in Table 1. We chose these 25 journals to simply implement and test our ideas. Therefore, we have selected multidisciplinary and specialized journals related to medical studies. Only publications of the Web of Science document type “article” were included in the data collection.

3.2. Pairwise comparison
JIF (or journal average citation) is often used to assess the performance of individual researchers. A researcher with a single paper published in a higher JIF journal is customarily thought to possess greater academic influence than a researcher with a paper published in lower JIF journals. This claim is established in low confidence, even if it may be true. For example, as shown in Fig. 3(a), the citation distribution of Nature and Nat Cell Biol shows a high degree of overlap, rendering the citation distribution indistinguishable between individual papers although the average number of citation in Nature is higher.

Taking these two journals as our test set of journals, and using citations of papers in the two journals, we calculate the minimum number of representative papers $\kappa$ for each of the two journals, as according to Eq. 5 and Eq. 6, where $\delta$ is determined as the variance of the average citation amount $C$ of the respective journals. We found that $\kappa$ for Nature and Nat Chem Biol is $\kappa_{NCB}^N = 38$ and $\kappa_{NCB}^N = 9$ respectively. Here, we introduce a notation $\kappa_c^r$ to denote the minimum number of representative papers of journal $r$ when compared against journal $c$. The large value of $\kappa_{NCB}^N = 38$ associated with Nature is partially due to the highly heterogeneous citation distribution of Nature, in addition to the comparability between the average citation values of the two journals.

The distributions of average citations of $\kappa$-sample, which is the calculated average of a random selection of $\kappa$ papers from a journal are shown in Fig. 3(b). A clear distinction between the average citations of Nature and Nat Cell Biol emerges, and the intra-journal variance shrinks sharply; this is indicative of high confidence in correctly distinguishing the journals based only on citations.

Complete results of the pairwise comparison are shown in Fig. 4. Each small square at position $(r, c)$ represents the value of $\kappa_c^r$ in logarithmic scale for the row journals when compared against the column indexed journals; the color red indicates that the average citation $C_r$ of the row journal is larger than that of the column journal, otherwise, it is blue. We observe that some journals, e.g., Nat Struct Mol Biol ($r = 10$) and PNAS ($r = 12$), yield consistently low $\kappa$ when compared to other journals with $C$ ranging from high to low; this indicates that the two journals exhibit a high degree of consistency in their publications. Conversely, JAMA ($r = 8$), as compared with the remaining journals, has a relatively high $\kappa$. One possible reason for this is the highly skewed citations of the papers published in 2010. For most journals, the darkest squares are along the quasi-diagonal ($\pm 1$ shift), which is indicative of the journal pairs along the quasi-diagonal having similar average citations, thereby resulting in a small $\delta$, and thus a large $\kappa$. This is understandable since the two neighboring journals are not significantly distinguishable according to their JIFs, and if we want to distinguish them, a substantially large $\kappa$ is required, in some cases even much larger than their publication size. Furthermore, the white-dominated portion in the lower left of Fig. 4 represents a large difference in the average citation $C$ between the compared pairs of journals. The selected journals belong to various disciplines that may have significantly different citation patterns. However, for simplicity, we did not include any disciplinary normalization method, although it should be noted that whenever possible a disciplinary normalization should always be used (Radicchi & Castellano, 2008, Waltman, 2016) and we will do so in future works which will be more results oriented than the current method oriented work. Thus, in principle, here interdisciplinary journal Nature and Science should not be compared with Nat Cell Biol.

From the above pairwise comparison, each journal $i$ gets one value of $\kappa_c^j$ when compared with a journal $j$. Thus, in total, each journal gets $N - 1$ such numbers, thereby disallowing the
assignment of only one number to a journal. In order to define one number as the minimal amount of representative papers of each journal based on the pairwise comparison, we then divide the entire set of papers corresponding to all journals into two sets, one set being papers from journal j and one set the remaining papers.

Figure 3: Box-plot for the citation distribution of *Nature* and *Nat Cell Biol*. (a) The original citation distribution for Nature (left purple) and Nat Cell Biol (right green) are shown in logarithm because of their highly skewed distributions. The vertical-axis ‘citation + 1’ is used in consideration of papers without citations to avoid log (0). The five horizontal lines in each box represent the maximum, third quartile, median, first quartile and minimum amount of citations, respectively. The black plus markers represent the average citation. (b) Distribution of the bootstrap K-sample average citation when the typical minimum number $\kappa = 38$ for *Nature* and $\kappa = 9$ for *Nat Cell Biol*, respectively.

Next, we compare the two sets and define a single indicator of the minimal representative size of journal j under pairwise comparison to be $\kappa^j_R = \kappa^{\text{rest}}_j$. Values of $\kappa^j$ for all the journals studied in this work are provided in Table 1. It was worth noting that $\kappa^j$ is similar to its publication size for *NAT CHEM BIOL* and is even much larger than the publication size for *JAMA*. 
Figure 4: Heatmap of the pairwise compared $\kappa$. Journals are sorted in descending order based on their average citation (same order as Table 1). The darkness of each small square represents the value of $\kappa$ in logarithmic scale for its corresponding row journal $r$ when compared with its column journal $c$: red squares indicate the average citation of the corresponding row journal is larger than that of the column journal, and vice versa for blue squares. For example, the darkness of the square (3, 7) represents the value of $\kappa^3_7 = 38$ of Nature ($r = 3$) when comparing with Nat Cell Biol ($c = 7$).

3.3. Group Comparison

Next, let us extend this comparison between two journals or two sets to a comparison of many journals. Consider all of the journals from which we collected individual paper citations as a group $J$. This is applied in Eq. 5 and Eq. 6 to calculate $\kappa$ for each journals in the set, where $\delta_j$ is calculated as the variance of $C$ for all the journals in group $J$. This $\kappa^G_j$ indicates the minimum number of papers required to represent the impact of journal $j$ while also yielding distinguishability among the group of journals $J$.

The original citation distributions of all journals in our set are shown in Fig. 5(a). Although the journals are ordered based on their average citation $C$, there are high degrees of overlaps between the left-most journals and the right-most journals. Such overlaps prevent us from using the JIF to evaluate individual researchers and individual papers. However, after calculating $\kappa^G_j$, the $\kappa^G_j$-sample average become well separated as can be seen from Fig. 5(b). Thus, this may facilitate distinguishing of a single journal from the entire set of journals.

The list of values of $\kappa^G$ for each journal is shown in Table 1. For Nature, 11 papers are needed to represent its impact as compared with the remaining journals, and for Science, 6 papers are enough. Note that when Nature and Science are compared directly, the pairwise $\kappa$ for each are $\kappa^S_N = 173$ and $\kappa^S_N = 90$, respectively, which are different from their respective group $\kappa^G$ values. For journals with $\kappa = 1$, e.g., Mol Psychiatr and Alcohol, their sizes are small and they exhibit consistency in the impact of publications when compared with the remaining journals in the entire set; however, the consistency does not hold true when performing direct comparisons between individual journals.

The details of all chosen journals are shown in Table 1. We note that in most cases, the value of $\kappa^p_j$ of journal $j$ is larger than $\kappa^G_j$. This is particularly seen for example of Nat Chem Biol and JAMA. Yet, both $\kappa^p$ and $\kappa^G$ are often much smaller (except Nat Chem Biol and JAMA) than the corresponding publication size. This implies that JIF for those journals is representative in the sense that if approximately $\kappa^p_j$ or $\kappa^G_j$ papers were randomly chosen from the journal $j$, the average is close enough to JIF. However, when $\kappa^{p,G}_{j} \gg 1$ it also implies that it is not a good idea to use JIF to evaluate individual papers of those journals. Or when $\kappa^{p,G}_{j} \sim P_j$ close to the size of the journal, then it is not a good idea to use JIF even to evaluate this journal, for example, in the case of JAMA. Therefore, we think that calculating this $\kappa$ and comparing it against 1 and $P_j$ tells us valuable information on the reliability of using JIF to evaluate journal J.
Figure 5: Box-plot for the citation distributions of all journals in Table 1. (a) The original citation distribution for all journals considered in this work. The journals appear in descending order according to their average citation $C$. (b) The distribution of $\kappa^G$-sample average citations, where $\kappa^G$ of each journal is calculated according to Eq. 6 and listed in Table 1. Compared to (a), the distributions in (b) are in much narrow ranges. The five horizontal lines in each box represent the maximum, third quartile, median, first quartile and minimum amount of citations, respectively.

4. Conclusion and Discussion

Quantifying the performance of scientists and impact of papers is a trending and controversial topic. Our above analyses demonstrate that, although it is not appropriate to utilize a journal-level metric, such as JIF, to evaluate individual researchers and papers, it is still a reasonable metric and effective in practice to evaluate a group of papers if the sizes of such groups are significantly large. In this work, we proposed the following three definitions: pairwise $\kappa_{ij}$, one-against-the-rest $\kappa^P_j$ and group-based $\kappa^G_j$. We find that $\kappa^P_j$ and $\kappa^G_j$ are often much smaller than the publication size of the journal $j$. Knowing $\kappa_j$, the minimum number of representative papers of journal $j$, means that if JIF is part of the indicators according to which journals are going to be evaluated, then $\kappa_j$ must be much less than the size of the journal, $\kappa_j << P_j$.

For journals, often this condition can be easily satisfied since it is not that hard to increase the number of papers of a journal. However, it might become a problem when using JIF-like indicators to rank universities or departments since for some of them we may find that their number of total publications might not be much larger than their necessary size of representative samples. In practice, often there is a hand-picked threshold, like universities with less than 500 publications in the dataset are discarded (Bornmann et al., 2014). Having a definition of the necessary size of representative samples in this case helps to draw a line, although it might be a very fuzzy line, between the large enough universities/departments and the not so large ones according to their own consistency levels. For example, some small universities, which would be discarded previously, can still be taken into consideration if they have high consistency levels.

It should be noted that, according to the definition, journals with papers yielding greater consistency in the number of received citations have a smaller $\kappa$. Therefore, $\kappa^P$ and $\kappa^G$ can also be regarded as journal-level indicators of consistency. When ranking journals both JIF and these $\kappa$ should be considered.
However, we admit that like percentile ranks the value of \( \kappa \) depends on the choice of the entire set of journals and thus their values are more complicated than the JIF. In future studies, one might want to divide the journals into different groups according to for example JIF and then do the group comparison \( \kappa_G \) within the predefined groups since it is not very possible that a journal with very low JIF will like to be compared against a journal with very high JIF. In the current work, we treated all journals as a whole group.

As shown in Table 1, many journals possess a minimum number of representative papers equal to one. This means that those journals have small within-journal citation variations while the inter-journal group variation is much bigger. We suppose one reason for this is related to the current set of chosen journals, where the average citations of the journals are relatively already well separated. This results in the value of the group variation \( \delta_J \) being large while some journals have small single-paper variations \( \Delta(K = 1) \) just as illustrated in Fig. 1(c). In practice, this problem may be overcome by choosing a sufficiently large group of journals to cover all the journals of interest to the researchers, or by dividing the data set into subsets with a smaller group variation \( \delta' \) within the subsets. We are planning to collect a larger set of journals and perform a more detailed study.

Lastly, we would like to emphasize again that even if we do find \( \kappa_j \ll P_j \) and \( \kappa_j \approx 1 \) for a journal \( j \) when it comes to evaluating individual papers from the journal, quantitative indicators should only be supplementary to peer review, just that we might feel more comfortable in using these indicators.

Besides the investigation on minimum representative size of journals, we think our explicit mathematical statement of ‘reliably evaluating single papers according to indicator \( \theta \)’, i.e. Eq. 1, \( P_r \left( c_{p(\theta_1)} > c_{p(\theta_2)} \mid \theta_1 > \theta_2 \right) \sim 1 \), is also meaningful and it may stimulate further investigations on applicability of all journal-level indicators.

Table 1: \( \kappa \) values for the medical journals considered here. For each journal, its name, number of papers (\( P \)), average citations per paper (\( C \)), and minimum number of representative papers (\( \kappa_C \) and \( \kappa_P \) ) are shown.

Do Mathematicians, Economists and Biomedical Scientists Trace Large Topics More Strongly Than Physicists?

Abstract
In this work, we extend our previous work on largeness tracing among physicists to other fields, namely mathematics, economics and biomedical science. Overall, the results confirm our previous discovery, indicating that scientists in all these fields trace large topics. Surprisingly, however, it seems that researchers in mathematics tend to be more likely to trace large topics than those in the other fields. We also find that on average, papers in top journals are less largeness-driven. We compare researchers from the USA, Germany, Japan and China and find that Chinese researchers exhibit consistently larger exponents, indicating that in all these fields, Chinese researchers trace large topics more strongly than others. Further correlation analyses between the degree of largeness tracing and the numbers of authors, affiliations and references per paper reveal positive correlations – papers with more authors, affiliations or references are likely to be more largeness-driven, with several interesting and noteworthy exceptions: in economics, papers with more references are not necessarily more largeness-driven, and the same is true for papers with more authors in biomedical science. We believe that these empirical discoveries may be valuable to science policy-makers.

Conference Topic
Scientometrics

Introduction
How researchers choose their research topics has received sustained attention (Busch et al., 1983, Diamond, 1994, Gieryn, 1978, Foster et al., 2015). This will not only directly affect scientists’ output and recognition, but also indirectly affect the science itself. This problem has been widely investigated from sociology of science (Merton, 1957, 1968, Latour, 1987), philosophy of science (Kitcher, 1995, Strevens, 2003, Kleinberg & Oren, 2011, Bikard et al., 2015, Boyer-Kassem & Imbert, 2015), and new economics of science (Dasgupta & David, 1994, Stephan, 1996). Quite often previous investigations on this issue are rather qualitative. In this work, we want to study this empirically based on data.

Researchers may determine their research topics primarily according to their research interests, their perceived potential in making progress on the topics or simply by the largeness of the topics, or some combination of all these factors (Foster et al., 2015). Here, largeness refers to how many publications are on the topic during a time interval denoted as \([t_0, t]\). For example, based on knowledge network of chemical reactants, Rzhetsky et al. explore the probability of selecting a pair of molecules as a function of the importance (represented by degree) and the difficulty associated with combining them (measured by network distance). It is found that biomedical scientists prefer to explore the local neighborhood of central, important (i.e., higher-degree) molecules in biomedical chemistry (Rzhetsky et al., 2015). In this work, we focus on the effect of largeness of topics on scientists’ choices of topics. It has been found that the scientists tend to trace large topics in physics (Wei et al., 2013), and in environmental science (Grandjean et al., 2011).

“The rich get richer” or Matthew effect is a common social phenomenon (Barabasi & Albert, 1999, Price, 1976, Simon, 1955). Matthew effects in science have been investigated
also in scientometrics, for instance, on scientists’ credit (Merton, 1968) and on citations (Bonitz et al., 1997, Biglu, 2008). Only a few previous studies are on scientists’ choice of topics in a certain discipline (Wei et al., 2013, Rzhetsky et al., 2015, Grandjean et al., 2011). Thus, in this paper we ask: Does tracing large topics differ across disciplines? What is the difference of degree of largeness tracing among different countries? To what degree is the intensity of largeness tracing relevant to properties such as the number of authors, references and affiliations of articles? We hope that discoveries from this study will provide valuable information for scientific policy makers especially on the issue of funding and evaluation.

The question of hot topics, prominent topics, or research fronts itself has also been widely investigated in scientometrics (Boyack & Klavans, 2010, Small et al., 2014, Upham & Small, 2010, Chen, 2004, Cozzens et al., 2010, Klavans & Boyack, 2016). Research fronts are generally defined as the areas attracting the most scientific interest in a period of time, especially before publication size of the considered field becomes really big and the field is clearly under exponential growth. Therefore, the studies of hot topics conventionally refer more to identifying emerging hot fields. We will refer these studies as studies on emerging hotness. One might use the number of received citations of papers on a topic (Boyack & Klavans, 2010, Small et al., 2014, Upham & Small, 2010, Chen, 2004, Klavans & Boyack, 2016), or simply use the number of publications (or scientists) on a topic (Cozzens et al., 2010) for this purpose. In this work, we do not need to identify emerging research fronts and our use of hotness or largeness is more like the current size (in terms of number of publications) of the fields. We call the hotness in this sense the realized hotness, or simply largeness.

Furthermore, for each of the four disciplines that we study, which are mathematics, physics, economics and biomedicine, there is an established hierarchical classification system of topics and all the publications under our investigation have been annotated with such a hierarchical code from the system. Therefore, we do not even need to do classification or clustering of publications to identify topics. In this work, articles with same code at a certain level are considered to be on the same topic. Both the number of papers and the number of received citations of the papers on a topic can be used to quantify the largeness of the topic. However, these two quantities are not really independent: the number of citations more or less follows a power law relation with respect to the number of papers (Katz, 1999). In the following analysis, we use only the number of publications belonging to a topic as a measure of the largeness of the topic as for example in Rzhetsky et al. (2015), Grandjean et al. (2011). In principle, one can also consider how new publications are attracted by received citations of topics, but this will be the topic of another investigation. Thus, using established hierarchical classification systems of topics and classifications of papers in these systems, our definition of large topics in this paper is much simpler than that of research fronts: We only need to count how many papers belong to a topic at a given level. The more papers, the larger the topic and the bigger the realized hotness. Using the established hierarchical classification systems of topics is not ideal since new topics emerge constantly. One may use various clustering methods based on citation relation among publications to establish classification systems and identify topics (Subelj et al., 2016, Boyack & Klavans, 2010, Klavans & Boyack, 2016). However, in this work, we will use the established coding systems based on controlled vocabularies for the above four disciplines.

Using the above measure of largeness, in this work, we investigate the degree of largeness tracing in mathematics, economics and biomedical science, and then perform a comparison among them and also between these three fields and physics. Intuitively, it might be expected that mathematicians would be more likely to choose their topics of investigation according to their scientific interests and the scientific value of the questions, partly due to the fact that mathematicians intend to work individually and partly since often mathematicians claim so.
One might also guess that it is possible that biomedical scientists choose research topics mainly according to medical values of problems rather than the largeness of topics. Economists might choose their topics according to their urgency to the current economic situation rather than their largeness. Here, we empirically examine whether or not this is the case.

Aside from pure curiosity, such a comparison among various fields might have value in the study of science policy. For example, we wish to examine the correlation between the impact of papers and their degree of largeness tracing. As researchers, we would prefer to see that less largeness driven papers have a greater impact. For science policy makers and administrators of universities, funding agencies and institutes, such a correlation, whether positive or negative, could potentially provide guidance regarding their duties, as one of their goals is to seek strategies to improve the scientific impact of the academic units under their administration. We would also like to examine whether larger teams tend to produce more value-driven papers or more largeness-driven papers. An answer to this question might have strategic policy value regarding how large research teams should be supported.

In our previous work, using data obtained from the American Physical Society (APS) concerning publications in APS journals, we investigated and confirmed the occurrence of largeness tracing in physics (Wei et al., 2013). In this work, we extended this analysis to the fields of mathematics, economics and biomedical science based on publications from the datasets of the Mathematical Review (MR), the Journal of Economic Literature (JEL) and PubMed, respectively. Each of these databases uses a field-specific classification scheme – the Physics and Astronomy Classification Scheme (PACS) for physics, the Mathematics Subject Classification (MSC) for mathematics, the JEL Classification Codes (JEL) for economics and the Medical Subject Headings (MeSH) for biomedical science – and classifies each paper into one or more categories, which we call fields or subfields when the categories become finer and finer. When more specific information is needed, we use the following notation, \( n \)-digit topics, such as 1-digit topics, 2-digit topics etc. to denote the fields and subfields at the level of \( n \)th number/letter of the corresponding classification system. In this sense, we call the 0th level topics discipline, namely here Physics, Mathematics, Economics and Biomedical science. We test how likely a newly published paper is to be in a large field, where the largeness of each field is measured simply by the current number of published papers in that field accumulated starting from some early years about which we still have publication data. Further details on our methods and data can be found in section 2, where we also define a quantity called the relative contribution ratio, \( R_c(k) \), to describe the extent to which researchers from a given country contribute to fields of size \( k \) compared with the overall contributions of this country to academia. The exponent \( \alpha \) and the relative contribution ratio \( R_c(k) \) are the statistics that we analyze throughout the remainder of the paper.

**Methods and Data**

Given a set of newly published papers in a time window at time \( t \) with size \( \Delta t \) ([\( t, t + \Delta t \)]), we first record in which fields each paper of them belongs to. We also record the current number of published papers in each field till time \( t \) (papers published between \( t \) and \( t + \Delta t \) are not included) starting from some early years \( t_0 \) about which we still have publication data. Then by combining the above two pieces of information, we count how many of the newly published papers appear in fields of size \( k \), which we denote by \( p_k(t) \). We are interested in knowing how \( p(k) \) depends on \( k \). According to various previous studies (Barabasi & Albert, 1999, Price, 1976, Simon, 1955, Wei et al., 2013, Rzhetsky et al., 2015, Grandjean et al., 2011), often there is a power law \( p(k) \sim k^\alpha \). In principle, one can extract this component \( \alpha \) by directly fitting \( p(k) \) with respect to \( k \).
However, there might be more than one topic with size \(k\) (we denote number of size-\(k\) topics as \(n(k)\)) and often \(n(k)\) also follows a power law with respect to \(k\), \(n(k) \sim k^{-\gamma}\). Considering that for each single size-\(k\) topic \(p(k) \sim k^\alpha\) (this exponent \(\alpha\) is what we really want) and there are \(n(k)\) such topics, we will have \(p(k) \sim k^\alpha n(k) \sim k^{\alpha-\gamma}\). Therefore, if we directly fitting \(p(k)\) to \(k\), we would have to know the \(\gamma\) of \(n(k)\). In order to get rid of this additional parameter, we define

\[
T(k) = \frac{\sum p(t)}{\sum \tau(t)}
\]

The normalization is to make \(T(k)\) more like a distribution function. It has been found that in physics this curve is close to a power law (Wei et al., 2013). We then fit this curve of \(T(k)\) to a power law

\[
T(k) \sim k^\alpha
\]

and refer to the exponent \(\alpha\) as the degree of largeness tracing. In fact, to smooth the curves, we use the integral of \(T(k)\) over \(k\), which we call the accumulated distribution function

\[
K(k) = \int_0^k T(x)dx
\]

Consider a special case where the likelihood of each current paper leading to a new publication is the same, then \(p(k) \sim n(k) k\) and \(T_k \sim k\). This is a constant ‘birth rate’ model, which is unlikely to be true since some papers might lead to a lot of new papers while many other papers will not inspire any further publication. Thus \(\alpha = 1\) is an interesting special case. Another special case is \(\alpha = 0\) which means that large fields and small fields are equally attractive or inspiring for researchers when they decide to work on which topics. What are the empirical values of the exponent \(\alpha\) for various disciplines, or for authors from various countries, might reveal valuable and interesting information about the disciplines and the countries. Therefore, in the following, besides comparing empirical values of \(\alpha\) against 1 and 0, we will also focus on cross-discipline/cross countries comparisons, and a few other comparative studies to reveal how other corresponding factors influence largeness tracing.

In addition to the degree of largeness tracing \(\alpha\), we also define the relative contribution ratio \(R_c(k)\) for each individual country \(c\). Given a set of papers and the fields to which they belong, we calculate a quantity \(m^c_k\), which is equal to the number of papers contributed by country \(c\) in fields of size \(k\) considering all publications from \(t_0\) to \(t\) in our datasets. In counting \(m^c_k\), we use fractional counting towards countries, in the sense that a country that occurs \(y\) times among the \(x\) affiliations of a paper is counted as a contribution of \(y/x\) from that country. Using this \(m^c_k\), we define

\[
R^c(k) = \frac{\sum m^c_k}{\sum \sum m^c_k}
\]

Intuitively, the numerator represents the fraction of the contributions made by country \(c\) out of all papers in fields of size \(k\), whereas the denominator represents the fractional contribution of country \(c\) to all fields. More detailed information can be found in (Wei et al., 2013).

In our datasets, each paper is recorded as a data entry that includes the title, year of publication, subject classification code(s), author(s), affiliation(s), reference(s) and number of received citations. The classification schemes in these datasets are all hierarchical. In this work, we use the finest level of each classification system. Articles with the same code are classified into the same topic. Moreover, we regard each paper as one unit of contribution to each assigned topic even when it is assigned to more than one topics. It is not exactly accurate but reasonable for now and we should consider how to evaluate the contribution of each paper.
to their topics more accurately in future studies. It is found that the size of topics follows a skewed distribution (Wei et al., 2013).

The physics dataset is a collection of all papers published in APS journals from 1976 to 2013. Here, we consider only those research papers, e.g., articles, brief reports and rapid communications, that have been annotated with PACS numbers. In physics, we consider 6-digit topics, e.g., 03.65.-w (Quantum mechanics). We consider a total of 389912 papers, 5823 PACS numbers, and 1131566 classification labels.

The mathematics dataset is a collection of all papers collected by Mathematical Reviews from 1969 to 2015. Here, we consider only those research papers recorded by both Mathematical Reviews and Web of Science (WoS). The MSC codes for each paper are taken from Mathematical Reviews, and other information is from WoS. There are significant differences between different versions of the MSC codes. Thus, we study the mathematics dataset separately for three different time periods, from 1991 to 1999, from 2000 to 2009 and from 2010 to 2015. In mathematics, we consider 5-digit topics, e.g., 40C05 (Matrix methods). We have respectively 92992, 289554 and 261504 papers, 5143, 5124 and 5487 MSC codes, with 456994, 456994, 755121, 711349 classification labels for the period of 1991-1999, 2000-2009 and 2010-2015.

The economics dataset is a collection of all economics papers collected in the American Economic Association JEL database from 1970 to 2013. Here, we consider only those papers recorded by both JEL and WoS. The JEL codes are taken from the JEL database, whereas other information is from WoS. In economics, we consider 3-digit topics, e.g., D12 (Consumer Economics: Empirical Analysis). We consider 241751 papers, 1125 JEL codes and 582150 classification labels.

The biomedical science dataset is from PubMed, which covers a wide range of important journals in the biomedical and life sciences dating back to 1950. We downloaded the 2015 baseline version provided by PubMed. We consider only those papers which have been assigned with MeSH codes. MeSH codes is a classification tree and different branches might have different depths. Some branches stop at 12-digit codes such as A01.456.505.580 while others have a depth of 9-digit such as A17.360.296 or depth of 24-digit such as D27.505.696.875.360.276.210.277. In this work, we only report results on the 12-digit topics.

Figure 1: Empirical preferential attachment to large fields for newly published papers. The cumulative probability functions $K(k)$ for the (a) physics, (b) mathematics, (c) economics and (d) biomedical science datasets show various values of $\alpha$. The biomedical science dataset is from PubMed, which covers a wide range of important journals in the biomedical and life sciences dating back to 1950. We downloaded the 2015 baseline version provided by PubMed. We consider only those papers which have been assigned with MeSH codes. MeSH codes is a classification tree and different branches might have different depths. Some branches stop at 12-digit codes such as A01.456.505.580 while others have a depth of 9-digit such as A17.360.296 or depth of 24-digit such as D27.505.696.875.360.276.210.277. In this work, we only report results on the 12-digit topics.
At last, we have 21850751 papers, 6855 MeSH codes, and 123446643 classification labels. We have not yet integrated this data with WoS; consequently, many entries have no affiliations and/or no references.

Results

We first consider sets consisting of all papers published in each year in each of the three disciplines, determine the overall degree of largeness tracing in each discipline in each year, and compare the results with the degree of largeness tracing in physics. We then divide the set of papers in each discipline according to various characteristics of each paper, including whether it was published in a top journal, its country of origin, the number of authors, the number of affiliations and the number of references, and study the correlations between these features and the degree of largeness tracing.

![Figure 2: Evolution of exponents. The exponents for different years obtained by least-squares fitting of the curves from k = 10 to k = 300 for physics, mathematics and economics and from k = 10 to k = 3000 for biomedical science. These fitting ranges were so chosen because the curves deviate from straight lines at large k due to empirically the rarity of such extreme values. The standard deviations of the fitted value of \( \alpha \) are smaller than 0.01. The goodness of regressions \( R^2 \) are larger than 0.99. Unless otherwise stated, \( \Delta t \) is equal to one year for physics, mathematics and economics and one month for biomedical science. The results for biomedical science are the average values for the corresponding 12 months. In the year 2000 and 2010, there is a significant change to MSC so that the exponent cannot be calculated.](image)

Overall, scientists do trace large topics

As shown in Fig. 1, the accumulated distribution function \( K(k) \) follows a power law, namely, \( K(k) \sim k^\alpha + 1 \). All of the power-law exponents \( \alpha \) are positive, indicating that hotter fields (those that are larger in size) do attract more newly published papers. These results are qualitatively consistent with our observations in physics: generally, scientists are more likely to choose to publish in hotter subfields. The reasons may be as follows. Scientists publish their achievements with high probability by following large topics, so they may more easily achieve enough recognition to maintain a position. It is also possible that development of science has made a strong correlation between scientific value and largeness of research topics, such that the large topics are the one with most scientific value. In this case, then it is not surprising that overall scientists trace large topics. Unfortunately, it is hard to put this to a test since so far there is no good objective measure of the scientific value of topics. However, differences between the degrees of largeness tracing among the various disciplines are still informative. In particular, the exponent in mathematics is markedly larger than those in the other three fields, as is also shown in Fig. 2 for more than 20 years. This is surprising and counter-intuitive, as it is widely claimed, at least among mathematicians, that the scientific efforts of mathematicians are more independent and more interest-driven or value-driven rather than largeness-driven. The reasons for this discrepancy are not yet known to us. What is
also noteworthy is that the exponent in biomedical is less than those in other fields, indicating probably that biomedical scientists are more interest-driven rather than largeness-driven.

**Figure 3: Relation between largeness tracing and cited number.** The preferential attachment exponents $\alpha$ increase slightly with respect to the cited number $N_{\text{Cited}}$.

*Influence of journals on largeness tracing: Papers in top journals are less largeness-driven*

We also like to know whether, on average, largeness-tracing papers have less impact on academia as a whole. To this end, we can investigate the correlation between the exponent $\alpha$ and the number of received citations. As shown in Fig. 3, doing so reveals no clear-cut pattern, except that in mathematics, there is an overall trend of an increasing value of the exponent with an increasing number of received citations. However, it is generally accepted that papers that are published in top journals are more likely to be original and have a higher impact. Thus, it is possible that they are less largeness-driven. Here we compare the degree of largeness tracing among papers published in top journals with that among papers published in other journals.

We classify the papers into two subsets, i.e., those published in top journals, which are chosen from our databases by disciplinary experts to choose only the highest recognized ones, and those published in other journals, and for each subset, we calculate the exponent $\alpha$. As shown in Fig. 4, overall, the exponents $\alpha$ for papers in top journals are smaller than those for papers in other journals in all four disciplines. This finding indicates that publications in top journals are indeed less largeness-driven. The values of the exponent $\alpha$, as indicators of the degree of largeness tracing, are 0.59 (0.73) in physics, 0.68 (0.92) in mathematics, 0.52 (0.64) in economics and 0.33 (0.45) in biomedical science for top (other) journals. We also apply the two-sample Kolmogorov-Smirnov test (KS test) to the sets consisting of the recorded $k$ values of each paper at the time of its publication in top and other journals, and the results of the KS test indicate that for all these disciplines, it is safe to reject the hypothesis that these two sets of $k$ values are drawn from the same underlying distribution. This supports the discovered difference between the exponent $\alpha$ that it is possible that the degrees of largeness tracing of top journal papers are statistically different from that of other papers.

*Comparison of the degrees of largeness tracing among various countries: Chinese scholars are more largeness-driven*

General public and science policy-makers have a great interest in the research performance of various countries. Here, we compare the degrees of largeness tracing among various countries. We classify the papers into subsets according to the countries that appear in their affiliations. When the authors are from more than one country, the paper is included in the set corresponding to each country. The absolute contribution ratios are listed in table 1. Note that in economics, the contributions from Japan and China are very low. As we will see later, this leads to extremely large fluctuations and, consequently, less reliable observations.
As seen from Fig. 5(a-c), the exponents calculated for China are consistently larger than those for the other three countries in physics, mathematics and economics. Note that the value of Chinese scholars on mathematics is even larger than 1. Recall that $\alpha = 1$ means constant ‘birth rate’ model, where the likelihood of inspiring/attracting/leading to a new publication is the same for each current paper. With this $\alpha > 1$, it implies that for Chinese mathematicians it is even possible that larger fields are disproportionately more attractive than the other fields. We do not want to speculate further on why it is the case in China. However, since this observation that Chinese scholars have larger $\alpha$ is there in all the three disciplines (In Economics, it is still larger but not that much larger than the $\alpha$ of others countries), other researchers should look into possible systematic reasons behind it. To further characterize the differences among these countries, we consider the relative contribution ratios $R_c(k)$.

Figure 4: Comparisons of largeness tracing between top journals and other journals: (a) physics, in which the top journal is Physical Review Letters; (b) mathematics, in which the top journals are Inventiones Mathematicae, Annals of Mathematics, Acta Mathematica, and the Journal of the American Mathematical Society; (c) economics, in which the top journals are the American Economic Review, Econometrica, the Journal of Political Economy, the Quarterly Journal of Economics, and the Review of Economic Studies; and (d) biomedical science, in which the top journals are Nature, Science, the Proceedings of the National Academy of Sciences of the United States of America, Cell, the New England Journal of Medicine and Lancet.

As shown in Fig. 5(d-f), in all three of these disciplines, the relative contribution ratio $R(k)$ of China is smaller in cold fields (for small $k$ values) and larger in large fields (for large $k$ values), whereas the opposite is true for the USA. Thus, Chinese scholars make more (fewer) contributions to large (cold) subfields compared with their average contribution to all subfields. These results further indicate that Chinese scientists are more likely to follow large topics. We have not investigated potential institutional reasons for this qualitative difference in behavior between Chinese and US scholars, although we strongly suspect that causes may exist at a systematic level. In our definition of $R(k)$, in principle, the numerator $\sum \mu m_k^\alpha$ should eliminate the influence of the absolute sizes of the fields. Therefore, proportionally speaking, in the absence of any other determining factor, the relative contribution ratio should be approximately constant, as in the case of mathematics in Germany and Japan, as illustrated in Fig. 5(e). It should be interesting to investigate the possible reasons behind the observed unevenness of the relative contributions to these fields. An educated guess is that the early development of a research program may be regarded as a catch-up period, during which it is easier to focus more strongly on hotter topics, resulting in smaller contributions in cold subfields and larger contributions in large subfields. If this is the case, then it appears that in
the field of economics, research in Germany, Japan and China is much less developed compared with research in the USA. This is partially confirmed by the small percentage contributions from Germany, Japan and China.

With respect to the numbers of authors, affiliations and references: The more the stronger, with exceptions

Next, we investigate the influence of the numbers of authors, affiliations and references on the degree of tracking large topics. We classify the papers into subsets according to the numbers of authors, affiliations and references and calculate the largeness-tracing exponent $\alpha$ for each subset. It has been found that in recent years, the size of teams and the share of multi-university collaborations have been larger than ever, and the work of such teams tends to attract more citations (Adams, 2012). In addition, it has also been claimed that research works with many authors or many affiliations are typically more focused on large topics (Wei et al., 2013, Adams, 2012). We would like to examine the relation between team size and the degree of largeness tracing. Knowing whether work from large teams is more likely to be largeness-driven rather than interest- or value-driven may have policy value with regard to explicit support for the building of large teams.

As shown in Fig. 6(a), $\alpha$, the exponent quantifying the tracing of large topics, increases with an increasing number of authors, from 0.63 to 0.82 in physics, from 0.87 to 1.2 in mathematics and from 0.55 to 0.68 in economics. These results indicate that large teams typically focus more on large topics, which is consistent with the argument that studies with many authors are typically more focused on large topics (Adams, 2012). Therefore, on average, establishing large teams is not necessarily a good strategy for encouraging value-driven research. However, the exponent $\alpha$ does not increase with an increasing number of authors in biomedical science. This implies that in biomedical science, large teams are not necessary less interest- or value-driven than small teams. In this field, forming large teams might be a good strategy for encouraging value-driven research. Thus, we see that differences between disciplines lead to differences in good team-building strategies. A pure educated guess will be that in the field of biomedical science, there are a significant amount of valuable projects which only large teams can do.
Fig. 6(b) shows that the exponent $\alpha$ increases with an increasing number of affiliations $N_{Aff}$, from 0.65 to 0.83 in physics, from 0.92 to 1.23 in mathematics and from 0.6 to 0.72 in economics. Thus, the above results indicate that on average, cross-affiliation collaborations are not necessarily a good strategy for encouraging value-driven research.

As seen from Fig. 6(c), the exponent $\alpha$ also increases with an increasing number of references $N_{Ref}$, from 0.56 to 0.75 in physics and from 0.82 to 1.01 mathematics, indicating that papers that cite a larger number of references are more likely to address large topics. Interestingly, however, in economics, the exponent $\alpha$ decreases overall with an increasing number of references, from 0.73 to 0.44, implying that papers with a larger number of references are more likely to focus on value-driven research topics. The reasons for this exceptional observation regarding the correlation between largeness tracing and the number of references in economics as well as the exceptional correlation between largeness tracing and the number of authors in biomedical science are not yet known to us.

In principle, one can try to adjust $t_0$ to see more recent trends. We have performed the same analysis with various $t_0$ in measuring sizes of topics. Overall, our above observations on the exponent $\alpha$ and $R (k)$ still hold for shorter periods between $t_0$ and $t$, although their numerical values are different. Moreover, we also have performed the same analysis on various level of MeSH code, such as 6-digit, 9-digit and 15-digit. It is found that the results are qualitatively similar with a different exponent.

**Conclusion and Discussion**

In this paper, we investigate the phenomenon of largeness tracing among scientists from four disciplines, namely, physics, mathematics, economics and biomedical science, all of which have yielded a large number of papers with associated subject classification codes. It is found that overall, scientists in all four disciplines are more likely to publish in large fields, but surprisingly, the values of the exponent $\alpha$ are larger for mathematicians than for the others. We also compare the degrees of largeness tracing between top journals and other journals and find that in all four disciplines, papers published in top journals are less largeness-driven than those in other journals.

In addition, we find that Chinese researchers trace largeness more strongly than US, German and Japanese researchers in all these disciplines. Moreover, it seems that large teams and cross affiliation collaborations are not necessarily beneficial for encouraging the pursuit of value-driven studies: We find that on average, papers with larger numbers of authors, affiliations and references tend to exhibit larger exponents of largeness tracing, although there are interesting exceptions. Papers with more authors are more largeness-driven in physics, mathematics and economics, whereas in biomedical science, such papers are, in fact, less largeness-driven. It is found that cross-affiliation collaborations are more likely to choose...
large topics in physics, mathematics and economics. In addition, the degree of largeness tracing increases with an increasing number of references in physics and mathematics, whereas the opposite is true in economics. It is not surprising that papers with large numbers of references are not particularly value-driven or innovative, so this observation in economics is quite non-trivial. The nature of the unique characteristics of biomedical science and economics that cause them to be exceptions to the generally observed trends remains an open and interesting question.

Scientific innovation is an important goal of science. Ideally, we would hope all scientists choose their research topics mainly based on the scientific values of the questions. Of course, it will be even better if scientific value and largeness agree with each other to a large extent. Otherwise, for individual researchers pursuing innovation is risky (Foster et al., 2015) and maybe working on large topics is a better strategy. However, at levels of nations or societies, an important goal of science policy is to encourage scientific innovation. For that, we might need a policy to balance innovation and largeness tracing. For example, we have seen that Chinese scholars trace largeness most severely and we speculate that it is related to the fact that researchers got additional bonus payment according to the total number of published SCI papers and also the fact that large teams and big players got a dominantly large portion of national research funds. Publications of large teams, according to our preliminary results, are rather more largeness tracing. In fact, it should be further examined in our future studies whether or not large teams and big players are becoming more and more dominant in China. If it is indeed so, then it in a way helps to make a better sense of our discovered empirical results.

The results presented in this paper are based on the available data. In particular, the investigated physics papers are limited to all papers published by APS journals, which is only a subset of all physics journals. In principle, we should collect all papers published in physics journals, but many journals do not use PACS numbers. Moreover, in PubMed datasets, the affiliation information is often inaccurate and the references are not included, and at present, we have not merged PubMed data with WoS data. In this work, we regard papers published in top journals as high-impact papers. In principle, however, we should consider other measures of impact, such as normalized measures (Leydesdorff et al., 2013) or measures based on network analysis (Bergstrom et al., 2008). A corresponding study of technological developments could also be interesting, for example, by considering largeness tracing in patents. In this work, we used established hierarchical classification systems to define topics and as we mentioned earlier, clustering methods based on citations might identify different topics and thus lead to different classifications of papers. How various classification methods influence largeness tracing should also be investigated in the future.

Abstract
Most novelty detection studies in Bibliometrics or S&T management are focused on finding academic papers or patents, in this work, we proposed a novelty detection approach for scientific awards based data mining and machine learning algorithms, designed a machine learning model for identifying novel awards from previous awards structure. Application abstracts of previous and recent awards have been used as training data and predict data, then applying text clustering, dimensionality reduction and one-class SVM classifier to identify the novel data from previous training data. A performance evaluation experiment was designed and implemented, the average accuracy of the proposed approach is 73.78%. A case study of six years on the material awards from the National Science Foundation (NSF) was exemplified, 41 potential emerging awards have been detected from previous awards. This approach could help researchers or decision makers to detect possible novel awards at an early stage, furthermore track the newest evolution of a research field from a scientific funding perspective.

Conference Topic
Knowledge discovery and data mining

Introduction
Discovering the emerging or novel research at the early stage is important to researchers and scholars, there have been many studies in this area. Most of the emerging or novelty studies were focused on finding novel papers or topics. Many related works have been done by researchers in the following approaches: such as text mining and data mining approaches (Glänzel & Thijs, 2011; Zitt & Bassecoulard, 2008; Tu & Seng, 2012), literature-related discovery (Kostoff 2008; Chen 2006; Berry et al. 2009), topological analysis of citation networks (Shibata et al. 2007, 2011); And combinations of other methods or other data, for example patent data (Daim et al. 2006; Verhoeven et al. 2016). As we know the published paper reflects the past work of researchers, the novel research paper or topics detected based on published papers maybe already outdated, but scientific awards represent current and even future research focuses, especially the awards funded by National research funding agencies. If there was an approach that could extract the layout of scientific funding and detect the novel researches at an early stage, it could help researchers and decision makers to track trends and predict the direction of scientific development. There have not been many studies on funding information analysis, particularly novelty detection based on funding data. Most studies for funding analysis were based on statistics or related paper analysis (Huang et al. 2006; Liu et al. 2006, 2008; Jacob & Lefgren, 2011).

This study proposed a novelty detection approach for funding information based on data mining and machine learning algorithms that attempts to discover potential “new” awards. The novel awards that were identified from previous awards which have a better opportunity to be more innovative research. This approach would minimize the number of potential awards, helping researchers or decision markers to track the evolution of a research field.
Methods

In this section, we briefly describe the technical background, the algorithms, and procedures that have been applied. The first subsection refers to the outlines of the proposed machine learning approach; This is followed by the description of the data collection, the text clustering algorithm, the Linear discriminant analysis (LDA) for dimensionality reduction and the one-class SVM classifier for novelty detection. The second subsection designed and implemented a performance evaluation experiment. Four test sets have been tested with proposed approach.

Proposed novelty detection approach

The following methods were proposed to find awards that are “different” or have not been seen in previous awards. The “different” or “new” awards may represent a new research content or direction. As can be seen in Figure 1, the suggested approach employs various methods such as text mining feature extraction, text clustering, dimensionality reduction and novelty detection by classification. The One-class SVM classifier was used as a novelty detection method to find novel awards in this research, but due to the complexity of the classifier, dimensionality reduction techniques needed to be applied in the pre-processing step before later classification for improving computational speed. The One-class SVM classifier will detect the soft boundary of previous “normal” awards in a low-dimensional vector space, then classify new awards as similar or different to that set. As the involvement of many methods and complex algorithms may lead to conceptual misunderstanding and imprecise use in practice, the proposed approach is designed to be executed in four steps: data collection and pre-processing; Find structure of previous awards by K-means++ clustering algorithm; Apply linear discriminant analysis (LDA), a supervised dimensionality reduction technique, to reduce features and enhance computational speed. The K-means clustering labels were used for improving the dimensionality reduction effect; The Final step is identifying novel awards from previous awards via the One-class SVM classifier; The proposed approach described in the following step by step.

Step 1: Data collection and pre-processing

Every year, NSF receives approximately 30,000 new or renewal support proposals for research, graduate and postdoctoral fellowships, and approves approximately 9,000 new awards (Liu et al. 2006). In order to accomplish the proposed approach, more than 2900 awards data from 2010 to 2016 were downloaded from the NSF material department. Downloaded data included title, abstract and start date as the most important information. Because the goal of this research is finding new scientific awards, some unnecessary information contained in abstracts, like applicant and college background, non-technical parts and broader future impact parts were removed. Also, any awards purely supporting international conferences or global cooperation were removed too.

Step 2: Find structure of awards by text Clustering

To detect novel awards from a particular area of awards based on application abstracts, we assumed that if all the awards were grouped into sets by similarity, all of the similar awards
should have been distributed around the centroid of each group set, but perhaps novel awards would have been distributed far away from centroid, so the structure of awards needed to be found first. An improved K-means++ clustering algorithm has been chosen to subdivide previous awards into clusters in this paper, which was proposed in 2007 by Arthur David Arthur and Sergei Vassilvitskii, it is an algorithm for choosing the initial values (or "seeds") for the k-means clustering algorithm to avoid the sometimes poor clustering found by the standard k-means algorithm. The performance of k-means++ clustering algorithm with NSF awards data has been proven by our previous work. (Chen et al. 2015) But some as the standard k-means algorithm, to find the right number of clusters is a challenging issue in clustering analysis, for which no unique solution exists (Zoubi & Rawi, 2008). A method was devised to combine the means of silhouette coefficients and human expert’s option to select the right value of K.

**Step 3: Dimensionality reduction for improving computational speed**
The novel detection model often creates a kernel based model, which means that it is not very scalable. The abstract of awards application usually contains a large number of TF-IDF features, with the purpose of avoiding the overfitting problem in the classification with high dimensional space (Joachims 1998) and reduce computational costs, the high dimensional space needs to project onto a lower-dimensional space with good class-separability. The Linear discriminant analysis (LDA) is a generalization of Fisher's linear discriminant (Fisher 1936), it is the most commonly used as dimensionality reduction technique in pre-processing step before later classification. LDA is very similar to Principal Component Analysis (PCA), they are both inner transformation techniques that are commonly used for dimensionality reduction, but LAD is “supervised” and computes the directions that will represent the axes that maximize the separation between multiple classes. For novelty detection based on structure, the K-means clustering labels can be used as training labels in reducing dimensions, the LDA dimensionality reduction technique is more suitable in this case. The comparison of the two-dimensional projection of awards text features with LDA and PCA is shown in Figure 2, LDA had much better class-separability than PCA with awards data.

![Figure 2: Comparison of 2D projection of LDA and PCA with awards data](image)

**Step 4: Identify emerging awards via One-class SVM**
Novelty detection is the identification of new or unknown data that a machine learning system has not been trained with and was not previously aware of (Markou & Singh, 2003), it is the fundamental requirement of a good classification system. A machine learning system can never have been trained on all possible object classes whose data the system is likely to encounter hence the performance of the network will be poor for those classes that are under-represented in the training set. In this study, the one-class SVM classification algorithm with non-linear kernel was used as a novelty detection method to detect new awards that have not been seen in previous awards (training data). It is a type of one-class classification algorithm, also known as unary classification, tries to identify objects of a specific class amongst all objects, by
learning from a training set containing only the objects of that class (David 2001). This module is particularly useful in scenarios where you have a lot of "normal" data and not many cases of the anomalies you are trying to detect. In this case, the low dimensional LDA features of the past four year’s awards were used as training data, the One-class SVM model will detect the soft boundary of that set in a low-dimensional vector space, in other words, the model will draw a circle in vector space to delineate the scope of “normal” awards, if any new awards were distributed outside the scope, the model will classify it as a novel award.

Performance evaluation
To test the performance of purposed novelty detection approach, an evaluation experiment designed based on NSF materials awards. 1914 NSF material awards in a period of 2012-2015 were used as test data for the experiment. The flowchart of the performance evaluation experiment is shown in Figure 4.

1. Construct dataset with truth ground
To test the performance of the classifier in this awards data, we need to construct a test dataset with truth ground, because it is no labelled novelty award within this research dataset, so the truth ground dataset must be created manually. Firstly, the K-means++ clustering test datasets were applied, which found 30 clusters from the datasets and used clustering labels as truth ground labels for later evaluation tests. Then each cluster was split into previous awards (2012-2014) and recent awards (2015) by a range of year, randomly picking 6 clusters from previous awards as training data and using the training data to train the novelty detection model later. After training data was created, we needed to make test data for the model. The test data should include some awards that are similar to the training data, some awards are different from the training data, so we picked any of the four clusters from the recent data that are the same as the training data, then added the awards from two random clusters that differed from the training data. The awards from the two different clusters were considered as novel awards.

2. Test performance
Use the training data to train the One-class SVM to obtain the machine learning model, then apply the test data to the model for predicting novel awards, awards from two different clusters should be predicted as novel awards, then compare predicted result with truth label and calculate the accuracy of trained model prediction. The result of experiment as shown in table 1, tested the proposed approach four times with different random training and predict data sets, the average accuracy of the model prediction is 73.78%, the accuracy is not particularly high because the truth ground labels are not known for awards data, no human expert involved to identify the real emerging awards during this research. The clustering labels used as truth ground for this were not real truth ground for our test data, so our results are acceptable

### Case Study

A case study of novelty detection for NSF material awards is presented. In order to find out the novel awards these material awards, 2967 NSF material awards collected from the year 2010 to 2016, 2818 research awards remained as case study data after cleaning processing, previous awards data was used to train the novelty detection model which was mentioned earlier, the trained one-class SVM model was then used to predict recent potential emerging awards from training data structure, detailed as follows: Step 1: The documents have been split into training data and predict data by range of year. The training data contained 2362 awards which being awards starting from 2010 to 2014, predict data contained 456 awards which being awards starting from 2015 to 2016. Step 2: Convert training data to TF-IDF vector space which contains a total 6439 words, then subdivided it into 17 clusters through K-means++ clustering algorithms with means of silhouette coefficients and expert judgment. Clustering results and NLP extracted keywords of each cluster are shown in the appendix table 4. Predict data was also converted into the same TF-IDF vector space and used it as feathers of predict data. Step 3: After clustering, both label information and document TF-IDF features were used to reduce dimensionality via LDA. In this research, 6439 training TF-IDF features were reduced to 100 LDA features with good class separation. Step 4: LDA features of training data were used for training the one-class SVM model, which then determined novel data from test data by learning from training data, the parameters of one-class SVM model used in this case study has shown in table 2.

</table>
Novelty detection model predicted 41 novel awards (456 awards in predict data) from 2362 training awards which listed in table 3, 14 clusters have novel awards, but 3 other clusters (cluster 2,7,8) do not have any novel awards. Two-dimensional projection of learning results, shown in Figure 4, the dots are awards data in this case study, the white dots are training data (previous awards), the red lines are the learned frontiers from training data, the green dots are predicted data (recent awards) which are considered normal awards that are distributed within the learned frontiers, and the red dots are also predict data, but are considered novel data that is distributed outside of the frontiers.

According to the well distributed two-dimensional projection of training awards and predict awards seen in Figure 4, the results of the proposed model for this case study are reliable. Firstly, the clustering approach applied to the NSF awards provided good clustering results. Each cluster had a clear silhouette showing good separation. Secondly, most novel awards detected
by the learning model have distributed far away from the frontier line of each cluster, this shows
the novel awards detected by the model are quite different from previous awards, those awards
have a good possibility to be identified as emerging awards.

Conclusion and limitations

This study has proposed a machine learning approach to discover potential novel awards based on funding application documents. Firstly, we designed an approach combining a clustering algorithm, dimensionality reduction technique and one-class SVM algorithm to identify recent novel awards from previous awards. Secondly, a performance evaluation experiment was designed and implemented using clustering predicted labels as truth ground labels to test the performance of the proposed approach (average of 73.78% accuracy). Finally, regarding practical implementation, this study adopted a case study based on NSF material awards from 2010 to 2016, a total of 2363 awards, where 41 potential emerging awards have been detected. As this study is only at the explorative stage, it is subject to certain limitations as outlined here. First, data cleaning of application documents is not fully automated, a lot of manual work was involved in this step. Second, this approach detects novel awards based on an awards structure, awards should be subdivided into groups first. The accuracy of novelty detection is dependent on clustering performance, also the One SVM classifier is one of the most commonly used novelty detection algorithm, but may not be the best one, we will test more algorithm and find the most the most accurate one in future, also to obtain good clustering performance required participation of human experts. Finally, the results of the case study are also not verified by human experts due to the vast variety of NSF material awards and the difficulty of judgment for novel awards, hopefully, in future human experts can be involved in furthering this research to improve the accuracy of the approach.

Abstract
We measure the knowledge flows among the countries by analyzing publication and citation data. We argue that not all citations are equally important, therefore, in contrast to existing techniques that utilize absolute citation counts to quantify knowledge flows among different entities, our model employs citation context analysis technique using machine learning approach to distinguish between important and non-important citations. We use 14 novel features (including context based, cue words based and textual based) to train Random Forest classifier on labeled dataset of 20,527 publications downloaded from the Association for Computational Linguistics anthology (http://allenai.org/data.html). Finally, we present a case study to elucidate our deployed method on the dataset of PLoS ONE full text publications in the field of Computer and Information Sciences. Our results show significant volume of important knowledge flows from the United States consumed by the international scientific community. Of the total knowledge flow from China, we find relatively less proportion (only 4.11%) fall under the category of important knowledge flow. We believe that such analyses are helpful to understand the dynamics of the relevant knowledge flows across the nations.

Conference Topic
Knowledge discovery and data mining

Introduction
In the past few years, the world has seen remarkable development of scientific knowledge-research interactions at progressively quick rate (Schott, 1994). Researchers have tried to represent knowledge as static and have developed various methods to extract, discover and reason about it. However, knowledge is dynamic and requires human brain for its discovery, circulation, synthesis, generalization, and problem solving. Scholarly publications are the most significant medium that transfers knowledge between scientific communities (Yang & Wang, 2015; Zhuge, 2006). In addition to measure knowledge flows among the scientists – this phenomenon has been measured at institutional or country level (Ingwersen et. at, 2000; Albert & Adam, 2003). Undoubtedly, knowledge has become crucially important in global economies, since many economies are becoming knowledge based. The emerging economies are participating in the production of new scientific knowledge that contribute to an accelerated pace of technical and scientific advance. The rapid growth of scientific publications is one key indicator to quantify the production of these new knowledge powerhouses. In last two decades, the world has seen a remarkable growth in the production of scientific knowledge. While the scientific literature index in Scopus database has increased 2.27 times in 2014 compared with ~1.14 million publications in 1996, China has remarkably published 15.8 times more in 2014 compared with ~28k publications in 1996. This significant increase in creating new knowledge sources is a key indicator to measure the scientific advancement of knowledge driven economies. However, the retentions of these knowledge sources does not
solely be contingent on single isolated entity, rather depends upon transfer and exchange among the knowledge based economies (Hassan & Haddawy, 2015a; Hassan & Haddawy, 2015b). Recently, knowledge flows have been measured by analyzing citation networks among the publications produced by the scholars from different parts of the world (Hassan & Haddawy, 2015a; Hassan & Haddawy, 2015b). Citations indeed provide a quantitative way to measure the knowledge flows among the published works but not all citations are equal. While some certainly indicate that the cited work is conceptually used or, more importantly, extended in the new publication, some are incidental, e.g., they discuss the cited work in the context of related work that does not directly impact the new effort. Therefore, it is important to differentiate between non-important (incidental) and important (conceptual) citations because measuring knowledge flow using absolute citations counts would not be adequate.

This paper measures knowledge flows among the countries by analyzing publications and citations data. Unlike existing techniques that utilize absolute citation counts to quantify knowledge flows among the entities, our proposed model utilizes citation context to distinguish important knowledge flows. The followings are the objectives of this paper: a) to study the knowledge flows using citation exchange among the papers published by the scientific communities across the countries; b) to identify the ratio of important knowledge flows w.r.t to total knowledge flows from the countries; 3) and to study the global network of knowledge flows across the countries. The remaining paper is organized as follows. The related work is discussed in the next section followed by our deployed methodology and data collection process. Further, we present a case study to elucidate our deployed method in the field of Computer Science. Lastly, we present concluding remarks along with future directions.

**Literature review**

This section presents a brief literature review in two directions: while the first half discusses related studies that deploy citation analysis to measure knowledge across different entities, the second half presents a review on methods on classification of citations in order to distinguish most important knowledge flows.

**Knowledge Flows among the scientific literature**

Indeed, knowledge does not exist in isolation; rather, it is defused, circulated and exchanged among various entities. Citations among the papers have been employed to measure knowledge flows in science (Zhuge, 2006). By aggregating citations among the paper into several higher levels, scientists have presented journal level, university level, scientific discipline level and national level knowledge flows by analyzing citation exchange of the following entities: journal/conference citations (Borgman & Rice, 1992; Leydesdorff and Probst, 2009; Zhao & Wu, 2014), institution citations (Börner et. al, 2006; Yan & Sugimoto, 2011, Liu et al., 2014), scientific discipline citations (Van Leeuwen & Tijssen, 2000; Yan et al., 2013) and country citations (Hassan & Haddawy, 2013).

At the journal level, examining citation exchange is used to study patterns across the fields. Leydesdorff and Probst (2009) point knowledge out flow of political science and social psychology journals on communication science journals. At the institute level, a study of spatio-temporal changes of 500 most cited institutes shows an inverse relation between the log of distance and log of citations among the institutes (Börner et. al, 2006). This results in favor that knowledge flows are less dependent on physical distances (Yan & Sugimoto, 2011, Liu et al., 2014). At field level, publications by Cronin & Davenport (1989) and Cronin & Pearson (1990) may consider pioneers to study knowledge exchange among different disciplines. Their work deploys trading terminologies and considers only two ends of knowledge flows ecosystem i.e. knowledge exporter and knowledge importer but lack to discuss concrete knowledge flow paths. However, recent work of Yan (2015, 2016), explores knowledge paths among scientific
disciplines. At country level, Hassan & Haddawy (2013) introduce a quantitative approach to measure the international scholarly impact and present geographical maps to visualize knowledge flows across the countries. Zhang et al (2013) analyze the database of the entire publication of the American Physical Society and discovered the trends of production and consumption in physics in different cities.

Apart from the quantitative representations of knowledge flows, scientists have been working on semantic representations for better understanding of knowledge flows. Zhuge (2006) is one of the pioneers who proposed several techniques for the discovery of knowledge flows in science by deploying hyper cycle model and semantic link network in e-science environment. He also presented an effective e-learning system using semantic link network to find out semantic relationship between learning resources and communities to support effective browsing of knowledge (Zhuge, 2009; 2010; Zhuge, 2011). Furthermore, Zhang et. al. (2013) analyzed the database of the entire publication of the American Physical Society and discovered the trends of production and consumption in physics in different cities. More recently, a methodology to semantically analyze the knowledge flow across countries using Latent Dirichlet Allocation model and Euclidian distance was proposed by Hassan and Haddawy (2015a, 2015b). Their method consisted of identifying the research topic of the publications produced by a given country in a given research area. Then they determine the scholarly impact of the actual research topics in the cited topics across the countries.

Citation Classification Methods

According to Borgman(1990) and Luukkonen (1992), citations are commonly used to measure the impact of a research article by how often they are cited, however, researchers have always criticized the pure quantitative analysis of citations quoting that most citations are done out of “politeness, policy or piety” (Ziman, 1968). It has been argued that citations used in negation or passing citations should not weigh as much as central citations in a paper (Bonzi, 1982). One of the best-known and most widely used schemes for citation functions is devised by Moravscik & Murugesan (1975). They divide citations into four categories namely conceptual vs operational, juxtapositional or evolutionary, perfunctory or organic and finally negational or confirmative. Chubin and Moitra (1975) slightly modify this scheme by making each of the categories mutually exclusive. Oppenheim & Renn (1978) devise a unique scheme to classify citations in the physical sciences to determine why old papers are cited more. Small (1986) devise a simple classification scheme for cancer virology citations using cue words. Garzone (1997) developed an automated classification mechanism for citations using the linguistic semantic grammar. Teufel et al. (2006) also devise a supervised learning model to classify citation function utilizing linguistically-inspired features. Furthermore, the work on the proximity of co-cited references by Liu & Chen (2011) while conducting co-citation analysis and the work of Hu et al (2013) that present a model to learn from the citation instances distributed in 350 full text scientific articles and are also notable ones.

More recently, Valenzuela et al (2015) introduce a novel task of identifying important citations in scholarly literature, i.e., citations that indicate that the cited work is used or extended in the citing document. They devise a mechanism to separate important and meaningful citations from the unimportant ones. They model this task as a supervised classification problem at two levels of detail: a coarse one which classes important vs. non-important and a more detailed one which classifies into four categories i.e. Incidental (related work), Incidental (comparison), Important (using the work) and Important (extending the work). Hassan et al (2017) extend this work by introducing six novel features that outperforms the results produced by Valenzuela et al (2015) with producing very promising 0.91 ROC area under the curve with Random Forest classifier on the same dataset.
Summary

The presented literature review discusses solid theoretical and methodological foundation for quantitative and semantic representations of knowledge flows among several entities: scientific papers, scholars, institutions, disciplines and regions using citations analysis. In addition, we also present an overview of citations classification methods that we use to distinguish important relevant knowledge flows across the entities. We observe that the literature review of knowledge flows and citations classifications is discussed in two separate research streams. The goal of this research is to fill this gap by presenting holistic view of knowledge flows in order to distinguish most important one, since using simple absolute citations counts is not adequate.

Data and Methodology

Data

We measure scientific knowledge flows across the countries using publications and citations on PLoS ONE dataset. We download 4,138 papers in XML format indexed in Computer and Information Sciences field during Jan 01, 2014 to Sep 01, 2015. Since the cited references do not provide affiliation related information of authors, therefore, we procure metadata information such as (affiliation, abstract, author defined keywords etc.) of 31,839 unique references of our downloaded dataset from Scopus database using its API. Note that we find 21,804 matches in Scopus data since not all references in PLoS ONE are indexed in Scopus. This final set of 4,138 papers and 21,804 references is used to measures scientific knowledge flows across the countries. Table 1 shows country wise distribution of PLoS ONE publications for the countries having at least 2% publication in our dataset. Note that we use double counting method that gives full credit to publications co-authored by the institutions from different countries. In addition, Table 2 shows country wise distribution of references indexed in Scopus database cited in the selected PLoS ONE publications. Since the Scopus API only provides affiliation information of first author, therefore, in reference dataset we assign each publication to only one country corresponding to the affiliation of first author. Thus, for the reference dataset the implication of double counting method is not applicable.

*R= References published by the authors affiliated with an institution in a given country; **T_R= Total references indexed in Scopus citing publications downloaded from PLoS ONE.

Approach

Our machine learning model classifies citations found in full text publications into important and non-important, using Random Forest classifier. The deployed model has three aspects: 1) a given cited paper is important to a citing paper if it is cited several times in full text; 2) the location of a given citation in full text is important to determine its influence on the citing paper e.g. citation in method sections would probably be more important than the citation in related work; 3) and the text around the citation in full text since the it would indicate the reason for the citation. Using the above aspects, we selected total 14 novel features (eight context based, four cue words based and two textual based) to classify cited references into important and non-important.

Features for classification

The followings are context based feathers: F1 = Total number of citations received by a reference till Dec 2016; F2 = Number of citations from the current paper to the cited paper; F3 = Citations in introduction section; F4 = Citations in literature review section; F5 = Citations in method section; F6 = Citations in experiment section; F7 = Citations in discussion section; F8 = Citations in conclusion section. The cue word based feathers are: F9 = Cue words for Related work citations; F10 = Cue words for Comparative citations; F11 = Cue words for Using the existing work; F12 = Cue words for Extending the existing work. Finally, the textual based features are: F13 = Similarity between the abstract of cited paper and text of citing paper and F14 = Author overlap - we set it to TRUE if the cited paper and citing paper share at least one common author.

Experimental setup

Finally, to prepare data for experiments, we normalize all features by centering on the mean and scaling to unit variance. We generate 46,956 number of records in our feature data which naturally exceed from the total number of unique references. Since we find many papers in...
PLoS ONE dataset that share a given reference. In addition, a given reference may also be cited more than ones in a given paper. Therefore, for each pair of cited reference and citing paper (or context within a paper) a separate record is inserted in feature dataset. For learning, we implement Random Forest classifier in python using the Scikit Learn toolkit that run all features with equal weights. We used Gini index in Random Forest as a criterion to measure the quality of a split. For the experiment, we set the max_feature to auto that allow the classifier to consider all the features that seem optimal in every tree because our dataset consist of 14 features that does not need any selection restrictions.

For training the model, we use labeled dataset of 20,527 publications from the Association for Computational Linguistics anthology (http://allenai.org/data.html). Figure 1 presents the pseudo code of the method deployed.

**Pre-process and feature extraction:**

4. Web links → download corpus
5. XMLtoText in Python→ Convert XML files to plain text
6. Python Code ← Input plain text files
7. Fetch citation text and occurrence ← Using Python
8. Tokenize ← Citation text
9. Remove punctuation, numbers, HTML tags stop words ← Using Python
10. Lemmatization ← Python
11. POS tagger → Get synonyms using wordnet in R
12. Extract features
   a. Total citation count received by reference ← using Google scholar
   i. Normalize count by (2016-y)
   b. Occurrence of citation to cited paper ← Using Python
   c. Section titles → Normalize titles → count total citations in each section
   d. Cue words for each class, citation text → Cosine similarity
   e. Citation text, Reference abstract → cosine similarity
   f. Authors list of cited and citing paper → Return true if any match

**Classification procedure:**

13. Normalize features
14. Train on the labeled dataset D
15. Make prediction for each instance in test dataset T and obtain results

**Figure 1: Pseudo code of deployed methodology**

**Results and discussion**

In this section, we show the results of our case study that presents the knowledge flows across the nations using all citations, important citations, their ratios. We also show comprehensive citation networks across the countries to identify nations that exhibit highest knowledge flow impact across the glob using important citations.
Figure 2: Distribution of references published by the authors across the countries cited in the papers published by the authors from the United States

Figure 2 shows the distribution of references published by the authors across the countries to the papers published by the authors from the United States. Of the total references appear in the publication by the United States, 8692 references (53.24%) are from the papers published by the United States. This shows that a large proportion of references are self cited - if we treat the whole country as a unit. In other words, more than half of the knowledge produced by the United States is consumed within the country. Despite the fact, China’s huge volume of publication output, of the total references appear in the United States publications only 5.21% are from China in our dataset. Interestingly, the dependence of the United States on the knowledge produced by its own scientific community is even more significant when it comes to the most important one. Of the total important references cited by the authors from the United States in PLoS ONE publication dataset, about 75% (738 references) are authored by the authors from the United States. This shows huge influence of important knowledge produced by the United States within the country. Interestingly, the significance of knowledge flow from China is even reduced when it comes to important knowledge flows only. This shows even weaker dependence of the United States on the knowledge produced by the Chinese scientific community.

Figure 3: Distribution of references published by the authors across the countries cited in the papers published by the authors from the United Kingdom

Figure 3 shows the distribution of references published by the authors across the countries to the papers published by the authors from the United Kingdom. Of the total references appear in the publication by the United States, 1636 references (27.90%) are from the papers published by the United States, followed by 26.02% from the United Kingdom. This shows that more than one fourth of the total knowledge consumed by the United Kingdom comes from the United States. However, the United Kingdom shows 47.81% (186 references) of self consumption of important knowledge flows.
Figure 4 shows the references appear in the publications by the Canadian scientific community. Of the total, 912 references (i.e. 30.55%) are from the papers published by the United States, followed by 23.85% from Canada. In terms of important knowledge flow towards Canada, we find increase in the the significance of knowledge produced by the United States. Similarly, the United States appears to be the main contributor whose knowledge is consumed by France, Australia and Japan.

In contrast, the analyses of the distribution of references cited in the papers published by China shows that unlike many other nations in our dataset, the United States is not the main contributor of knowledge that is consumed by China (see Fig. 5). We show that of the total references appear in the publications by China, 2934 references (i.e. 39.2%) are from the papers published by China itself. Interestingly, the dependence of China on the knowledge produced by its own scientific community is even more significant when it comes to the most important flows with more than 40% (130 references) are authored by the authors from China. The case of China in terms of self dependence on its own knowledge resources is somewhat similar to the United States. Interestingly, we find similar pattern of knowledge self dependence in case of Germany and the Netherlands in our dataset.

Figure 5: Distribution of references published by the authors across the countries cited in the papers published by the authors from China

In addition, to analyze the distribution of knowledge consumed by a given country from other countries, we also show the proportion of important knowledge flow from a given country w.r.t to total knowledge flow from that country. Table 3 shows the list of countries having more than 30 important references in our dataset. We find Austria appears at the top in the list with 13.71% of total published references fall under the category of important ones. The Netherlands and Germany appear among the top five despite a relatively large volume of total references published by these nations. Interestingly, Spain, Japan, France and China show less than 5% of their total published references classified as important.
Table 3: Country wise proportion of important references w.r.t total references (indexed in Scopus) cited in selected PLoS ONE publications dataset.

Figure 6: Knowledge flow network (using all references) across the countries
Finally, by deploying the mapping technique proposed by Rosvall & Bergstrom (2008), we draw two networks to analyze the knowledge flows across the countries. We show 22 nodes and 145 direct links for each network, where a node represents a given country and the flow from a given country $A$ to county $B$ represents the references published by $A$ and cited in the paper published by $B$. Similarly, the flow from a given country $B$ to county $A$ represents the references published by $B$ and cited in the paper published by $A$. Here, color intensity, thickness of the directed line and size of a node shows the volume of knowledge flow. While the inner circle in a given node shows the knowledge flow within the country, the outer circle shows knowledge flow outside the country.

Figure 6 demonstrates the knowledge flows across the countries. We find the United States, followed by China, the United Kingdom, Germany and the Netherlands appear to be the most influential nodes in the network. We find significant knowledge flow from the United States to other nations. Further, analyzing only the important knowledge flows reveals even more influential role of the United States across the countries (see Fig. 7). Interestingly, of the total important knowledge flow from China, a large proportion is consumed within the country. Overall, the significance of the United States is raised in the network of important flows (Fig. 7) compared to the network created by using both important and non-important ones (Fig. 6).

![Knowledge flow network]  
*Figure 7: Knowledge flow network (using important references) across the countries*
Concluding remarks

In this paper, we have measured the knowledge flows among the countries by analyzing publication and citation data. Our deployed Random Forest based machine learning model classifies important and non-important citations which we have further used to distinguish between important and non-important knowledge flows. Our results have shown that despite an exponential increase in publication output by the Chinese scientific community, the most important global knowledge flows that are consumed by the international scientific community are still exhibited by the United States, followed by the United Kingdom and Germany. We have also highlighted that in contrast to many other nations analyzed in our dataset, the dependence of China on the knowledge produced by its own scientific community is even more significant when it comes to the most important knowledge flows produced by China.

In summation, the machine learning approach deployed in this paper helps to distinguish between important knowledge flows. In addition, the method deployed is also fundamental for the systems that detect and track emerging research themes and to measure the impact of scientific literature in increasingly scholarly big data. In future, using the deployed methodology, we plan to build bibliometric enhanced information systems for improved retrieval of bibliography databases. Finally, we also plan to improve our machine learning model by including more features such as citation sentiments (negative, positive or neutral) - we believe that this would significantly improve the accuracy of our model.

Effect of publication month on citation impact

Abstract
Bibliometric studies most commonly take whole years as temporal units of analysis, implicitly treating all publications as if they were published at the exact same point in time. This leads to systematic bias in favor of early-months publications and to the detriment of late-months publications in citation analyses. This contribution demonstrates the size of this distortion on a large body of publications from all disciplines over citation windows of up to 15 years using bivariate correlations between publication month and two citation impact indicators. It is found that early-month publications enjoy a substantial citation advantage which arises from citations of the first three years after publication and remains detectable for much longer citation windows.

Conference Topic
Data Accuracy and disambiguation; Methods and techniques

Introduction
Citation impact normalization is a core methodological concept for the construction of advanced bibliometric indicators, i.e. those which remove the effects of different scientific discipline, the kind of document and the time of publication. By delineating sets of publications similar to each other with regards to content and formal characteristics and using these sets to compute reference values and relative impact indicators, heterogeneity due to these factors is reduced. The intention is to make fair comparisons; that is, to compare like with like (Schubert and Braun, 1986). The basic formal characteristics, as opposed to the content (disciplinary area), that are taken into account are publication type (such as journal papers, conference proceedings papers, books and book chapters), document type (such as research articles, review articles, letters, editorials etc.) and publication date.

One important component of normalization is controlling for publication time, as, ceteris paribus, the more time has passed since publication the more citations will accrue. The publication year is commonly used to define publication periods. This practice is based on the implicit assumption that, for the question of interest of a study, it makes no difference when exactly in a year a paper was published. The fact that documents published in January have eleven months more to be read and cited than works published in December of the same year raises the question if this assumption is justified, and, if it is not always justified, under which circumstances and how a more precise publication date should be taken into account in citation analysis.

The question of the influence of a more exact publication date is also related to the problem of finding adequate citation windows, the time period in which citations to papers in a set of publications are counted. A too short citation window, say two years, would clearly lead to bias against papers published towards the end of the investigation period compared to those published towards the beginning. Consider the following simple illustration. Citations are tallied at the end of the year after publication (2-year citation window). Then papers from January had 23 months to be read and cited while December papers had 11 months less, just 12 months, which is 52 % of the time period of the January papers. This relative disadvantage becomes smaller as the citation window length is increased. In a five year citation window, for example, the December papers had 83 % of the citation time of the January papers.

Recently, Gai et al. (2015) studied the month citation bias in one field, one specialty and one journal for citation windows from 1 to 9 years. They exclude a few very highly cited papers and group publication months into six two-month periods. For papers in physical geography they find significant group differences for citation counts for up to five years after publication. The results are similar for papers on the topic of diabetes. For the Journal of
Biological Chemistry, group differences are significant up to the seventh year after publication.

As that study been limited to specific disciplines I investigate if the effect is general to all disciplines, as far as covered in Web of Science journal collections. Two disciplines with very different citation dynamics are investigated additionally to provide insight into field differences. Field differences in publication month effect on citation counts can be hypothesized to mirror fields’ size (in terms of number of papers) and citation speed. The present study takes into account citation windows of up to 15 years. Month effects are measured for the two bibliometric indicators mean citations per paper and share of highly cited papers for single-months groups of papers. The online publication date is tested for influence on citations in addition to that of the issue publication date. Finally, it is demonstrated how to eliminate publication month bias by constructing citation windows of equal length for month cohorts of papers.

Data and methods

Datasets
Dataset A consists of all journal publications of document type ‘Article’ from the year 2000, obtained from Web of Science \( (n = 767,959) \), for which publication month data was either available in the source data or could be estimated. 6539 articles from 2000 had to be excluded from analysis because they had neither a publication date value nor enough contextual data to obtain estimates of publication month. The number of citations to the articles in each year were computed from citation link data constructed using the ‘iFQ’ procedure described in Olensky, Schmidt & van Eck (2016) which has improved recall compared to WoS-provided citation links, using references data from all journal publications that appeared between 2000 and 2014. Citations from identical citing to cited first authors were removed. It was found that neither including all self-citations or excluding all self-citations affected results substantially.

Dataset B will be used to assess the combined influence of online and print publication months. It is comprised of articles contained in PubMed, based on 2016 base files. Publications of the print publication year 2009 which had a DOI datum available were selected and matched to WoS records based on the DOI. The records were restricted to the WoS document types ‘Article’ and ‘Review’. This results in 253,292 publications. Citation counts were computed by CWTS by their method which was also described in Olensky, Schmidt & van Eck (2016). Self-citations are not removed.

Indicators and statistical methods
The indicators of citation impact for which differences in the values of month-cohorts of publications are investigated are the average citations per paper and the share of highly cited papers. In the case of the latter, the share of papers of each publication month among the 10% most highly cited papers over all months. The statistical association of the impact indicators with the months variable is measured with the Pearson correlation coefficient on the level of monthly aggregates of publications. In the case of the association with individual papers’ citation counts, the correlation is also computed for the log-transformed citation count in order to minimize the effect of the non-normality of the citation distribution. To assess the compound effects of issue and online publication month on individual publication citation counts, we perform linear regression with log-transformed citation counts as the dependent variable (Thelwall, 2016).
Results

Effect of publication month on citations at the level of month-cohort groups of papers

To examine the effect of the publication date on citations to papers published within one year, all publications published in each month are considered as natural groups. The average numbers of citations per paper (CPP) of all month groups are calculated in order to characterize the groups’ citation impact. I examine first the average CPP per month based on citations from single years for the first four years. The results are shown in Table 1. For the first three years the earlier months’ publications receive on average more citations. In years one and two the relationship between publication month and CPP is almost exactly linear negative. The association weakens in year three to \( r = -0.74 \) and in year 4 the effect is no longer present.

Pearson r

\[-0.96^* \quad -0.97^* \quad -0.74^* \quad -0.37\]

Note: * \( p < 0.01 \)

For year one, the year of publication, December papers have almost no time at all to be cited. In year two, the CPP of December papers is 44% that of the January papers’. For year three December papers reach on average 82% of the CPP of January papers and for year four 82% as well. However, at that point the January publications are no longer the most highly cited and the December papers are not the least cited any more.

Clearly, early-month publications enjoy a considerable citation advantage for three years. Having established the effect for single citation years, we now move to citation windows of multiple years. Citation windows of two and three years after publication will clearly exhibit the correlation. However, how long does it take for the effect of those early years to become negligible? In order to answer this question in the next step of analysis citations are cumulated for subsequent years.

The results presented in Table 2 indicate that the effect decreases rather slowly. The correlation is as high as \(-0.8\) after nine years, \(-0.7\) after eleven years and at the end of the observation period, after 15 years, it is down to \(-0.6\). The correlation remains statistically significant at the 1% level up to year 11.

It could be possible that CPP is affected more by publication month than other impact indicators because citation count distributions are very skewed and the mean of this distribution is less robust than indicators based on other characteristics of the distribution. The means of the citation counts of the month cohorts might be distorted in this way. To rule out such an effect, the publication month bias is also assessed with another impact indicator, the
share of highly cited publications. In a publication set not influenced by a publication month effect, about equal shares of highly cited publications are expected be present in every month group. We consider the share of each month’s publications among the approximately 10% most highly cited publications. The issue of the publications having a citation count exactly equal to the threshold value, the 0.9-quantile, is disregarded here, as it of no consequence with respect to the central issue of this analysis, namely the association of publication month and indicator values. The computed values for selected citation windows, presented in Table 3, show the results of the calculations. In that table, the row labeled “actual share of publications >= threshold” shows the exact percentage of articles that have as much or more citations than the threshold value, which is given one row above. In the absence of bias, each month’s percentage should be very close to that overall percentage, which is the expected value. For example, in the column for year 1 to 8 (9-year citation window) 11.8% of January papers reach or exceed the threshold citation count while 9.1% of December papers do. Evidently, citation impact as operationalized by this indicator is also affected by publication month bias, even up to very long citation windows.

Effect of publication month on the level of individual publications

I turn now to the association between citation scores of individual articles and publication month for the entire dataset A and the two discipline subsets that can be formed by selecting only papers in the WoS subject categories of Cell Biology (N=14510) and Mathematics (N=5538). Contrary to the averages and ratios used earlier for month-based groups of papers, the distribution of individual article citation counts exhibits severe skewness. Therefore Table 4 shows correlations for both untransformed and log-transformed citation counts for selected citation windows. Pearson correlations are intended to measure the linear associations between normally distributed variables. The log-transformation of citation count plus 1 results in a distribution approximating a Gaussian. The associations measured by Pearson correlation coefficient are small but statistically significant. The reason for this is the very large variability of citation counts due to reasons other than publication month. Nevertheless, the explanatory power of publication month is considerable on the individual article level shortly after publication. The results are quite similar for the entire dataset and the mathematics and cell biology subsets.

“3/5/10y cits” is short for 3/5/10 year cumulative citation counts

Effect of online publication month

Up to this point, the publication month of the completed issue has been studied. Individual articles might be published online, usually in advance, at a date quite different from the publication date of the issue. This raises the question if it might not be better to use the online publication date instead of the issue date to eliminate publication date bias. Dataset B (sourced from PubMed) is used to study this issue.

Print publication month and online publication month are counted as months since January of year 1 CE, so that for example January 2009 has the value 24109. The correlation between the two variables is 0.77. The Pearson correlation of print publication month and citation count on the article level for a three-year citation window for this dataset is -0.081 and the correlation of month and log(1+3y cits) it is -0.144. These associations are a little stronger than for the cell biology subset of dataset A. The correlation of online publication month and three-year citations is 0.007 and that of online publication month and log-transformed citation count is 0.040. For all five values, p<0.01 holds.

We use linear regression to assess the individual and combined relationship of print and online publication months on papers’ citation counts. The independent variable is the natural logarithm of citations after three years plus one, in order to account for the heavy skewness of the citation distribution (variable cits3y), following the recommendation in Thelwall (2016). The transformation results in a variable with mean=1.79, sd=0.95 and skewness=0.13. Three models for different specifications of the independent variables are used to investigate the individual and combined influence of relative earlier publication in print and online of papers from the same year on citation counts. The three dependent variables are pub.month (print
issue publication month), *epub.month* (online publication date month) and *abs.d* (absolute difference of *pub.month* and *e-pub.month*). Specifications (1) and (2) in Table 5 confirm that both print issue month and online publication date month are individually significant predictors of citations count, being responsible for a 4% reduction and a 1% reduction in 3-year citation count on the original scale per increase in one month. Specification (3) includes the variable *abs.d* in addition to issue publication month. This leads to an improvement in total predictive power compared to either variable. These findings suggest that it is useful to include both the print issue and the difference between issue and online date as control variables in regression analyses of citation count data. The two publication date variables are complementary to some degree and it is thus not advisable to substitute one for the other.

**Note:** *p<0.01

**Month level precision citation windows**

It has been shown that publications of different month-cohorts of the same year have systematically shifted citation distributions. It was also found that the effect can be detected on the level of individual publications. The consequences for research using regression methods are as simple as including the publication month and, if possible, the difference of online and issue publication month, as control variables. This approach is not expedient in bibliometrics-informed research assessment. One obvious possibility to eliminate the distortion is to use month-based citation windows. This requires publication month data for both the cited and the citing documents. This allows the calculation of the exact number of citations to source publications within a specific number of months after publication which is equal for all publications, thus eliminating the bias. To verify this proposal, the publication month data was constructed for all citing documents in dataset A. New citation counts based on month-precise citation windows were calculated for 12, 24, 36, etc. months. The citation windows for each month cohort are then of the same length, not of lengths differing up to 11 months. The month-based citation windows are also longer than the corresponding year-based windows. Take for example the 3-year citation window and the 36-month citation window. The three year window ranges from 35 months (from January, year 1, to December, year 3) to 24 months (from December, year 1, to December, year 3). All month-based citation windows are 36 months long. Table 6 shows the average citation counts for some selected citation windows which may be contrasted with the simple year-based method results in Table 1 and
Table 2. In the former case, there is no correlation between publication month and mean CPP. Figure 1 shows the differences in average citation counts of each month’s publications for the two citation window methods in the 3-year case.

</tr>
</tbody>
</table>

When month-level precision citations are available, it also is possible to assess how many citations were not included when using year-level precision citations even though they cite an article within the indicated time period. Consider the example of a nominal three-year citation window. In our dataset A, counting citations in the first three years gives a total of 2,740,173 citations. Setting up 36-month citation windows for each publication month cohort, however, gives a total of 3,432,353 citations. The nominal year-based method therefore takes into account 80% of the 36-months citations. Similarly, in the case of a nominal 5-year vs. actual 60-month citation window, the year-based method takes into account 89% of the month-precise method’s citations.
Discussion

It has been demonstrated that publications of early months have a citation advantage compared to publications of late months from the same publication year. This advantage is of considerable magnitude and cannot be eliminated by removing author self-citations. The effect is present in citations from the first three years after publication but influences metrics using cumulative citation windows for many years afterwards.

The present study has some limitations. The study considered only two publication years. No temporal dynamics in publication month bias were investigated. The predictor variable of interest was the point of publication of individual articles within a year which was approximated by using the recorded or estimated month of publication of an issue. The publication month was estimated in a portion of the data with some bias and inaccuracy. Another limitation is that the official month of publication must not necessarily be close to the time when the article could first be read. Since the observed early-month bias is quite large, it should be a matter of concern in particular in situations when distinct sets of publications are compared for their citation impact and the sets are so small as to not allow enough variability in publication months so that the systematic effect may cause distortion. A set of publications will probably not be affected by this bias if it can be demonstrated to be distributed uniformly over months and the number of observations is large enough.

In regression analyses which use citation counts as the dependent variable, publication time point within a year and if available also the absolute value of the difference between print publication date and online publication date in months should routinely be included as control variables.

Abstract
In this study we investigate if sleeping beauties, also known as articles suffering delayed recognition, can at the same time be under-cited influential articles. Theoretically these two types of articles are independent, in the sense that being a sleeping beauty depends on the number and time distribution of received citations, while being an under-cited influential article depends only partially on the number of received (first generation) citations, and much more on second and third citation generations. Among 49 sleeping beauties we found 13 that are also under-cited influential.

Conference Topic
Citation Analysis

Introduction
In diachronous studies and depending on their citation curves or ageing profiles articles can be categorized in different ways. In (Smith Aversa, 1985) the author makes, for highly cited papers, a distinction between delayed rise in received citations combined with a slow decline, on the one hand, and early rise combined with a rapid decline, on the other. More recently, Costas et al. (2010) classify documents into three general types: delayed documents, which receive the main part of their citations later than normal documents; flashes-in-the-pan (van Dalen & Henkens, 2005), which receive citations immediately after their publication but are not cited or influential in the long term; and normal documents, documents with a typical distribution of citations over time. The delayed documents include articles known as sleeping beauties (van Raan, 2004), articles suffering from delayed or late recognition, being premature discoveries, being ahead of one’s time, suffering from Mendel’s syndrome or being late bloomers (all synonyms or near-synonyms, describing the same phenomenon).

Recently, and especially in China, sleeping beauties attracted a lot of attention (Ke et al., 2015; Li, 2014; Li & Shi, 2016; Li & Ye, 2016; Du & Wu, 2016), leading among others to “all-elements-sleeping-beauties” (Li & Ye, 2012), i.e. articles that at first receive some attention, then go through a period in which they are hardly noticed, followed by a period of being highly cited, awakened by a prince, so to speak. Figure 1 shows the citation curve of (Romans, 1986), a typical sleeping beauty studied by van Raan (2004). It received no citations for nine years and then received more than 100 citations over the next six years. After a peak (it received 32 citations in the year 1999) its citation curve shows a gradual and irregular decline similar to that of ‘normally cited’ articles.
A different type of articles: under-cited influential articles

All the types of articles mentioned above were based on the – direct – citation distribution. Yet, recently Hu and Rousseau (2016, 2017) introduced another type of articles in which first, second and third generation citations play a role, leading to the sparkling index (Hu & Rousseau, 2017). These articles are referred to as under-cited influential articles. Such articles are characterized by three properties: (1) they are reasonably well-cited (a basic requirement to be influential); (2) citations of citations (second generation citations) are rather high, so that the original one is influential in an indirect way (a more refined token of influence); (3) given condition two, these articles received fewer citations than expected (being under-cited). Each of these three requirements is operationalized leading to a two formulae referred to as sparkling indices. There are two types of sparking indices depending on the number of received citations: a sparking index on the 1% level, denoted as S1 (for articles that are cited at least 201 times) and a sparking index on the 10% level, denoted as S10 (for articles that are cited at least 21 times but less than 201). Details are provided in (Hu & Rousseau, 2016, 2017). These two articles also show that such under-cited influential articles are neither common, nor extremely rare. Many articles written by Nobel Prize winners, but also other, including recent articles, fall into the group of under-cited influential articles.

Before continuing our investigation we want to clarify the terminology of under-cited influential articles. It is clear that these articles are influential: they are reasonably well cited and, through citing articles, their influence on the development of the ideas that started with them is even higher. Many of them, like the Nobel prize winning articles studied in (Hu & Rousseau, 2017), can even be described as foundational articles. These articles are also referred to as under-cited. By this we do not mean that they are treated unfairly. We just want to stress that many articles that built on them received more citations. One reason could be that these articles added new results that incorporated the results of the ‘under-cited’ one, so that later investigators do not feel the need to refer to the original.

Clearly sleeping beauties and under-cited influential articles differ in many aspects except that in short-term evaluations based on bibliometric indicators, they both are under-valued. Sleeping beauties usually begin with a long period of few citations and then direct citations (first generation) go up. Under-cited influential articles usually are rather well-cited but
The number of received citations does not fully reflect their influence on their field. Probably only expert peer reviewers can see their importance. These considerations led us to the following research question.

**Are there sleeping beauties which are also under-cited influential articles?**

We looked through a set of articles dealing with delayed recognition or sleeping beauties and determined 49 articles considered to be sleeping beauties, restricting then to 1950 or later and included in the SCI-E. As a universally accepted, precise definition of a sleeping beauty does not exist, we do not discuss if these articles are really sleeping beauties. We just accept the opinion of the authors who studied these articles. For all these sleeping beauties we checked if they are also under-cited influential articles. Citations were collected and calculations made in February 2017. Bibliographic information on these sleeping beauties is given in Table 2 (Appendix), while the articles discussing these sleeping beauties can be found in Table 3 (Appendix). Results of our investigations are shown in Table 1. We found 13 sleeping beauties of the 49 checked that are also under-cited influential articles. This is 27%. Of course numbers are too small to accord any meaning to this percentage.

**Characteristics of articles which are sleeping beauties as well as under-cited influential**

The article by Romans (1986) turned out to be also under-cited influential according to our definition. This is illustrated in Figures 2-3 where, besides the original citation curve we also show the curve of the citing curves with the second most citations (in yearly distribution and in cumulative number). As the top 1% (rounded up) citing articles consists of four articles we show the second one among these (referred to as the median citing article). This median citing article, published in 1999, received already in the year 2000 more citations that Romans’ (Figure 2) and the next year its cumulative total citations was higher than Romans’ (Figure 3). This is just an illustration as such an intersection is neither necessary nor sufficient to be an under-cited influential article.
Discussions and conclusions

We note the following caveat: the definitions of sleeping beauties and under-cited influential articles depend on some ad hoc rules. This leads to the question: do these 13 articles, or most of these, really belong to the two types mentioned, or would a slight change in definition to one of the two types make a consequential difference?

Assume that we have a strict definition of a sleeping beauty, then we wonder after how many years is it clear that an article is a sleeping beauty? Is it, at that moment, also possible to say that this sleeping beauty is moreover under-cited influential (for which a strict definition exists), or is it then usually too early, as one needs three generations of citing articles and it took quite some time before the first generation was ‘large enough’ and hence does not easily lead to many second and third generation citations. Assuming that a ‘recent’ sleeping beauty is not under-cited influential is it then possibly to predict (i.e., determine a probability) if it will ever be?
We conclude that we have shown that there do exist articles that are sleeping beauties and are at the same time under-cited influential, Romans’ (1986) being a case in point.

Abstract
Based on the biblio-metrology methods and the visualization technology, this paper investigates the features of the highly cited papers of the aerospace discipline in Elsevier’s Scopus database, including research hotspots and international cooperation. Through tracking the conferences cited by the highly cited papers, of the highly academic influence in the discipline, the academic journals, conference proceedings, monographs, and the science and technology reports are listed. The research results provide a reference for aerospace discipline study.

Introduction
Established in China in early 20th century, the aerospace science and technology has been developed rapidly in recent years, which is based on mathematics, physics, and the modern technology science, and covers the fields such as aircraft design, propulsion theory and engineering, manufacturing engineering, man-machine and environmental engineering. This paper investigated the highly cited papers and analyzed the important literature characteristics of the discipline via biblio-metrology methods, including the research hotspots, international cooperation, and the academic influence, etc.

Data sources and research methods
Sample data
Scopus database contains over 21,500 titles from more than 5,000 international publishers. Across all research fields—science, mathematics, engineering, technology, health and medicine, social sciences, and arts and humanities—Scopus delivers a broad overview of global, interdisciplinary scientific information that researchers, so that is more suitable for the analysis of high-level papers in the field of engineering. In what follows, we take Aerospace Engineering in Scopus database as example to conduct a comprehensive analysis on highly cited papers published in last five years. By December 2015, the Aerospace Engineering journals have been included 41 kinds of journals issued by 11 countries, including 12 in America, 10 in Britain, 7 in Netherlands, 3 in China, 2 in India, 2 in Brazil, 1 in France, 1 in Russia, 1 in Lithuania, 1 in Germany and 1 in Egypt. Here, a total of 108,415 papers in 2010-2014 were taken in this study.

Definition of highly cited papers
“Highly cited” papers mean that they have world-class influence in the discipline. According to Essential Science indicators (ESI), those papers that the citing frequency accounts for the first 1% are called the “highly cited” papers. In this paper, the top 200 papers of aerospace fields annually are selected as highly cited papers as shown in Table 1, with a total of 1,001 papers within five years.

### Analysis of Highly Cited Papers

**Paper length**

In general, the length of a paper would have an impact on the quality and the academic level of the paper. By analyzing the lengths of 1,001 highly cited papers, it is found that the page number of the highly cited papers has a broad range from 1 page to 108 pages, with the average length of 13.97 pages, as shown in Table 2. The top-level academic journals in aerospace discipline have no limitation of the length of paper, this gives the authors an enough space to elaborate their research findings.

### Analysis of Cited Frequency

The cited frequency is one of the important indicators to evaluate scientific research achievements. From 2010 to 2014, the cited frequency of the highly cited papers in aerospace discipline is in the range of 8 to 317, the average value of which is 40.75, as shown in Table 3. The tendency change of the cited frequency of highly cited papers is shown in Figure 1. It can be seen that the cited frequency of highly cited papers is approximately linearly increasing following the increased age in five years.

Analysis of Publications

Highly cited papers are commonly published in influential publications. For aerospace discipline, 41 journals are cataloged into the influential publications. The first 20 journals published the highly cited papers are listed in Figure 2, in which the IEEE Transactions on Vehicular Technology ranks the first with 220 papers.

International Cooperation Analysis

As an important way, the international cooperation has received increased attention in the recent years, especially in China. In 1001 highly cited papers, most of the published papers are China, the United States, and the United Kingdom. Figure 3 gives the number of highly cited papers of aerospace discipline in the top 17 countries. By using Gephi, the cooperation network between the 17 countries is illustrated as shown in Figure 4, wherein the connection lines with the deeper colour represent much more cooperation between the countries. One can see from...
According to the frequency statistic of the keywords of highly cited papers within five years, it is found that the number of keywords of each highly cited paper ranges from 2 to 16, with an average of 4.8, as shown in Table 4. The frequently used keywords are Cognitive radio, Nanofluid and Fault diagnosis in order. The first 40 high-frequency keywords are shown in Figure 5. The high-frequency keywords can reflect the recent research hotspots of the discipline.

A total of 41548 references have been cited by 1,001 highly cited papers of aerospace discipline, with the average number of 41.51, listed in Table 5. Notice that the correlation between the number of references and the frequency of cited papers is not obvious. The top three years of most cited references are during 2005-2009, 2010-2014 and 2000-2005, as shown in Figure. 6. Figure 6 shows that the frequency of the cited references is gradually declined with time, with the obvious long-tail effect.

</table>
Literature types

Among the cited 41,548 references, the main types of literature are journal articles, conference papers, books, reports, dissertations, standard documents and patent literature, as shown in Figure 7.

Correlation Analysis of Journals

There are more than 400 journals listed in the references. According to the number of the published articles, the first three journals are Mechanical Systems and Signal Processing, Nonlinear Dynamics, and Journal of Sound and Vibration, respectively. According to the cited frequency of papers, nine of the top 50 journals are cataloged into the aerospace discipline, other 41 journals are closely related to the discipline, as shown in Figs. 8 and 9.
Correlation Analysis of Monographs

The statistics analysis on the monographs suggests that the first 50 monographs published in 1959-2009 averagely have a citation of more than 6 times, and most of which have second edition or fourth edition. They are classic books of aerospace discipline. The publication years of these important books are given in Figure 10. One can see from Figure 10 that the most cited books are published in the 1990s, which means that half-life period of books are much larger than that of journals. The top 50 closely related books are shown in Figure 11.
Important Academic Conferences

The conference literature is a very important way to disseminate the latest scientific research achievements. According to the number of the published papers, the top three are *Proceedings of the IEEE, American Control Conference, and IEEE Conference on Decision and Control*, as shown in Figure 12.
Figure 12. Academic meeting TOP30

Important Scientific and Technological Reports

The science and technology report is an important special document of aerospace discipline. With the statistical analysis of the scientific reports cited by the highly cited papers, it is found that the most cited scientific and technical reports are AIAA Paper, SAE Paper and NASA’s Report, as shown in Figure. 13.

Figure 13. Technical report TOP 9

Conclusions

According to highly cited papers and their references, the research hotspots, the international cooperation, and the literatures’ types of a discipline can be found. Based the world-famous citation database Scopus, this paper studied the characteristics of aerospace discipline. The results show the average length of highly cited papers is 13.87 pages, and the average number of references is 41.51; The countries contributed most in highly cited papers
are China, the United States and the United Kingdom; The figure of the high frequency word revealed the academic research hot spots of nearly five years; The paper reveals the highly influential journals, books, science and technology reports and academic conferences related to the subject by the way of charts: The most cited books are published in the 1990s. Half-life period of a book is much larger than that of a journal.

Abstract
Based on researchers’ personal websites, the extents of citation personal display (CPD) in three disciplines of social science (economics, sociology, and psychology) are investigated. Eight universities in the U.S. are targeted according to the 2016 US News & World Report ranking by subject. Results show that the overall level of CPD in social science is not high (7.5%), and researchers in psychology have the highest level of CPD (8.3%), followed by economics and sociology, which means that CPD does not behave the same in three disciplines. Furthermore, the present work suggests that researchers in different universities indeed have differences in CPD when controlling them in the same disciplines, embodying in that the statistically significant differences on CPD exist in economics and psychology, yet differences between universities are insignificant in sociology.

Conference Topic
Citation analysis; Emerging Issues
Introduction

With the development of scientometrics and informetrics, there are a great number of citation-based indices which are presented to evaluate scientists, such as h-index (Hirsch, 2005), g-index (Egghe, 2006), and w-index (Wu, 2010). Previous studies have pointed out that some citation-based indices can be useful in measuring scientists’ achievement (Lehmann et al., 2006; Ball, 2007). Considering that citation itself is a kind of behavior which researchers may want to give recognition to scientists they cited (Merton, 1973; Merton, 1988) or persuade others to support their findings (Knorr-Cetina, 1981; Gilbert, 1977; Collins, 2004), hence, researchers are more likely to show different attitudes towards citations and citation-based indices. Then the intriguing question to ask is whether these indices have been used or adopted among researchers, which remains an open question and brings this study’s value. The primary aim of this research is to investigate the extent to which researchers use citations or citation-based indices in some way.

Since there are many studies shown that the personal website can be a wonderful tool to assess an individual researcher (Ajiferuke & Wolfram, 2004; Máñ-Bleda & Aguillo, 2013; Kousha & Thelwall, 2014), this research wants to study the extent to which researchers use citations or citation-based indices with the help of researchers’ personal websites. Here, the behavior that researchers mention or display citations or citation-based indices or provide a link to Google Scholar Citations (GSC) on the personal websites is defined as citation personal display (CPD) (Li et al., 2017). Li et al. (2017) view citation personal display as a kind of recognition of index validity, and believe that researchers who have CPD may admit the value of citation in highlighting achievements. Hence, studying the degree of citation personal display can help researchers better understand the popularity and values of citations or citation-based indices.

In addition, Li et al. (2017) have studied the extent of CPD with regard to physicists in 11 well-known universities in USA, Britain, and China, and found that the overall proportion of CPD is not high (14.8%). Do researchers in other disciplines also have the low levels of CPD? This will be a question worth studying, which may be able to reflect disciplinary difference on CPD. Based on the above settings, this study tries to answer the question from the perspective of three disciplines of social science (economics, sociology, and psychology). Besides, this paper also intends to analyze the disciplinary differences and tests whether CPD differences are significant across disciplines and universities.

Data and Method

This paper has selected three disciplines of social science (economics, sociology, and psychology) as the objects to investigate the extent to which researchers display citations on their personal websites. Universities in the U.S. are targeted, whose standard of selection is in the top 15 in all three disciplines according to the 2016 US News & World Report ranking by subject. The number of such universities is 8, listing as follows: Harvard University (Harvard), Princeton University (Princeton), Stanford University (Stanford), University of California--Berkeley (UC-Berkeley), University
of California--Los Angeles (UCLA), University of Michigan--Ann Arbor (UM-Ann Arbor), University of Pennsylvania (UPenn), and University of Wisconsin--Madison (UW-Madison).

Then, this study manually examined whether individual researchers provided CPD on personal websites from each university’s economics, sociology, and psychology departments, dividing them by discipline. With regard to the targeted researchers, this study only focused on regular university professors (i.e. full professor, associate professor, and assistant professor). Taken together, the datasets consist of personal websites of 1,004 researchers, among which 367 are economists, 213 are sociologists, and 424 are psychologists.

Results

Difference in disciplines

Table 1 shows the results of CPD in three disciplines. It can be found that, overall, 75 of 1004 researchers provide CPD on their personal websites, accounting for 7.5%, which is far lower than researchers in physics discussed by Li et al. (2017). This reveals that researchers in these three disciplines of social science pay less attention to citations or citation-based indices compared to researchers in science. As Table 1 indicates, researchers in sociology have the lowest level of CPD, only with 5.6% sociologists having CPD. The percentage of CPD in economics is almost the same as in psychology, accounting for 8.2% and 8.3% respectively. As for the significance of disciplinary differences on CPD, the chi-square test suggests that it is not significant among three disciplines (p > .05).

In addition, Table 1 also gives the shares of CPD which are directly provided on researchers’ personal websites. In economics, among the 30 researchers who display CPD, only 5 economists directly show their citation information. As for researchers in sociology, all the number of CPD derive from the link to Google Scholar Citations. In psychology, there are 10 researchers who directly show citations or citation-based indices on personal websites, with the percentage being highest among three disciplines of social science (2.4%). This reflects that most researchers who mention CPD may not have a strong desire to use or display citation-related information.

Difference in universities

Noting that Table 1 has suggested that the extent of CPD in three disciplines of social
science is not high, then does every university have a low level of CPD? In order to know the degree of CPD in eight universities, this paper also analyzes distribution of CPD by universities (Table 2). In economics, there are big differences on CPD between universities, reflecting in that the highest level of CPD is up to 16.9% (UM-Ann Arbor), yet the proportion of CPD in UCLA is low to 0%. Economists in UC-Berkeley and UPenn possess a relatively high level of CPD, being 13.0% and 11.8% respectively. The remaining four universities have a relatively low degree of CPD: Princeton (7.3%), Stanford (6.8%), UW-Madison (6.1%), and Harvard (1.8%). The CPD differences between universities are tested, and the result shows that, in economics, the significant differences among the 8 universities indeed exist (p < .05).

Concerning sociology, this study finds that there are two universities in which no researchers mentions CPD, meaning that sociologists in UC-Berkeley and UW-Madison basically do not display or adopt citations or citation-based indices. Sociologists in Stanford have the highest degree of CPD, followed by Princeton (10.5%). The extent to which sociologists display CPD in other four universities is not high and has small gap, which may be the reason why there are not significant CPD differences between eight universities (p > .05). As for researchers in psychology, the highest percentage occurs in UPenn (20.6%), and the opposite case is in UW-Madison (2.7%). It can be seen that all psychologists in eight universities have provided CPD, which leads to the highest degree of CPD in psychology (8.3%). The chi-square test also shows that statistically significant differences among universities appear in psychology (p < .05).

Note. Pw: number of researchers who have personal websites; N.CPD: number of researchers who have citation personal display.

Conclusions and discussions

The present study aims to investigate the extent of citation personal display in three disciplines of social science (economics, sociology, and psychology) with the help of researchers’ personal websites. The findings show that the overall level of CPD is low, only 7.5% of 1004 researchers in question display citations or citation-based indices on their personal websites. Since Li et al. (2017) find that the degree of CPD in physics is 14.8%, hence, the low extent of CPD in this paper reveals that researchers in social science are less likely to use citations or citation-based indices compared to
researchers in physics. In addition, although the disciplinary differences discussed in this work are not statistically significant, it also can find that researchers in psychology own the highest level of CPD (8.3%), followed by economics (8.2%) and sociology (5.6%).

In addition, in terms of university, this study also finds that there are some differences among the eight universities, but its significance depends on discipline. In economics and psychology, the statistically significant differences on CPD exist, yet, for sociology, it does not show significant difference between universities. This hints that different universities’ policies and culture may have influences on researchers’ attention to citations or citation-based indices. It is an interesting phenomenon that the proportions of CPD in a university are not the lowest if the university has the highest level of CPD in any discipline. Taking psychologists in UPenn as an example, its extent of CPD is highest in psychology (20.6%), and UPenn also has the medium-high degree of CPD in economics and sociology. This may lead to such a problem whether researchers are affected by their peers in the same universities or not and how this affects others, which may be a valuable research topic.

Abstract
Usage metrics have become increasingly popular in scientometric with the advent of electronic resources. While most current researches relied on the usage data retrieved from English publishers. In this study, the usage data was extended to Chinese publishers. We collected and analysed the usage data of two well-known Chinese OA (Open Access) journals in the field of multidiscipline and library and information science respectively from journals’ official websites and Chinese Academic Journals Full-text Database (CJFD) in China National Knowledge Infrastructure (CNKI). It was found that websites’ information architecture affected usage pattern. “Progressive rule”-based site guided users to view full-text articles more than download them and “parallel rule”-based site guided users to download full-text articles more than view them. It also depicted that usage data of most articles was at their peak around pagination month and at the bottom at very earlier or later months. Articles published online as soon as they were peer reviewed did not get the attention of the community unless they were assigned to an issue. The average usage data in both journals overall started to decline after pagination month and then continued to sustain a steady level for several months.

Conference Topic
Usage data; Science of science

Introduction
With the advent of electronic resources, particularly electronic journals, and their increasing acceptance, this resulted in a rapid change in the user preference especially since 2002 (Kraemer 2006; Schloegl & Gorraiz 2010). Usage metrics have become increasingly popular in scientometric analyses beyond librarian practices (Glänzel & Gorraiz 2015). However, most researches up to now were based on the usage data retrieved from English publishers (e.g. Elsevier, Springer, Nature, IEEE Xplore, PLoS and PeerJ) or English citation index databases (e.g. Web of Science and Scopus). In reality, publishers and citation index databases of other languages also began to provide academic usage data. What’s the usage pattern of non-English academic articles? Whether non-English academic articles share the same pattern with English ones? What’s the unique pattern of non-English academic articles? Answering these questions could extend the vision from English platform to non-English platforms, which would provide a new perspective to promote the research on usage metrics. So, the purpose of this study was to explore the usage pattern of non-English academic articles by analysing the usage data of two well-known Chinese OA journals.

Literature Review
The definition of usage may be rather broad. Citation could be regarded as an official, real and essential form of usage of previous studies, while views and downloads are more of unofficial,
potential, unessential/peripheral forms of usage (Wang et al. 2016). In fact, usage metrics are even older than citation metrics, because librarians have been tracking usage since the beginning of their profession, ranging from basic user surveys to the usage tracking of physical journal issues and monographs to library loan statistics to the sophisticated analysis of e-media usage (e-metrics) (Glänzel & Gorraiz 2015).

Different from the librarian practices, usage metrics in Scientometrics mainly focused on the following topics. Firstly, the obsolescence of articles (Moed 2005; Kurtz et al. 2005a, b; Kurtz & Bollen 2010; Liu et al. 2011; Gorraiz et al. 2014; Wang et al. 2014a, b; Moed & Halevi 2016). Secondly, usage metrics were introduced as an alternative to traditional citation metrics (Bollen et al. 2005, 2008; Brody et al. 2006; Duy & Vaughan 2006; Rowlands & Nicholas 2007; Wan et al. 2010), in fact they should rather be regarded as supplementary metrics jointly with altmetrics measures (Barjak, Li, & Thelwall, 2007; Adie & Roe, 2013; Taylor, 2013). Thirdly, usage metrics were perceived as the indicator to evaluate the performance of journals, authors, groups and countries (Bollen et al. 2005; O’Leary 2008; Wan et al. 2010; De Sordi et al. 2016) and to identify the latest research trends (Bollen et al. 2003; Wang et al. 2013b). Finally, usage metrics were used as the approach to explore user behaviors (Davis & Solla 2003; Davis & Price 2006; Wang et al. 2012, 2013a, b; Khan & Younas 2017).

All the researches above were mostly based on the usage data from English publishers or English citation index databases, ignoring non-English publishers and citation index databases. For this reason, this study expanded the English usage data to Chinese usage data to explore their usage pattern. In this study, we were interested in following research questions in the context of two selected Chinese journals in the field of multidiscipline and library and information science respectively:

1. Whether two selected Chinese journals share the same usage pattern? And whether both journals share the same usage pattern with English journals?
2. What’s the correlation among different usage data in the same journal?
3. What’s the pattern of usage data before and after the issue/pagination date?

Data

Due to limited availability of dynamical data, we applied convenience sampling instead of random sampling for our data collection. In this study, we focused on two well-known Chinese OA journals in the field of multidiscipline and library and information science respectively, i.e., *Chinese Science Bulletin* (CSB) (New Site: http://engine.scichina.com/publisher/scp/journal/CSB) (Legacy Site: http://csb.scichina.com:8080/CN/volumn/home.shtml) and *Data Analysis and Knowledge Discovery* (DAKD) (www.infotech.ac.cn). The selected journals published academic articles on their official websites and the full-text articles were also indexed by CJFD in CNKI. So, the usage data in this study were collected from their official websites and CJFD.

*Chinese Science Bulletin* is a multidisciplinary academic journal supervised by the Chinese Academy of Sciences (CAS) and co-sponsored by the CAS and the National Natural Science Foundation of China (NSFC). CSB is a ten-day international journal publishing high-caliber, peer-reviewed research on a broad range of natural sciences and high-tech fields on the basis of its originality, scientific significance and appeal to a general audience. CSB provided monthly downloads data in recent 12 months for each article starting from April 2016.

*Data Analysis and Knowledge Discovery* (formerly *New Technology of Library and Information Service*), being sponsored by CAS and published monthly by the National Science Library of CAS, is one of the leading academic journals in library and information science and related fields from China. DAKD devotes itself to the study and application of the theories, techniques, practices using big data to support knowledge discovery for decision & policy
making. DAKD started to provide monthly downloads data for each article starting from November 2015.

Founded in June 1996 by Tsinghua University and Tsinghua Tongfang Holding Group, CNKI project has been dedicated to promote large-scale digitization of China knowledge resources and establish a platform for global dissemination and value-added services for nearly two decades. CNKI is mainly engaged in integrating the digital publishing of Chinese academic and educational literature resources, providing specialized knowledge services, and undertaking technology development such as digital publishing, content resources management and value-added information services. With complete coverage of China journals, doctoral dissertations and master theses, newspapers, conference proceedings, yearbooks, reference books, encyclopedias, patents, standards, scientific and technological research findings, laws and regulations, “China Integrated Knowledge Resources Database” is the most comprehensive knowledge system that integrates 90% of China knowledge and information resources (http://oversea.cnki.net/kns55/UserGuide/en/index.html). CNKI is a non-OA platform, authorization is required to use its service.

For CSB, only those issues (from issue 11 to 36) that were published from April 2016 to December 2016 were selected because CSB launched its new official site in April 2016 and its legacy site no longer updated new issues after April 2016. And the usage data of the two sites were different and it was hard to integrate them. We manually collected monthly usage data (full-text and abstract views of HTML formats, full-text downloads of PDF format) of these articles from the journal official website and total downloads information (full-text downloads) along with other metadata (e.g., article titles, authors, total cited frequency, keywords, etc.) from CJFD in CNKI. CSB updated its usage data daily, so all the data were downloaded on March 31, 2017 and revised on April 1, 2017. We found that CSB provided “early access” to their content and published some articles online as soon as they were reviewed. Then they were given pagination and assigned to an issue in later dates. Therefore, for CSB, each article had two dates, i.e., “publication date” (early access date) and “current version date” (pagination date/issue assigned date). After deleting the editorials, interviews, news and invalid records, 299 articles were kept.

For DAKD, only those issues which were published from January 2016 to December 2016 were selected because the usage data before 2016 were incomplete. We manually collected monthly usage data (full-text and abstract views of HTML formats, full-text downloads of PDF format) of these articles from the journal official website and total downloads information (full-text downloads) along with other metadata (e.g., article titles, authors, total cited frequency, keywords, etc.) from CJFD in CNKI. DAKD updated its usage data monthly, so all the data were downloaded on April 1, 2017. After deleting the editorials and news, 139 articles were kept.

Results

Statistics of usage data between CSB and DAKD

In Table 1, it showed that users preferred to download CSB articles on CNKI than its official site and view full-text articles more than downloading them on CSB official site. Conversely, users preferred to download DAKD articles on its official site than CNKI and download full-text articles more than viewing them on DAKD official site.

After visiting the official websites of CSB and DAKD, it was found that the differences of websites’ information architecture maybe the main cause to the opposite user preference. On CSB site, the easiest way to read each article is to click the title. After you click the title of each paper, the default link is the full-text html page. But on DAKD site, you can directly click any link (abstract, full-text in HTML or PDF format) you want at first glance in a page. In other
words, CBS site mainly follows “progressive rule” and DAKD site follows “parallel rule”. They revealed user preference of OA journals in a different way. Wang et al. (2014a) proposed that PDF tended to be the preferred format if researchers wanted to print the article or just save in hard discs for later study. User preference on DAKD, the “parallel rule”-based site, confirmed the viewpoints above.

As to “CNKI Download” data, it proved its popularity in China. Because CNKI is a non-OA platform and has a time delay in indexing full-text articles, but its average downloads were more than CSB and slightly less than DAKD.

Correlation analysis of usage data between CSB and DAKD

In Table 2 and 3, Spearman’s correlation coefficient among different usage data in the same journal were investigated. For CSB and DAKD, there was only significant correlation between full-text HTML view and PDF download data in CSB site. Other usage data showed no correlation with each other. It was found that usually most of the downloads take place in the first 2 years after publication (Schlogl et al. 2014). Maybe the datasets were mainly range from January 2016 to December 2016, the current usage data were not accumulated enough to fully reveal their correlations. As to significant correlation between full-text HTML view and PDF download data from CSB site, it further revealed the effects of “progressive rule”, the more full-text views, the probably more full-text downloads.

*Distribution of accumulated monthly usage*

The Figure 1, 2 and 3 depicted the accumulated monthly usage distribution (full-text view, pdf download and abstract view) of articles published in CSB and DAKD respectively. Each curve represented one paper and the starting point of each curve represented its published month. The red lines represented most viewed and downloaded articles. For most papers, the growth of accumulated usage showed slowly upward trend after the initial rapid growth period. Only a few papers continued to represent a new jump after the initial rapid growth. Among the most viewed and downloaded articles (denoted by red lines), most of them were published in earlier months than later months. The reason was obvious that articles published in earlier months complete more month accumulations than later months. But Attention should be paid to the most viewed and downloaded articles in later months because after several months they might receive more views and downloads. Besides, Figure 1, 2 and 3 showed the effects of websites’ information architecture on usage pattern between CSB and DAKD in the perspective of time series.

![Figure 1 Distribution of accumulated monthly HTML view between CSB and DAKD](image1)

![Figure 2 Distribution of accumulated monthly PDF download between CSB and DAKD](image2)
Figure 3 Distribution of accumulated monthly Abstract view between CSB and DAKD

Average usage distribution in the month of pagination

To understand the trends both prior and posterior to the pagination month, we aligned the usage data of articles with respect to their respective pagination months. Figure 4 showed the average usage distribution of articles with respect to pagination month for both CSB and DAKD. It depicted that usage data of most articles was at their peak around pagination month and at the bottom at very earlier or later months. Also, it can be observed that in both journals the average usage increases rapidly in the month of pagination except “DAKD PDF download” and “DAKD Abstract view”. After tracing the details of “DAKD PDF download” data, it was found that DAKD usually published its papers on 25th of each month. Obviously, usage data of five or six days in the month of pagination were usually less than the following whole month. As to “DAKD Abstract view” data, maybe users preferred to read newly published full-text articles than abstracts for OA journals.

Moreover, it showed that even articles were published online as soon as they were peer reviewed, but they did not get the attention of the community unless they were assigned to an issue. This finding was in accordance with Wang et al. (2014b) and Khan & Younas (2017), where authors found a rise in average usage data of new “issued” articles as compared to early access articles. The authors suggested that this might be due to the fact that publishers send email alerts to their subscribers which ultimately lead to more attention to newly issued articles. This reason seemed to be true in the case of CSB and DAKD. It is interesting that both Chinese journals also send alerts by journal “WeChat Subscription”, a popular public platform for any person or organization to promote themselves in China. Journal “WeChat Subscription” alerts maybe another way to attract their subscribers to newly issued articles.

Besides, the average usage data in both journals overall started to decline after pagination month and then continued to sustain a steady level for several months. This finding was also in accordance with Khan & Younas (2017), where authors suggested that alerts services might be the cause of growth in downloads in pagination month and its subsequent month. Another reason might be that users consider pagination as a kind of quality attribute that articles are fully reviewed and edited.
Conclusion and discussion

In this study, we analyzed the usage data of two Chinese OA journals in the field of multidiscipline and library and information science respectively. It was proved that the websites' information architecture affected the usage pattern. “Progressive rule”-based site guides users to view full-text articles more than download them and “parallel rule”-based site guides users to download full-text articles more than view them.

Also, for CSB and DAKD, there was only significant correlation between full-text HTML view and PDF download data from CSB site. Other usage data showed no correlation with each other. The results might be caused by limited time span of usage data accumulated from 3 to 15 months. But the significant correlation between full-text HTML view and PDF download data from CSB site also revealed the effects of “progressive rule”, the more full-text views, the
probably more full-text downloads. The effects of websites’ information architecture on usage pattern between CSB and DAKD were further confirmed in the perspective of time series analysis.

Finally, it depicted that usage data of most articles was at their peak around pagination month and at the bottom at very earlier or later months. It also showed that articles published online as soon as they were peer reviewed did not get the attention of the community unless they were assigned to an issue. Besides, the average usage data in both journals overall started to decline after pagination month and then continued to sustain a steady level for several months.

There are some limitations in this study. Only 2 journals in the field of multidiscipline and library and information science respectively were investigated, therefore, the conclusions about the usage pattern might be different in other journals or fields, which needed further experiments. Also, the usage data in the study has a limited accumulation period of 3-15 months. A long-term dataset should be tracked and investigated to support the conclusions.

Last but not least, this study focused on Chinese journals. Compared with previous research on international journals, the study is local and relatively limited. Although these limitations exist, we hope that this first try to explore the usage pattern of Chinese journals would provide a new perspective to promote the research on usage metrics.

Abstract

Academic article can reflect the performance of science research. It is necessary to learn the research progress of library and information science (LIS) from the perspective of English articles. This paper regards the articles written by Chinese scholars published during the period from 2001 to 2015 in Web of Science Core Collection as research object, and explores the research progress of LIS from three aspects, which include an overview of Chinese and world articles published in LIS, the most influential institutions and the main research contents. The performance of Chinese scholars in LIS has been enhanced in terms of both quantity and participation in the world. The threshold of the most influential institutions is gradually increased. Besides, the most influential institutions in LIS in China have shifted from Hong Kong to Chinese Mainland. Information retrieval, digital libraries, information systems, data mining, knowledge management and etc. can be considered as classic research contents in LIS. This paper provides the research progress of library and information science in China from three aspects.

Conference Topic

Mapping and visualization; Social network analysis

Introduction

Talent is an important guarantee for the sustained and healthy development of the national economy and society. In recent years, the Chinese government pays attention to the development of education and the cultivation of talents. In 2015, the State Council of China issued an Overall plan: Promoting the Construction of World-class Universities and Disciplines to improve the level of educational development, enhance the core competitiveness, and lay the foundation for long-term development. Library and information science plays an increasingly important role in the human production and life. The future development of Library and information science is particularly important. Considering the growing importance of library and information science, this study seeks to discover the research progress of library and information science in China from the perspective of English articles to offer reference for leaders and policymakers to make policy for scientific development of library and information science, and help Chinese scholars know the current international research fronts. The study is organized as follows: the first section is research background, the purpose and layout of this article. The second section is the status quo of research, which include the progress of LIS education and research. The third section presents data sources and
methodology. In the fourth section, the results are presented from three aspects, which contain an overview of Chinese and world articles published in LIS, the most influential institutions and the main research contents. Finally, it is discussion and conclusion.

The status quo of research
Many Chinese scholars have done researches on the process of library and information science, and have achieved fruitful results.

Progress of LIS education
Based on the actual materials provided by 24 educational institutions, Zhan (2000) analyzed and summarized the achievement and progress in LIS education, and pointed out the existing problems in Chinese LIS education. Wu and Yu (2015) reviewed the development of LIS educational idea, investigated and analyzed the current state and development trends of LIS education in recent five years. The results indicated that the studies mainly centered on the aspects such as curriculum reform, teaching methods transformation and education objects diversity. Empirical methods were widely used, and research topics were various. Besides, they thought the LIS education in China should emphasize the multi-disciplinary and international collaboration and pay attention to the relationships between people, information and technologies.

Progress of LIS research
Li (2012) took the National Planning Office of Philosophy and Social Science Projects as sample to analyze the hotspots, structures and characters of the research progress with keywords frequency analysis and co-words analysis to reveal the periodical changes in the library and information science research in China and to provide decision-making and reference information for the selection of research thesis, project establishment and educational program planning. Liu et al. (2014) reviewed the research progress of library and information science in China from 2010 to 2013 from four aspects, which included theoretical and librarianship research, information organization and retrieval, metrics and journal evaluation, and historical research of library science. The speculative research had been decreasing gradually, whereas LIS scholars were increasingly focusing on empirical studies on specific research questions resulted from LIS practices or misunderstanding of LIS thoughts. To enhance discipline status and influence of LIS, scholars needed to broaden academic horizons and pay more attention to the universal research questions in the interest of the whole society.

The existing researches in China are mostly based on educational institutions or articles published in Chinese. With the development and progress of Chinese education, institutions and Chinese government pay more attention to the international influence. Under this background, Chinese scholars began to pay attention to English articles, especially high impact articles. Therefore, it is necessary to reveal the research process of library and information science in China from the perspective of English article.

Data and methodology
Data sources
Web of Science Core Collection provides researchers, administrators, faculty, and students with quick, powerful access to the world's leading citation databases. Authoritative, multidisciplinary content covers over 12,000 of the highest impact journals worldwide—including open access journals—and over 160,000 conference proceedings. It'll find current and retrospective coverage in the sciences, social sciences, arts, and humanities, with coverage dating back to 1900 (Thomson, 2017).

The research papers from the field of library and information science are the measurement data in this study. In Web of Science Core Collection, “Advanced Research” was selected, the retrieval items were AD=(Peoples R China OR Taiwan OR Hong Kong OR Macao) AND WC=(INFORMATION SCIENCE AND LIBRARY SCIENCE), document types was article, timespan was 2001-2015, and indexes were SCI-EXPANDED, SSCI, A&HCI, CPCI-S, CPCI-SSH, ESCI, CCR-EXPANDED and IC. The date of data collection was March 21, 2017. The resultant dataset contains a total of 3,407 records.

Methodology
The main methods or algorithms used in this study are as followed:
Co-occurrence analysis is an important method in LIS. The word co-occurrences reflect the network of conceptual relations from the viewpoint of scientists and engineers active in the field. And the co-word frequency array is used to construct a co-word map that presents the intellectual content of a field (Tijssen and Van Raan, 1994). Now many researches in LIS use this method to explore the research trend of a field. For example, Xu et al. (2016) used co-occurrence analysis to explore interdisciplinary topics of information science.
Science mapping aims to externalize the big picture of science. Its origin can be easily traced back to the pioneering work of Eugene Garfield on historographics of citation, Belver Griffith and Henry Small on document co-citation analysis, and Howard White on author co-citation analysis (Chen, 2013).
In 2002, the Girvan–Newman algorithm proposed by Michelle Girvan and Mark Newman is a hierarchical method used to detect communities in complex systems (Girvan and Newman, 2002). The Girvan–Newman algorithm detects communities by progressively removing edges from the original network. The connected components of the remaining network are the communities. Instead of trying to construct a measure that tells us which edges are the most central to communities, the Girvan–Newman algorithm focuses on edges that are most likely "between" communities. In this study, the Girvan–Newman algorithm is used to cluster the high-frequency keywords, which lay the foundation to discover and interpret research contents in LIS.

Results
The main results are presented in three sections: an overview of Chinese and world articles published in LIS, the most influential institutions and the main research contents.
The growth of LIS articles

Table 1 presents the annual number of this selective set of articles. In 2001, there were 2,315 articles published in LIS. Among them, only 70 (7.60%) articles were published by Chinese scholars. However, in 2015, there were 4,537 articles published in LIS. Among them, 517 (11.40%) articles were published by Chinese scholars. From the above two sets of data, it can be noted that the performance of Chinese scholars in LIS has been enhanced: not only did the quantity increase but also the country’s relative participation in the world from 7.60% in 2001 to 11.40% in 2015. And, more importantly, in the later years, Chinese original articles display a stronger growth rate (7.39-folds) than that of the world (1.96-folds).

To better understanding Chinese performance, a correlation analysis was developed using time and total number of articles as variables. The Pearson coefficient was applied together with coefficient of determination, (r^2) and t test (t). The results indicate r^2 = 95.5%. In other words, 95.5% of the observed increased can be explained by the variable time. The t test (p value < 0.01) indicates that total articles and year of articles are statistically correlated.

The most influential institutions

In this study, the timespan (2001-2015) is divided into 5 time slices, i.e. 2001-2003, 2004-2006, 2007-2008, 2009-2012 and 2013-2015. The knowledge maps of institution network based on time slices are drawn by CiteSpaceIII software. As can be seen from in Figure 1, more and more institutions are involved in the research of Chinese LIS: in
2001-2003, the number of institutions involved in the research of Chinese LIS is 148; however, in 2013-2015, it is up to 664, increased 4.49-folds compared with the number in 2001-2003. Unfortunately, the density of knowledge map has decreased: in 2001-2003, it is 0.0071; however, in 2013-2015, it dips to 0.0015. Therefore, the collaboration and exchange among institutions involved in the research of Chinese LIS should be strengthened in the future.

The most influential institutions in the Chinese LIS are defined as the rank top 5% in each time slice. Table 2 lists parts of most influential institutions with numbers of articles. It can be learn that similar to the number of institutions, more and more institutions become the most influential institutions in the research of Chinese LIS. More importantly, the threshold of the most influential institutions is gradually increased from 9 in the period of 2001 to 2003 to 14 in the period of 2013 to 2015, which indicates that the research of Chinese LIS is always in progress..

Figure 1 Knowledge maps of institution network based on time slices

The most influential institutions in the Chinese LIS are defined as the rank top 5% in each time slice. Table 2 lists parts of most influential institutions with numbers of articles. It can be learn that similar to the number of institutions, more and more institutions become the most influential institutions in the research of Chinese LIS. More importantly, the threshold of the most influential institutions is gradually increased from 9 in the period of 2001 to 2003 to 14 in the period of 2013 to 2015, which indicates that the research of Chinese LIS is always in progress.
Taiwan Univ (29), Wuhan Univ (25), Natl Cheng Kung Univ (18), Natl Chengchi Univ (18), Univ Hong Kong (18), Fudan Univ (16), other 9 universities, etc

Natl Taiwan Univ (58), Wuhan Univ (54), City Univ Hong Kong (45), Chinese Acad Sci (40), Hong Kong Polytech Univ (33), Zhejiang Univ (27), Natl Cent Univ (24), Fudan Univ (23), Natl Cheng Kung Univ (21), Univ Hong Kong (20), other 13 universities, etc.

Wuhan Univ (113), Chinese Acad Sci (61), City Univ Hong Kong (59), Natl Taiwan Univ (57), Nanjing Univ (41), Dalian Univ Technol (32), Peking Univ (31), Zhejiang Univ (31), Natl Cent Univ (30), Tsinghua Univ (29), other 26 universities, etc.

For further describing the evolution process of most influential institutions, this study only selects and compares the top 9 of institutions in each time slice. The stacked column of institution based on time slices is drawn (Shown in Figure 2).

Compared with Table 2, it is easy to determine the time slices that most influential institutions are involved in based on the color of stacked column. As can be seen from Figure 2, among 19 institutions, there are only 2 institutions (City Univ Hong Kong and Natl Taiwan Univ) ranking in top 9 in each time slice. Dalian Univ Technol and Zhejiang Univ from Chinese Mainland firstly rank in top 9 during the period from 2013 to 2015. The influence of Tsing Hua Univ has declined in the research of Chinese LIS. During the period from 2001 to 2003, in the top 9 most influential institutions, most institutions come from Hong Kong; however, during the period from 2013 to 2015, most institutions come from Chinese Mainland. What’s more, among 4 institutions that publish more than 100 articles during the period from 2001 to 2015, two institutions (Wuhan Univ (192) and Chinese Acad Sci (119)) come from Chinese Mainland, however only one institution (City Univ Hong Kong (187)) does come from Hong Kong. In summary, those reflect that the most influential institutions in LIS in China have shifted from Hong Kong to Chinese Mainland.

Figure 2 Stacked column of institution based on time slices

The main research contents
The co-occurrence network of high-frequency keywords in articles can provide an effective way to identify research contents. According to 5 time slices, this paper generates five knowledge maps. The drawing process is as follows: first, use the matrix analysis function provided by the Thomson Data Analyzer (TDA) to generate the co-occurrence max of high-frequency keywords (about top 5% in each time slice). Second, adopt NetDraw to draw the knowledge map of high-frequency keywords. Third, use the GN algorithm in NetDraw to divide the network into clusters. And finally, the main research contents of each time slice are interpreted and decided.

In five knowledge maps, we can determine which nodes are in the cluster based on either the shape or the color of nodes.

The analysis of LIS in 2001-2003

As can be seen in Figure 3, the co-occurrence network of high-frequency keywords occurring in 2001-2003 can be divided into nine clusters. The main research contents of Chinese LIS during the period of 2001 to 2003 can be summarized as information retrieval, digital libraries, electronic commerce, education, information technology, data mining, information systems, telecommunications policy, information management and etc. In this period, Chinese scholars focusing on the acquisition, management and application of data, information and knowledge.

![Figure 3 Knowledge map of high-frequency keywords in 2001-2003](image)

The analysis of LIS in 2004-2006

As can be seen in Figure 4, the co-occurrence network of high-frequency keywords occurring in 2004-2006 can be divided into five clusters. Therefore, during the period of 2004 to 2006, the main research contents of Chinese LIS can be summarized as knowledge management, digital library, information technology, information retrieval, electronic commerce, ontology, e-government, user satisfaction, decision support and etc. In this period, while paying continuously attention to research of the acquisition,
management and application of data, information and knowledge, Chinese scholars focus on the research of user behaviour.

Figure 4 Knowledge map of high-frequency keywords in 2004-2006

The analysis of LIS in 2007-2009

As can be seen in Figure 5, the co-occurrence network of high-frequency keywords occurring in 2007-2009 can be divided into ten clusters. Therefore, during the period of 2007 to 2009, the main research contents of Chinese LIS can be summarized as digital library, information retrieval, knowledge management, customer satisfaction, information service, innovation, data mining, electronic commerce, consumer behavior, government, virtual community, artificial intelligence and etc. In this period, virtual community and artificial intelligence become new focuses of Chinese scholars.

Figure 5 Knowledge map of high-frequency keywords in 2007-2009
The analysis of LIS in 2010-2012

As can be seen in Figure 6, the co-occurrence network of high-frequency keywords occurring in 2010-2012 can be divided into nine clusters. Therefore, during the period of 2010 to 2012, the main research contents of Chinese LIS can be summarized as knowledge management, social network, digital libraries, model, information services, metric, e-government, patent, customer satisfaction and etc. In this period, Chinese scholars focusing on the research of measurement and evaluation, patents research are emerging.

The analysis of LIS in 2013-2015

As can be seen in Figure 7, the co-occurrence network of high-frequency keywords occurring in 2013-2015 can be divided into eight clusters. The main research contents of Chinese LIS can be summarized as metric, knowledge management, collaboration issue, research trend, big data, social media, satisfaction, digital library, e-commerce, virtual community, information quality, service quality, patent, information retrieval and etc. In this period, Chinese scholars focusing on the research of big data and social media.
Figure 7 Knowledge map of high-frequency keywords in 2013-2015(Threshold=2)

The evolution of research contents in LIS

Compared the research contents in five time slices, it is not difficult to find that the size of high-frequency keyword in a cluster becomes bigger with times. In other words, the results of research contents in the cluster are more and more difficult to distinguish. We also learn that with the continuous development and progress of science and technology, the research contents in LIS are highly integrated. Information retrieval, digital libraries, electronic commerce, information technology, information systems, data mining, knowledge management and etc., which appear both in five time slices, can be considered as classic research contents in Chinese LIS. Besides, Chinese scholars in LIS have new concerned research contents in each time slice. For examples, the research of user satisfaction and behavior shows that Chinese scholars begin to pay attention to the humanity factors and emphasize the core value concept of "humanity-oriented". With the continuous development and progress of science and technology, our society has entered the era of web2.0 and big data. The research contents of virtual community and social media in LIS have become new focuses of Chinese scholars. Of course, big data has become an important research topic. The 4V’s of big data (Gupta, Gupta and Mohania, 2012) – volume, velocity, variety and veracity—have caused people's thinking. Therefore, advanced kind of logical and physical storage structures, advanced kind of heterogeneous data structures, new mathematical theories and new models of big data are needed in the present day (Biswas,
Besides, the useful information and knowledge has become the focus of people's measurement and evaluation. In totally, the new research contents in Chinese LIS closely follows the development of science and technology, reflecting the discipline of LIS are getting opening.

Conclusion and discussion

In this study, the English articles in LIS written by Chinese scholars in Web of Science Core Collection are regarded as research object. From three aspects, this paper studies the research progress of library and information science. An overview of Chinese and world articles published in LIS, finding the performance of Chinese scholars in LIS has been enhanced: not only does the quantity increase, but also the country’s relative participation is strengthened in the world. In the research of the most influential institutions knowledge maps finding that there are more and more institutions participating in the research of library and information science. More importantly, the threshold of the most influential institutions is gradually increased. This further indicates that the research of Chinese LIS is always in a process of development and progress. We also learn that the most influential institutions in LIS in China have shifted from Hong Kong to Chinese Mainland. This reflects the progress of education in LIS in Chinese Mainland. Unfortunately, the density of knowledge map has decreased. Therefore, the collaboration and exchange among institutions involved in the research of Chinese LIS should be strengthened in the future. Despite its limitation (such as the results of research contents in the cluster are more and more difficult to distinguish with times), information retrieval, digital libraries, electronic commerce, information technology, information systems, data mining, knowledge management and etc. can be considered as classic research contents in LIS. This reflects the discipline nature of library and information science -- a continuously developmental and opening discipline. In the future, Chinese scholars should pay attention to both classical research content and new research content, and strengthen the international collaboration to increase the international influence of Chinese library and information science.

Abstract
The purpose of this paper is to explore the differences in distribution of disciplines of the National Natural Science Award (NNSA) in terms of year, age and collaboration, and further discuss the causes of these differences. Using the awards data published from the website of the National Office of Science and Technology Award Office, a scientometrics analysis was conducted to evaluate disciplinary differences. Through social network analysis to demonstrate the situation of collaboration. Results show that there are differences in the growth trend of the disciplines of the awards, applied disciplines grow faster. There is no significant difference between the basic and applied disciplines in terms of researchers’ age. The analysis of collaborative reveal that the collaboration of applied disciplines is more common, the number of partners and institutions have obvious advantages. The geographical distribution of the researchers’ institution also has a great effect on collaboration, the eastern part of China is mainly focused on basic disciplines, applied disciplines in South and North China. This paper intends to figure out the future research trends, and promote the disciplines construction in China's natural science field.

1 Introduction
With the rapid development of human society, countries are not only competing in economic, military, and cultural fields. Countries around the world have established various scientific incentives to encourage scientific researchers to create, and promote the development of basic research. China also invested a lot of funds to carry out research in the field of natural sciences (Feng and Pei, 2011). The most influential is the Nobel Prize, which granted to people who make a significant contribution to the world, especially in the field of natural science (Seechurn et al., 2012). In addition, there are Abel Prize in mathematics, Wolf Prize in physics, Turing Award in computer science etc (Socrates, 2015; Misa, 2015).
People's Republic of China State Council issued Regulations on National Awards for science and technology in order to reward citizens and organizations that have made outstanding contributions to the advancement of science and technology in May 1999, and set up five national science and technology awards in 2000. These five awards are the Highest National Science and Technology Award, the National Natural Science Award (NNSA), the State Technological Invention Award, the National Science and Technology Progress Award and the International Science and Technology Cooperation Award. The NNSA is granted to citizens who make a major scientific discovery and clarify the natural phenomena, characteristics and laws in basic research and applied basic research. There are three conditions for this scientific discovery: (1) not yet discovered or elucidated, (2) has great scientific value, (3) has been recognized by natural science communities both at home and abroad. It represents China's important contribution to the study of the world's natural sciences. Therefore, analysis of the NNSA is of great significance to the understanding of the current situation and trends in the field of Natural Science in China.

This paper analyzes the disciplinary differences through disciplines distribution of the awards each year, age distribution of researchers of different disciplines and the distribution of the collaboration in different disciplines. Through these differences, the present situation and development trend of China's research in the field of natural science are described.

2 Related research

At present, the study of Natural Science in China is mainly in the analysis of the National Natural Science Foundation of China, and lack of relevant research on the NNSA. Scientometric research on the award is very helpful to understand the potential information associated with the award. Charlton (2007) using a combined metric of Nobel prizes, Fields medals, Lasker awards and Turing awards to find best nations and institutions for revolutionary science. Some researchers analyze the institutions, collaborations and citation data of Nobel prize winners (Schlagberger et al., 2016; Chan et al., 2015; Harzing, 2013). These studies all analyzed the winners of Nobel Prize, so the analysis of the attributes of the winners is very important. Above all, the influence of age on creativity and productivity of scientific researchers is obvious (Sugimoto et al., 2016). For researchers, with the increase of age, there are many factors affect their research work. In the field of natural science, the results of the researchers are inversely proportional to the age (Bonaccorsi and Daraio, 2003). In addition, collaborative research has become the main way to solve the problem and promote the disciplinary development. The researchers can reflect the collaboration situation of the collaborative project, and collaborative researchers will continue to cooperate in depth research. The analysis of collaborative research can be carried out from three perspectives, researchers, institutions and regions (Zhang et al., 2012). Collaboration institutions are familiar with approaches and methodologies (Cummings and Kiesler, 2008), the probability of these institutions to work together again and produce new results is higher. In recent years, Chinese government sponsored a large amount of funds to promote scientific research institutions to deepen collaboration (Zhai et al., 2014).

Basic research is an important part of scientific research (Henard and McFadyen, 2005). The development of disciplines can not be separated from the basic research. The US government points out that it is necessary to maintain a leading position in all scientific
knowledge, and to strengthen the link between basic research and national goals in 1994 (Abelson, 1994). Human knowledge has been applied and verified, further development to the scientific level and form the knowledge system. The knowledge system continues to develop and evolve, and is divided into disciplines according to some common characteristics. There are significant differences in formation mechanism, research object, research methods, application areas in different disciplines. Some researchers have explored the phenomenon of disciplinary differences in scientific research behavior (Siemens et al., 2014; Weller and Monroe-Gulick, 2014; Thelwall and Pardeep, 2016). Some researchers have explored the phenomenon of disciplinary differences in scientific research results (Kalichman et al., 2015; Pull et al., 2016). Gazni and Didegah (2016) examined the association between author bibliographic coupling strength and citation exchange in different disciplines. Therefore, combine discipline difference with scientometrics has become a hot research topic.

3 Data and methods
3.1 Data collection
The data collected from the website of the National Science and Technology Award Office which announced the NNSA from 2000 to 2016. By the statistics, the NNSA has a total of 563 awards. In 2002, 2003, 2006, 2009, 2013, 2014, 2015 and 2016 have one first award, the others are second awards. Figure 1 shows the overall situation of the number of awards in each year. It can be seen that as time goes by, although the number of awards is different each year, but the number of the situation showed a gradual increase trend.

**Figure 1 The number of awards each year**

These awards belong to 23 disciplines, Table 1 classifies this 23 disciplines according to the disciplinary code in evaluation of science and technology award of China National Standard. In addition, these disciplines can be divided into basic disciplines and applied disciplines for the holistic analysis.

3.2 Analysis Methods

The number of awards and disciplines, the physiological age and occupational age of the researchers, regional and institutional distribution were all analyzed by Microsoft Excel 2010. Collaboration frequency of Research institutions and regional were conducted using BibExcel 1.0.0.0 (Liu and Gui, 2016). Input the data to Microsoft Word 2010 according to BibExcel format requirements, counted the frequency of collaboration and generated the co-occurrence matrix. The co-occurrence network graphics were produced by Pajek64 4.10 (Leydesdorff and Schank, 2008), and combined with the map of China by Coreldraw x7. In this paper, only the primary researcher of the awards was considered for the researcher's age (Butler, 2001), that the primary researcher's contribution was greatest. Women account for only 5% of winners' gender, therefore, this article does not analyze the gender characteristics. Some awards are comprehensive, may belong to different disciplines, but there were only classified according to the disciplinary code in this article. In addition, some researchers belong to different research institutions, but they need to use the resources of different institutions in their research and, therefore, classified this situation as institutional collaboration. In the analysis of regional collaboration, only considered the collaboration between different regions.

4 Results

4.1 The distribution of disciplinary differences in awards

In China, NNSA is the highest prize in the field of basic research, and the award has no quantitative limitation for each disciplines at the time of application, the number of awards in various disciplines represents China's comprehensive plan for disciplines development.
Figure 2 The number of awards for high frequency disciplines

Analysis of the distribution of disciplinary differences in awards can reflect the advantages and development trends of the natural sciences. Figure 2 shows the number of awards for high frequency disciplines. First, Chemistry accounted for the largest proportion, several areas of China's cutting-edge research in the field of chemistry have a high level in the world. The proportion of Biology and Material Science are more than 10%. The proportion of basic disciplines is 54.71%, which shows that the research focus in the field of natural science in China is on these aspects. Second, Mathematics, Physics, Earth Science, Basic Medicine, Electronics and Communications Technology are all more than the average level of 4.35%, indicating that China's research on these disciplines is also more attention. In addition, the awards projects also include disciplines with Chinese characteristics, such as Traditional Chinese Medicine and Pharmacy, Civil Engineering and Construction, Water Conservancy Engineering.

Figure 3 The number of awards in basic disciplines and applied disciplines

Figure 3 shows the annual change trend of number of awards in basic disciplines and applied disciplines. Before 2013, the number of basic disciplines are more than applied disciplines, except for 2006. However, the growth trend of applied disciplines is relatively fast, and gradually narrowing the gap with basic subjects disciplines, in 2013 and 2014, both have the same number. Since then the number of awards of applied disciplines more than basic disciplines. China gradually transforms the ideas of discipline development to promoting transformation of basic theory and accelerate the development of applied disciplines to adapt to the international trend of vigorously developing new disciplines. In general, the number of awards for basic disciplines and applied disciplines has a growing trend. This is closely related to China's investment in the Natural Science Foundation, from China National Natural Science Foundation was set up when the annual investment of 80 million yuan, to the current 24.8 billion, 30 years to enhance the 300 times. At the same time, with the improvement of reward system and rating requirements, in order to ensure the quality and level of the project, the number of awards in recent years has slowed down.

4.2 The age distribution and disciplinary differences of the researchers

4.2.1 Annual distribution of age of researchers

The inherent law of science are very complicated, from quantitative to qualitative leap
requires certain knowledge accumulation. It is particularly for scientific researchers’ work. The researchers won the awards in different time. According to the previous work, this paper collects the physiological age and occupational age of researchers when they win awards, and combines with the disciplines to analysis differences. Physiological age refers to the age from birth to win the award, occupational age refers to the age from researchers started research work or received a Ph. D to win the award. Three researchers have passed away when they were won the award, not included in Statistics. The average age of the researchers of the year is shown in Figure 4.

![Figure 4 Average physiological age and occupational age of the researchers per year](image)

It can be seen that the trend of physiological age and occupational age changes is basically the same, which are older in the early time, and maintain a slow steady decrease after the first three years of rapid reduction. This trend reflects Chinese researchers become younger, especially in recent years. The podium is no longer belongs to those elderly people with gray hair, there are more young faces, and give the vitality to scientific research of China.

4.2.2 The physiological age and the disciplinary difference

The physiological age of 548 researchers can be queried. The youngest researcher is 38 years old, and the oldest researcher is 91. There are 20 researchers win awards at the age from 35 to 40, and 22 after the age of 76. A total of 333 people at the age between 41 to 55 years old, accounting for 60.8% of the total number. Previous research found that 80% of the researchers completed their studies before the age of 50 in the original scientific research (Cole, 1979). Therefore, the age of the winners of NNSA is generally high. It is inseparable from the history of China's development. 28.3% of the researchers were born before the founding of a new country. During that period of time the economic capacity was poor in China, and caused some researchers were forced to make a living and had to postpone the time to carry out research work.

By analyzing the researchers’ physiological age of each disciplines, can reflect the disciplinary differences in age of the researchers. In Figure 5, the researchers’ physiological age of Mechanical Engineering, Civil Engineering and Construction, Pasturage and Veterinary Science, Environmental Science Technology and Resources Science and Technology are relatively high, of Astronomy, Water Conservancy Engineering, Information and Systems Science Related Engineering and Technology, Basic Medicine are relatively low, the remaining disciplines are in the range of 4 years. The average physical age of basic disciplines
is 54.8, and the average physical age of applied disciplines is 53.9, so researchers of applied disciplines are younger at the time of awarding.

![Figure 5 The distribution difference of physiological age in disciplines](image)

**4.2.3 The occupational age and the disciplinary difference**

Previous studies have indicated that the occupational age of the researchers can also influence the output of scientific research (Dietz and Bozeman, 2005). There are 543 researchers can be queried. The researchers’ occupational age are in the range of 7 to 65, and 372 people between 16 to 30 years old, accounting for 68.5%.

![Figure 6 The distribution difference of occupational age in disciplines](image)

Combined with the physiological age of the researchers, the age are mainly distributed in younger intervals. In Figure 6, the researchers’ occupational age of Mechanical Engineering, Civil Engineering and Construction, Environmental Science Technology and Resources Science and Technology, are relatively high, of Water Conservancy Engineering, Astronomy, Basic Medicine, Information and Systems Science Related Engineering and Technology, Chemical Engineering, Computer Science Technology are relatively low, the remaining disciplines are in the range of 4 years. The average occupational age of basic disciplines is 28.8, and the average occupational age of applied disciplines is 27.4, so researchers of applied disciplines are younger at the time of awarding, same as the situation of physical age.

**4.3 Collaboration analysis and disciplinary difference**

With the rapid development of science and technology, the communication of disciplines is becoming more and more frequent (Prakasan et al., 2014). Affected by production, economy, society and other factors, the achievement of scientific research is no longer a single and
independent activity, often requires a number of researchers to cooperate with each other (Leclerc and Gagné, 1994). This analysis can reflect the situation of collaborative research and the distribution of research strength in natural science field of China.

### 4.3.1 Number of collaborators and disciplinary differences

By the statistics, the largest number of collaborators is 10. Awards for 5 collaborators are 390, accounting for 69.3% of all awards. There are 51 awards are completed by one researcher, and most of them is done by researcher from Hongkong. There are only 7 awards for more than 6 collaborators. In the collaboration of researchers of Chinese natural science awards, five collaborators are dominant. After statistics, awards of Mathematics and Astronomy are mainly done by a single researcher. The number of researchers in Mechanics is relatively average. Other disciplines’ researchers tend to work with others, and collaboration among 5 researchers is the most common. According to the regulations of the Ministry of Science and Technology of China, the number of applicants for principal researchers is generally no more than 5. So researchers tend to establish a five-researchers group, rational use of the most resources to obtain the best interests. The proportion of basic disciplines' collaboration is 84.64%, applied disciplines is 95.92%. Therefore, the research in the field of applied disciplines needs multiple researchers to complete.

### 4.3.2 Collaboration between institutions and disciplinary differences

Scientific research institutions provide instruments, facilities and working environments for scientific research. In recent years, China has introduced a number of science and technology policy to advocate scientific research institutions to strengthen scientific and technological innovation. Scientific research collaboration can combine different scientific research institutions, support each other and complete the research topic together, and also improve work efficiency. This paper only analyzes the collaboration between institutions, regardless of collaboration within the institution. There are 165 institutions participated in collaboration, among those institutions, Tsinghua University has the highest number of collaboration, which is 23. Most of institutions with higher collaboration frequency were universities.

Using social network analysis to reveal the present situation of collaboration. In Figure 7, each circle represents a institution. The circle with larger area are Peking University, Tsinghua University, Nanjing University, The Hong Kong University of Science and Technology, and so on. It shows that these institutions are in the central position in collaborative network, and have high impact in the field of natural science research. In addition, there are 17 lines with deeper color, it indicates that the collaboration between these institutions is more frequent.
The number of collaborative institutions in different disciplines indicates great different. Due to the small number of awards, Pasturage and Veterinary Science, Information and Systems Science Related Engineering and Technology are completed by one institution. Water Conservancy Engineering are completed by the collaboration between institutions.

The proportion of collaboration of Information Science and Systems Science, Civil Engineering and Construction, Water Conservancy Engineering, Environmental Science Technology and Resources Science and Technology are higher than 50%, and most of them are completed by two institutions. Further more, The proportion of collaboration of applied disciplines (34.12%) is higher than basic disciplines (28.57%). Therefore, the applied disciplines needs more institutions to participate in.

4.3.3 Collaboration between regions and disciplinary differences
In order to explore the key regions of scientific research and collaboration, this paper classify awards base on the local area of the institution, and reflect hot area of China's natural science research.

In Figure 8, the biggest size of circle is Beijing, that participate in the 96 times collaboration, accounted for 45.07% of the total. In addition to universities, there are many institutions of the Chinese Academy of Sciences to participate, and most of the important institutions set up in Beijing. So Beijing is in the absolute core position. The collaboration frequency of HongKong, Shanghai, Nanjing, Guangzhou, Wuhan and Dalian are also relatively more. The line between Beijing and HongKong is widest, because of 18 times collaboration frequency, accounted for 8.45% of the total. The connection between Beijing
and HongKong is very tight, especially in universities. Professors often teach in both places, and there are many excellent researchers to visit each other (Lam and Minghung, 2001). The majority of the awards which belong to Beijing-HongKong are applied disciplines.

Generally, the collaboration of the NNSA has produced cluster effects. The active regions are mainly distributed in the North China (include Beijing, Dalian, Jinan etc.), East China (include Shanghai, Nanjing, Hangzhou etc.) and South China (include Guangzhou, Hongkong, Shenzhen etc.). Collaboration with regional research institutions is more convenient, easier to communicate and reduce the cost of resources. North China and South China are mainly based on applied disciplines, and East China’s basic disciplines slightly more than applied disciplines.

5 Discussion and conclusions
This paper, by means of correlation analysis tools, used of scientometrics methods to explore the related situation of NNSA in China. From the perspective of disciplines, combined with the age of the researchers and collaboration, intended to figure out the future research trends, and promoted disciplines construction and development in China's natural science field. The following conclusions can be obtained in this study.

The number of awards are increasing, and the increasing trend of applied disciplines is more obvious than basic disciplines. The proportion of traditional disciplines is gradually declining, while the emerging applications increase. This trend is closely related to the development of China. Since China's reform and opening up, a large number of basic disciplinary research have been carried out to keep up with the trend of world development. With gradual strengthening of China's economy, the application of computer technology and communication technology is becoming more and more popular, it is urgent for China to carry out further research on these disciplines. Therefore, the development of these emerging disciplines is rapid. At the same time, the development of these emerging disciplines will also promote the progress of traditional disciplines (Schneider, 1982).

The age of researchers showed inverted U-distribution. Indicating that the output of scientific research is mainly concentrated in the younger stage. There is no significant difference between the basic and applied disciplines in terms of researchers’ age. Only in several special areas have some differences. Because of the special background of the researchers, the time their participated in scientific research work were uncertainty. But overall, the age of the winners of NNSA is generally high.

The disciplinary differences of the collaboration are obvious. In the research of the co-researchers, applied disciplines are more inclined to cooperate by a number of researchers. In the research of the co-institutions, applied disciplines are also more inclined to cooperate by a number of institutions. The research of applied disciplines need to combine theory with practice, so it need more collaboration. So Collaboration between institutions become mainstream. In the research of the co-regions, shows three core regions of North China, East China and Southern China. East China is mainly based on basic disciplines, but North China and South China are applied disciplines. There are also core regions of China's economic development. China has accumulated a good economic capacity since the reform and opening up, has promoted the development of scientific research (Shen et al., 2001). At the same time, the development of the economy cannot be separated from the ability of continuous
innovation of scientific research.

Several limitations of this study should be noted. First, in age analysis section, the date of birth of a small part of researchers can not be queried, the time of researchers start research work is also fuzzy in some data, this may affect the results. Second, in discipline classification, there is no consideration of interdisciplinary situation. In addition, due to the lack of collaboration in some disciplines or some regions, may result in deviation due to insufficient data samples. Therefore, further research need to overcome these limitations, consider the work of this paper, establish a common reward analysis system.

Evaluating Effects of World-Class University Program Using Propensity Score Matching: Evidence from China’s Project 211

Ou Yufang
365068580@qq.com
Zhejiang Normal University, Jinhua (China)

Abstract
This study evaluated the effects of China’s Project 211, a key program of China’s world-class university policies, on related variables of funded universities’ research, teaching and service. The effects were measured by examining the frequency of academic paper, monographs, R&D projects, postgraduates, doctoral students, technology transfer contracts and technology transfer income of Project 211 by propensity score matching model. The model results indicated Project 211 had produced a positive effect on funded universities’ variables related to research in generally, greatly increased the quantity of funded universities’ academic paper and scientific research projects, but it was helpless to increase the quantity of funded universities’ academic monographs. Besides, the Project had also caused positive effects on funded universities’ variables related to teaching through increasing the quantity of postgraduates and doctoral candidates; however, it generated negative effects on funded universities’ service variables.

Keywords: world-class university; Project 211; propensity score matching (PSM); program effects

Conference Topic
University policy and institutional rankings

Introduction
Raising the educational and academic status and ranking of universities to that of internationally accepted world-class universities (WCUs) has become the goal of developing as well as developed countries around the globe in recent years. As a result, policymakers in those countries have prioritized building world-class universities that would help their countries obtain a superior position in the global competition (Shin, 2009). Against this backdrop, world-class university programs (WCUPs) were frequently created in some Asian and European countries: Project 211 of China in 1993; Brain Korea 21 program of South Korea in 1999 (Shin, 2009); Center of Excellence program of Japan in 2002 (Yonezawa, 2007); Initiative for Excellence of Germany in 2005 (Hur and Bessey, 2013) and d’excellence initiatives of France in 2010 (Cremonini, Benneworth, Dauncey and Westerheijden, 2013) etc.

Although many of WCUPs are young, having started in the past decade or even more recently, they have impacted participating universities in a significant way (Salmi, 2016). This makes it imperative to assess what effects these WCUPs have produced and draw lessons from recent and ongoing experiences. However, there are at least two challenges, i.e. time and attribution, to measure effects of WCUPs on universities (Salmi, 2016). The time challenge requires a thorough analysis looking at a reasonably large sample of institutions for comparison purposes, either within a given country or across countries, over many years. The attribution challenge requires an in-depth evaluation to judge whether WCUPs rather than other factors caused the positive or negative changes in universities (Salmi, 2016).

Studies on effects of WCUPs are relatively few, if any, because of the above mentioned two challenges (Seong, Popper, Goldman, Evans and Grammich, 2008; Hou, 2012; Hou, Ince and Chiang, 2012; Salmi and Froumin, 2013). As most WCUPs focus on research excellence (Kehm, 2013; Zhu, 2014), thus it is not surprising that a flood of literature has demonstrated that WCUPs can effectively improve targeted universities’ research performance. For instance, Jung Cheol Shin (2009) found the growth of research publications from Korean research universities increased significantly following the implementation of the BK 21 project in 1999. After performing a meta-frontier analysis, Yaisawarng and Ying (2014) found research performance of Project 211 universities is better, on average, than of non-Project 211 universities during the period of 2007-2009. Möller, Schmidt and Hornboutstel (2016) found Excellence Initiative had succeeded in concentrating excellent research and fostering
collaborations between universities and the non-university research sector, but had not caused massive changes on the overall German research system.

Because there is a close link between teaching and research, evaluation studies about WCUPs have been involved in universities’ teaching performance. Hou (2012) found 11 universities funded by WCUP of Taiwan in 2006 had been expected to increase their research and improve teaching quality both. The result was echoed by Schmoch, Fardoun and Mashat (2016), who found that building a WCU and a more focus on research did not imply squeezing out of teaching, because new staffs for research were employed, the quality of teaching was even improved. On the contrary, crowding-out effects and stagnation of university teaching were found in WCUPs (Chang, 2013). Kehm (2012) got a similar research result that the importance of teaching was downgraded after the execution of Excellence Initiative in Germany. Thus, it was no wonder that Jamil Salmi (2016) worried about the risk of harmful effects on teaching and learning quality because of the research emphasis of most WCUPs.

While many scholars thought WCUs should be excellent in their third mission, i.e. society services (Shin, 2012; Montesinos, Carot, Martinez and Mora, 2008), there was lack of research done on the relationship between the achievement of WCUPs and the service delivered by WCUs. WCUs have been encouraged to lose their “sense of territorial identity and with … ties to local and regional public support for … educational, research and civic missions” as they sought global recognition (Christopherson, Gertler and Gray, 2014). Performances of research, teaching and service differentiated WCUs from national-class universities and local-class universities (Shin, 2013). The aim of Project 211 was building high-level national universities by improving their capacity in teaching, research and public service (Liang, Wei and Liang, 2016).

Although previous studies have demonstrated that WCUPs can effectively improve universities’ all kinds of performance, research performance especially, a potential problem in empirical studies on this topic regarding targeted universities is ample selection bias documented in Heckman (2013). More specifically, universities with good prior performance are more inclined to be funded by WCUPs. Consequently, observed improved performance may be driven by other reasons, rather than WCUPs themselves. Besides, as it seemed that there was no comparability between funded universities and non-funded universities, most of those studies only focused on funded universities’ performance rather than compared them with non-funded universities. The reason was that most WCUPs were non-random funded projects, that was to say the performance of universities’ three missions, i.e. teaching, research and service, were better in target universities than in non-target universities before the WCUPs started, and Project 211 in China was one of classic example of such performance. If we still directly compare Project 211 universities with non-Project 211 universities under this non-random condition, the compared results will overestimate the effects caused by Project 211 on the one hand, and compared advantages cannot be judged as caused by the Project or by natural development of universities on the other hand. To solve the sample selection bias problem, propensity score matching (PSM) model is utilized in this study.

In this study, the author measures effects of Project 211 on related variables of funded universities’ research, teaching and service. This study attempts to meet the first challenge by gathering a unique dataset that provides detailed information on related variables of research, teaching and service from a set of 71 Project 211 universities and 171 non-Project 211 universities over 6 years covering three phases of the Project. Besides, this study tries to conquer the second challenge by the application of propensity score matching. The analysis is guided by the research question, i.e. does Project 211 truly improve research, teaching and service in participating universities?
PSM Model Specification

Research Hypothesis

In the present study, Project 211 administrators contracted with funded universities to perform multiple tasks, such as conducting research, teaching classes and serving the public, all of which were valuable to the Project. The research performance-based incentive system was adopted in funded universities to motivate themselves to spend more time and efforts on research, thus enhanced their research productivity, but reduced their opportunistic behaviours, such as spending time on their teaching and service. Besides, previous study proved research and teaching were mutual promotion (Hou, 2012; Schmoch, Fardoun and Mashat, 2016), thus the research hypothesis is proposed as below:

**H1** : Project 211 has produced positive effects on variables related to research and teaching but negative effects on variables related to service of funded universities.

Methodology

As sample selection bias must be controlled just as mentioned above, propensity score matching model developed by Paul R. Rosenbaum and Donald B. Rubin (1983) is chosen in this study. Utilizing observable characteristics (covariates), the model integrates various covariates into one variable (dimensionality reduction), divides samples into treatment group and control group and performs an equilibrium treatment that is near randomized on various confounding factors in non-randomized studies after balancing the distribution of covariates between treatment group and control group to reduce selection bias (Koolwal and Gayatri, 2010). Using this approach, this study can obtain propensity scores (PS), which measure the extent of matching of the treatment group and the control group in multi-dimensions.

In the following, this study will briefly introduce how to calculate PS value, followed by discussions regarding the three matching approaches and the average effect of treatment on the treated (ATT).

PS is defined as “the conditional probability of receiving a treatment given pre-treatment characteristics” by Rosenbaun and Rubin (1983).

\[
\text{PS is defined as} \quad \Pr(D = 1|X) = \frac{e^{\beta X}}{1 + e^{\beta X}}
\]

where \(X\) is the multidimensional vector of independent variables which may affect the propensity of universities to get Project 211 funds, and \(\beta\) is the vector of coefficients. PS is the predicted value of the Logit model.

To estimate PS score, following Dehejia and Wahba (2002) and Becker and Ichino (2002), this study uses the Logit model with the following steps.

This study starts with estimating probabilities using the Logit model,

\[
\Pr(D = 1|X) = \frac{e^{\beta X}}{1 + e^{\beta X}}
\]
Sample and Variables

To prove hypothesis H1, this study chooses 71 Project 211 universities and 171 non-Project 211 universities that were listed in the top 200 in the *Chinese Universities and Discipline Evaluation Consult Report* released by Research Center of Chinese Science and Evaluation (RCCSE) in the past 5 years. Those universities are divided into two groups, i.e. (a) treatment group——71 Project 211 universities, and (b) control group——171 non-Project 211 universities. As Project 211 was launched in 1993 and quitted in 2016, this study should have got 23 years’ data covering each year from 1993 to 2015 as a perfect longitudinal study. However, the actual building of Project 211 consists of three phases, i.e. Phase I (1995-2000), Phase II (2001-2005) and Phase III (2008-2011) (Guo, 2012), in addition, it is indeed unlikely that effects on universities would be significantly with the first few years immediately after the beginning of a WCUP (Salmi, 2013), thus data of 2003, 2004, 2006, 2009, 2011 and 2014 is got to calculate ATTs in accordance with the principles of data availability and random sampling.

In accordance with selection requirements of PSM’s covariates and outcome variables and overall goals and selective criteria of Project 211, this study chooses the following indicators in Table 1 as PSM’s variables to evaluate Project 211’s effects.

<table>
<thead>
<tr>

<tbody>
<tr>
<td><strong>dependent variable</strong></td>
</tr>
<tr>
<td><strong>covariates</strong></td>
</tr>
<tr>
<td><strong>PSM variables</strong></td>
</tr>
<tr>
<td><strong>outcome variables</strong></td>
</tr>
</tbody>
</table>

**Reasons for covariates selection.** The first step in the application of PSM is establishing Logit or Probit model to get PS, which involves in covariates selection, and there are ongoing controversies in the literature as to which variables should be included in the propensity score model. Donald Bruce Rubin and Thomas Neal (1996) thought PSM should incorporate all variables that were related to outcome variables but need not to consider the relationship between dependent variables and outcome variables, while Susan Perkins et al. (2000) proposed to adopt only confounding factors that were related to dependent variables and outcome variables both. This study approves the latter point of view. Therefore, in accordance with Susan Perkins’s view, i.e. covariates should be related to dependent variables and outcome variables both, and the selection criteria on funded universities by Project 211, i.e. own a relatively stable faculty team with high quality; be equipped with advanced level of teaching and research conditions; have a certain number of doctoral programs, national key disciplines
and instruct high-level professional talents; have rich research funds and remarkable research achievements, and make a great contribution to the country with high efficiency in school management; have a significant academic influence at home and abroad; have clear building goals with their own characteristics and guaranteed building funds (National Education Commission, 1993), this study makes building area, library books, teaching and research instrument value, assets value, full-time teacher, teacher with senior title, teacher with secondary title, Yangtze scholar, academicians of the Chinese Academy of Sciences (CAS) and Chinese Academy of Engineering (CAE), doctoral program, national key discipline, technology income and technology expense as PSM’s covariates. The relationship between selection criteria and covariates see the following figure.

Figure 1 the Relationship of Selection Criteria and Covariates

Reasons for research outcome variables selection. The effects of WCUPs on research are difficult to assess, as the outcome of research has a variety of different dimensions. The primary dimensions of research outcome are the performance in terms of publications, provision of doctoral students, contributions to the scientific infrastructure (editorships, leading positions in scientific associations etc.) and the transfer to society (participation in advisory boards, local councils, patent applications etc.) (Schmoch and Schubert, 2009a), among which the publications prove to be a lead indicator (Schmoch and Schubert, 2009b). As academic paper and monograph play a considerable role in publications (Moed and Allg, 2004), and research grants is also a frequent indicator evaluating a university’s research performance (Liefner, 2003; Tammi, 2009), and thus three indicators, i.e. academic paper, monograph and research project of universities are chosen to reflect universities’ research.

Reasons for teaching outcome variables selection. While the components of teaching in universities consists of teachers, measures, students etc., in a broad sense (Wescott, 1978), this study prefers to a narrow sense of teaching that only consists of students, i.e. all kinds of students, including undergraduates, postgraduates, doctoral students and overseas students etc., for evaluation target. Although Project 211 has produced effects on teachers and measures, for instance, Liu, Xianjun (2010) thinks the goal driven by blindly pursuing “world-class”, improper evaluation and assessment system and unscientific teaching management system have affected the perception and disposition of teachers on the relationship between teaching and research. In addition, the measures of teaching must have been influenced by one goal of Project 211 in China’s Tenth Five Plan, i.e. quicken the informatization pace of higher education (State Development Planning Commission, 1995). However, there is no evaluation indicator that directly measures the changes of teachers’ perception or psychology, and thus the effects of those changes are difficult to be assessed. To compensate for this limitation, this study chooses variables related to teachers and measures, i.e. full-time teacher, teacher with senior title,
teacher with secondary title, fixed assets and teaching and research instrument as PSM’s covariates. Besides, considering the teaching goal of Project 211, i.e. make targeted universities become cultivation base of high-level talents in China (State Development Planning Commission, 1995) and many scholars think the higher level of postgraduates and doctoral students be an enhancement in teaching (Schmoch, Fardoun and Mashat, 2016). Thus, this study sets postgraduates and doctoral students as PSM’s teaching outcome variables.

**Reasons for service outcome variables selection.** At present, a consensus on the definition of universities’ service has not been achieved in academic circles. Service has traditionally been mentioned in almost every institution’s mission statement, but less commonly has it been internally and externally clearly defined or fully incentivized (Holland 1997). Weerts and Sandmann (2008) found that institutions tended to frame service as knowledge transfer to the public. Therefore, technology service indicators were chosen as service outcome variables in this study, i.e. technology transfer contract and technology transfer income.

**Empirical Results and Discussion**

*Propensity to be Funded by Project 211*

The first step to perform propensity score matching analysis is estimating PS. PS summarizes several pre-treatment university characteristics of each subject into a single-index, which makes matching subjects on a n-dimensional vector of characteristics feasible for large n. In this study, the study chooses building area, library books, teaching and research instrument value, assets value, full-time teacher, teacher with senior title, teacher with secondary title, Yangtze scholar, academicians of the Chinese Academy of Sciences and Chinese Academy of Engineering, doctoral program, national key discipline and science and technology income as covariates of PSM model. Descriptive statistics of those covariates see the following table.

Note: Considering the lagged effect of policies, 6 years of covariates’ raw data is adopted after Project 211 executed in accordance with the principle of random sampling, i.e. 2003, 2004, 2006, 2009, 2011 and 2014.

In line with previous literature (Lian, Foley and Boylan, 2011), the study estimates the Logit model (3) to get PS. Such a multi-dimensional matching is expected to help the study find the control universities that were capable but not selected to the Project 211. The study estimates model (3) with various specifications, and the results are presented in Table 4. It is shown that a university’s probability funded by Project 211 is significantly positively related to full-time teacher, teacher with secondary title, Yangtze scholar, academician of Chinese Academy of Sciences and Chinese Academy of Engineering, teaching and research instrument, doctoral students, national key discipline and science and technology income, but negatively correlated to building
area and fixed asset. The probability to be built by Project 211 is not significantly related to senior teacher and technology cost.

Pseudo-R²          | 0.302  | 0.297  | 0.288  | 0.282  | 0.271  |
AUC                 | 0.864  | 0.862  | 0.859  | 0.857  | 0.852  |
Observations        | 1666   | 1666   | 1666   | 1666   | 1666   |

Note: ① The dependent variable of Logit model is “wcu”, a discrete variable, equal to 1 if a university is funded by Project 211, and 0 otherwise.
② ***, ** and * represents 1%, 5% and 10% significance level, respectively, with t-values in parentheses.
③ The AUC denotes the area under the ROC curve.

The final goal of Logit Model is to estimate the propensity scores, according to which the study could match Project 211 universities with their control pairs. Obviously, the model specification is an important thing to ensure the validity of the matching procedure. Unfortunately, there is no straightforward criterion to properly specify the Logit model in the literature. The study uses two diagnostic proxies namely pseudo-R² which is widely used in Logit analysis, and the area under the ROC curve (AUC). The reason this study uses AUC is that, the dependent variable, i.e. “wcu”, in the Logit model is a discrete variable (0/1), while the propensity scores (which is the predicted values of the Logit model) is a continuous variable, thus the traditional statistics (such as Pearson correlation coefficient) could not be used to analyse their correlation (Hosmer and Lemeshow, 2013).
In this case, the pseudo-R2’s value is in the range of 0.271–0.302. Comparing Pseudo-R2 and AUC in Table 5, we can see that specification (1) is better than others. Stürmer, Joshi, Glynn, Avorn, Rothman and Schneeweiss (2006) find that, when we use Logit model to get PS, an AUC value larger than 0.8 can be regarded as a good indicator that the model is well specified. In model (1), the AUC is 0.864, well above the value suggested by Stürmer et al. (2006). Therefore, this study uses model (1) as the basic specification to calculate PS, and then compares university performances between Project 211 universities and non-Project 211 universities.

Sample Matching Results
Austin, Grootendorst and Anderson (2007) find that the quantity of matched sample will increase 20% if PSM is reasonable, and the quantity would be reduced and estimated precision of ATT would be decreased otherwise. As the larger of matched sample, the more precise of ATT, while PSM depends on PS to match controlled universities with treatment universities. Therefore, the quality and reasonableness of matching could be determined by the distribution of the PS kernel density function before and after matching (see figure 2) and the nature of covariates (see table 4). PS value on this figure is calculated by the nearest neighbour method.

![Figure 2 Kernel Density before and after Matching](image)

The following discussion is based on the nearest neighbour matching approach. Figure 2 shows the kernel density functions of the treatment group and the control group, based on pre- and post-matching of the two groups, respectively. Prior studies used all universities in the control group to compare with the treatment group, and thus their results were biased. In contrast, the study chooses universities from the control group to match those in the treatment group, based on propensity scores. After matching, as shown in Figure 2, the kernel density functions of the two groups are much closer, indicating that the characteristics of variables in the two groups are similar after matching. Table 4 below further proves significant differences no longer exist between two group’s characteristics after matching, and thus PSM is reasonable and matching quality is good in this study.

Table 4 the Nature of Covariates between Two Groups before and after Matching
Previous empirical research indicated PSM is effective if reduced standard error (%bias) is less than 3% or 5% (Caliendo and Kopeinig, 2008). In this study, most standard errors are less than 5% after matching, which indicates the balance of covariates is good and common support assumption of PSM has been verified. Besides, the results of paired T-test after matching show the difference of each covariates between treatment group and control group is not significant and proves common support assumption has been verified. At finally, LR chi2 is 11.86 and P value is 0.221 exceeding 0 in the table at the end, which implies a university no longer can be judged from covariates characteristics as a Project 211 university or not after matching, and proves PSM’s common support assumption has been satisfied again.

**Analysis on Effects of Project 211**

To prove H1 hypothesis, the study chooses academic paper, monograph and academic project as indicators that measure universities’ research, postgraduates and doctoral candidates as indicators measuring universities’ teaching, and technology transfer contract and technology transfer income as indicators measuring universities’ service. ATTs of Project 211 on outcome variables after calculating PS through Logit model and verifying PSM, see Table 5.

</table>

Note: ****, ** and * represents 1%, 5% and 10% significance level, respectively.

In terms of outcome variables of universities’ research, the above table showed the number of academic paper in treatment group, 1721.79, is greater than in control group after matching, 1521.45; the comparison of academic project shows academic project of treatment group,
988.63, is also greater than that in control group after matching, 880.61; but the ATT of monograph is -0.05 and insignificant (T-value is -0.06), which indicates we cannot judge Project 211 has produced negative or positive effects on monograph. The reason possibly is that the overall context of monograph publications in China is trapped into a vicious circle, i.e. Chinese researchers, facing obstacles of scientific funds, press selection, monograph’s cognition and publication period, have a low intention to publish monograph, which causes printings of monograph are rare but prices are high, and thus the purchasing power of all kinds of libraries is weak. Therefore, Project 211 has produced positive effects on universities’ variables related to research in general, but the effects caused by the Project on monograph are insignificant.

In terms of outcome variables of universities’ teaching, the above table shows the number of postgraduates in treatment group, 3889.57, is greater than that in control group after matching, 2310.69; the comparison of doctoral candidates shows doctoral candidates of treatment group, 714.25, is greater than that in control group after matching, 260.51. This indicates that Project 211 has produces positive effects on Project 211 and non- Project 211 universities both through increasing the quantity of postgraduates and doctoral candidates. This result is greatly possibly caused by one target of Project 211, i.e. make funded universities become the base of high-level teaching (State Development Planning Commission, 1995).

In terms of outcome variables of universities’ service, ATTs of technology transfer contract and technology transfer income are 8.70 and 3449.93 respectively before matching, while -16.57 and -2440.56 respectively after matching, which indicates that Project 211 has produced negative effects on variables related to universities’ service. The possibly reason is that most Project 211 universities are research universities focusing on basic research, while non-Project 211 universities are local universities with orientations of serving the development of their local economy.

In conclusion, the results of PSM show Project 211 has produced positive effects on universities’ variables related to research and teaching, greatly increased funded universities’ academic papers, research grants, postgraduates and doctoral students. However, Project 211 has produced negative effects on variables related to service, i.e. technology transfer contract and income. In a word, Project 211 has produced positive effects on variables related to research and teaching but negative effects on variables related to service in funded universities, and thus Hypothesis H1 to some extent is proved true.

**Conclusion**

The building of a WCU is often commented with deep skepticism, as it is associated with global competition and the pursuit of a superficial gain of reputation, sometimes even hampering a real strengthening of quality (Schmoch, Fardoun and Mashat, 2016). Project 211 of China shows that the decision to become a WCU can be realized with much cautiousness.

This study reveals hypothesis H1 has been proved true. Project 211 in China has produced positive effects on variables related to research, greatly increased funded universities’ academic papers and research grants, which is somewhat consistent with the finding of Yaisawarng and Ying (2014), but is helpless to enhance the quantity of monograph. Although the Project has also produced positive effects on universities’ variables related to teaching, i.e. the quantity of postgraduates and doctoral students, it has produced negative effects on variables related to service, i.e. technology transfer contract and technology transfer income.

This paper contributes to the existing literature in an important way. In term of the overall higher education, time and attribution challenges in WCUPs evaluation (Salmin, 2016) have been solved in a new way. This paper analyses the effects of Project 211 on Project 211 universities and non-Project 211 universities both by PSM which solves attribution challenge. It contributes to the higher education literature by using PSM approach to control for sample selection bias that prior studies in literatures do not control for. In specific, it uses nearest
neighbour matching to identify proper target universities for each of the observations in the sample. Besides, it uses a more recent and extensive data set, covering the period before, at and after of the Project with 6 years of data, which solves time challenge.

The present study has several limitations. Firstly, there are only 71 Project 211 universities in the sample, 2 military medical universities and 39 Project 985 universities that are also funded by Project 211 are excluded from the sample because of data unavailability of the former and weak matching quality of the latter, which would induce the incomplete sample bias. Secondly, as the sample ranges from 2003, 2004, 2007, 2009, 2011 and 2014, which may bias the estimation to some extent. Therefore, further studies should utilize the other proper method, i.e. difference-in-difference model, to evaluate effects caused by Project 985 on 39 universities funded by Project 211 and Project 985 both to compensate for those limitations in the future.

Abstract:
The country of authors of 5.9 million Web of Science (WoS) publications with DOI from the years 2012 to 2015 have been compared with the country of Twitter users tweeting these WoS publications in order to study the main scholarly users of Twitter across 10 different countries. For this purpose, the visibility of country’s publications in the WoS and geographical distribution of Twitter users tweeting WoS publications have been analysed. The aim is to study how do they differ and what are their preference in tweeting their own vs. other country’s publication. The findings show that in general, US and UK with the highest proportion of outputs in the WoS, are among the main users of Twitter as well. Moreover, except for US, users tweet publications affiliated to other country more than those from their own country. Also, similar to WoS, it seems that altmetric providers are not free of international biases in their coverage and collection of metrics. Finally, various possible reasons on why publications from some countries attract more Twitter users than others have been discussed.

Conference Topic
Altmetrics; Twitter users and usage; Geographical distribution; Altmetric.com; Web of Science (WoS)

Introduction:
Sharing and discussing scholarly content on social media platforms and particularly on Twitter has become popular in recent years. With about 20-30% of Scholarly WoS publications mentioned on Twitter (Robinson- García, et al., 2014), this platform is considered to be a prominent source of altmetrics after Mendeley (Haustein et al., 2014). Moreover, mentions of publications on this platform could be interpreted as an ‘early indicator of attention or publicity’ (Haustein et al., 2014). However, tweets have been proven to have a low correlation with citations (Thelwall, et al., 2013; Costas, Zahedi, Wouters, 2015a). This could be an indication that tweets capture a different type of impact in contrast to citations (Bornmann, 2014). Also, its uptake varies across fields (Costas, Zahedi, Wouters, 2015b) and countries (Alperin, 2015).
The study of the different typologies of Twitter users interacting with the publications has been proposed as a way to better understand Twitter-based metrics (Haustein, Bowman, & Costas, 2015). In this paper we follow-up on the idea of studying the interactions between Twitter users and scientific publications. Thus, here we focus on the analysis of the geographic distribution of scholarly Twitter users in contrast with the countries of the authors.
of the scientific publications. Based on the geographic info of Twitter user accounts captured by altmetric.com, the aim of this paper is to study to what extent Twitter users are tweeting papers from their own or different countries. The following main research question is targeted:

- How are countries tweeting WoS publications in relation to their scientific outputs in WoS?

**Data and methodology:**

We have used a dataset of 5,989,022 million Web of Science publications with DOI published between 2012 and 2015. The publications were matched based on their DOIs with the Altmetric.com database (metrics until Jun 2016) and the Twitter accounts (users) mentioning these papers have been extracted. Altmetric.com provided country information of the Twitter accounts. This information has been analysed in order to study how the country of the Twitter users differs from the country of the authors of the tweeted publications. In this study, we focus on 10 different countries such as United States (US), United Kingdom (UK), Canada (CA), China (CN), Iran (IR), Brazil (BR), South Africa (ZA), Spain (ES), The Netherlands (NL) and Australia (AU). The following indicators have been calculated:

**Proportion of twitter users of a country:**

.  .  .

**Proportion of twitted papers of a country:**

.  .  .

**Proportion of tweets of a country:**

30% (n=1,747,021) of analysed publications (with an average of 6.27 tweets per paper) were mentioned at least once on the Twitter platform by the 1,327,643 distinct tweeter users, both with known and unknown country information. Table 1 shows the general overview of the share of WoS publications affiliated to authors and tweeted by users across the 10 selected countries. US, China, and UK are the most dominant countries in terms of producing WoS publications (28%, 15.1%, and 8.5% of 2012-2015 WoS publications respectively). Regarding the country of the Twitter users, 36.58% and 25.57% of all tweeted publications (n=1,746,933) are from the US and UK respectively. Moreover, 20.19%, and 9.35% of all Twitter users tweeting any of the publications under study come from the US and the UK respectively.

Results:

Country distribution of WoS author and Twitter users

Figures 1 and 2 show that the most dominant countries in terms of publications are the US, China, UK, and Germany. According to Figure 1, 28% of WoS publications are affiliated to the US, 11% to China, followed by 6% to UK and less than 5% of publications are affiliated to other countries (Figure 1).

Figure 1. Distribution of country of affiliation of authors of the 2012-2015 WoS publications with DOI

According to Figure 2, for 42% of Twitter accounts no country information is available. For those Twitter users with geographic information available, 20% of users come from the US and about 10% from the UK while other countries have less than 3% of the Twitter users.

Figure 2. Distribution of country of distinct Twitter users of 2012 -2015 WoS with DOI tweeted publications captured by Altemtric.com (NA refers to Twitter account for which the country information is not available by altmetric.com)
Country of Twitter vs. country of authors

Figure 3 shows whether the country of the Twitter users is the same or different from the country of the authors of the tweeted papers (share of tweeting own vs. other country’s publications). In general, papers affiliated by authors from the US are the most tweeted papers by the users from all the 10 selected countries. For example, out of the 1,128 WoS publications tweeted from Iran, papers from the US (46%), the UK (17%), Canada (9%) and Germany (9%) are the most tweeted ones by Iranian tweeters (n=341 Iranian tweeters). Iranian tweeters tweet only 4% of papers from their own country. Brazilian users tweet their own papers in the fifth place after those by US (44%), UK (16%), Germany (8%) and Canada (8%), and their own country (BR,7%). Dutch, Spanish, and South African publications usually are the third group of the most tweeted publications from their own nationals. British, Australian, and Chinese tweeters have the second place in tweeting their own publications after US publications. American Twitter users have the first place in tweeting their own papers (47%), followed by papers affiliated to the UK (12%), Germany (7%), Canada (6%), and China (6%).

![Figure 3. WoS author country (vertical line) vs. Twitter user country (horizontal line)](image)

Figure 4 shows the relationship between the outputs of each country with the share of the Twitter activity coming from the same country (i.e., the proportion of tweeted papers by users from a given country). Regarding the output, 28% of the 2012-2015WoS publications with DOIs (n= 5,989,022) are authored by US and in case of Twitter activity, 36.6% of all tweeted WoS publications (n= 1,746,993) are tweeted by users from the US. About 15% of WoS publications have a Chinese author but only 0.47% of all tweeted WoS publications are tweeted by users from China. The third country is the UK having 8.51% of the WoS publications authored by them and 25.57% of all tweeted WoS publications tweeted from the UK. Other countries show both less than 5% presence in the WoS and less than 10% Twitter
activity although the relationship between their output and their activity on Twitter is relatively aligned.

![Figure 4. Difference between 2012-2015 publication’s presence in the WoS and Twitter activity](image)

Conclusions and discussions:
In this study we have compared the country of authors of WoS publications with the country of Twitter users tweeting these publications in order to explore the main scholarly Twitter users across the world. The idea is to study how scholarly tweeters are distributed worldwide, and whether any country biases in tweeting scientific publications similar to those previously observed for citation databases (Van Leeuwen, et al., 2011) exists. A special focus has been paid on how users tweet publications from their own or other countries. The results show that the US and the UK are both high in their proportions of outputs in the WoS and users discussing scientific publications on Twitter. These two countries have been also reported to be the top countries of Twitter users in the study of Haustein and Costas (2015). China is the second most important country in terms of WoS publications, however Chinese tweeters are not very active in discussing scholarly outputs. This may have to do with the low uptake of Twitter among Chinese users as they use their local tool (Weibo). Publications from the US are observed to be the most important set of publications tweeted from non-US tweeters. This can be related to the overall size of the US as a scientific producer. This result is in contrast to that obtained for Mendeley in the study of comparing country of authors and readers of Scopus publications by Thelwall and Maflahi (2015). This study showed that, although the higher proportion of US authors leads to the higher proportion of a given country readers in some fields, it seems that in general, Mendeley users tend to select articles from their own country more often than publications from any other country (Thelwall & Maflahi, 2015).

However, based on the above results, the main question is what explains the difference in the country’s publication reach on Twitter and in the general scholarly Twitter usage across different countries. In other words, it is not clear why publications from some countries attract more Twitter users than others. Possible explanations for this could be due to biases in the coverage of Altmetric.com and WoS towards English sources and international publications (Mas-Bleda & Thelwall, 2016) as well as specific publishers or publications with digital identifiers (DOIs). Hence, it seems that local publications are underrepresented and similar biases towards developed countries as those observed for citation indicators can also be expected for Twitter indicators. Thus, the ideal of altmetrics serving scholars from developing countries (the so-called ‘alternative scholars’) is missed, as argued by Alperin (2013). Other
reasons for the observed differences could include cultural, technological, economical and political differences among countries. Among others, technological infrastructures, levels of user’s access to technology, education, information literacy, information behaviour, etc. could play a role here (Zahedi, 2016). Clearly, factors such as the familiarity with the Twitter platform of citizens from specific countries, as well as the extent to which they are oriented, adopted or motivated to use this platform for sharing and disseminating scholarly outputs could have an influence on a country’s scholarly Twitter usage. Hence, all these factors need further investigation on how they could influence scholarly Twitter usage across countries. In addition, understanding the different reasons and motivations of users from different countries to interact with scientific results, could give a better insight of the true potential and relevance of altmetric indicators to study national differences in the reception of scientific publications on social media platforms.

Abstract
The study of knowledge diffusion pattern in medical field is of importance to advance medical research, and eventually promote human health. Altmetrics might offer new ways to measure the impact of the sciences beyond the science. By using PLOS ALM data, we investigated the diffusion pattern of medical knowledge in social media. Our results shows that non-medical papers received more attentions than medical ones in terms of Twitter, Mendeley and Counter, however the pageviews and downloads for medical papers on PubMed Central were greater than non-medical ones in term of PMC. ALM scores such as Twitter, Mendeley and Counter shows a sharp increase over time at the very beginning after the papers are published. Then, the increase gradually slows down. China got a relatively low degree of public interest compared to the United States and German. Papers with more content and references tended to have a higher degree of public interest. These findings are informative for the scientists in medical field as well as policy makers and administrators for managing and financing medical research in the future.

Conference Topic
Altmetrics
**Introduction**

Medicine is a discipline closely related to human health. Medical research involves the basic research, applied research, or translational research conducted to aid and support the development of knowledge in the field of medicine. The study of knowledge diffusion pattern in this field is of importance to advance medical research, and eventually promote human health. With the development of social media, the current (medical) academic exchange environment has changed dramatically. As a result, a new term “Altmetrics” was born. Altmetrics was first proposed in September 2010 by Priem, Taraborelli, Groth, & Neylon (2010). Since then, it has received extensive attentions. Several definitions of Altmetrics have been proposed. The common understanding across all definitions is that Altmetrics is a new or alternative metrics to the established metrics for measuring scholarly impact (Erdt, Nagarajan, Sin, & Theng, 2016). Bibliometrics (citation analysis) has always been serving as the gold standard in measuring impact of the sciences. A great drawback of citation analysis is that it only measures the influence of scientific work on science itself. However, Altmetrics (alternative metrics) might offer these new ways to measure the impact of the sciences beyond the science, as it is based on social media platforms and tools, scholarly activities or various user activities in social media environments (Priem, 2014). At this time, Altmetrics may be best conceptualized as complementary and improvement the limitations of traditional metrics rather than replacement (Chisolm, 2016; Costas, Zahedi, & Wouters, 2015; Trueger et al., 2015).

In this paper, we will investigate the diffusion pattern of medical knowledge in social media based on Article-Level Metrics (ALM) data provided by Public Library of Science (PLOS).

**Literature review**

With the booming of social media in the last decades, sharing scholarly materials on social media is becoming increasingly popular (Wang, Fang, & Guo, 2016). Due to the advantages that social media have shown, an efficient channel for scientific communication and dissemination is established, and further strengthened by open access (Wang, Liu, Mao, & Fang, 2015). The spread of research results in social media not only enhances the interaction between scientific community and the public, but also provides a wealth of data for gaining new insights into the research activities. Therefore, many studies grow up. Li, Thelwall, & Giustini (2011) investigates scholarly influence by using CiteUlike and Mendeley data, suggesting that this type of influence seems to be still too small to challenge traditional citation indexes. In addition, Bornmann & Haunschild (2015) use Mendeley data to analyse who reads research articles and which people use which scientific papers. Haunschild & Bornmann (2016) investigates societal impact in scientometrics by using a relatively newly source of Altmetrics data.

With the development of the social media, scholars have more ways to disseminate research than ever before. These venues include open access archives, online journals, and social media tools, such as wikis, blogs, social bookmarking, Facebook, LinkedIn, Twitter and Wikipedia. Wang et al. (2016) found that most of the visits from social
media are generated within only one week after publication. However, social buzz about scholarly articles doesn't last long, which leads to the resulted article visits a rapid decay. In short, easy come, easy go. Allen, Stanton, Di Pietro, & Moseley (2013) quantified the impact of social media release on views and downloads of articles in the clinical pain sciences. They found that the mean±SD rate of HTML views in the week after the social media release was 18±18 per day, whereas the rate during the other three weeks was no more than 6±3 per day. The mean+SD rate of PDF downloads in the week after the social media release was 4±4 per day, whereas the rate during the other three weeks was less than 1±1 per day (p<0.05 for all comparisons).

Medicine, a discipline closely related to human health. However, few attempts were made to study how medical knowledge was diffused in the environment of social media. This study will discover the manifold ways in which medical research is disseminated by using with PLOS ALM data. Specifically, this study will address the following two questions:

- How medical knowledge is disseminated on social media over time?
- What are the differences in topics for papers with different diffusion pattern?

Data and Methodology

Data

PLOS ALM data were used as data source in this study. PLOS ALM, launched in 2009, tracks not only the influence of individual PLOS articles, from times downloaded to mentions in social media and blogs, but also the internal article metrics, including comments, html, readers, like and pdf (Chamberlain, 2013; Lin & Fenner, 2013b; Roemer & Borchardt, 2012). PLOS ALM tracks more than 20 different types of artifacts and collects 5 major categories of impact metrics (Bornmann, 2014; Lin & Fenner, 2013a; Melero, 2015). The ALM API and dataset are freely available for all PLOS articles. Our data in this study were harvested through an open-source application called Lagotto, which retrieves metrics from a wide set of data sources, like Twitter, Mendeley, and CrossRef (Erdt et al., 2016; Kraker, Lex, Gorraiz, Gumpenberger, & Peters, 2015).

We checked the PLOS website for the newly published articles every day and harvest the daily visiting data of each article. We have been collecting the DOI number for all the papers published on PLOS website in December, 2016. The ALM data for each of these papers have been collected through DOI numbers every day from 21 o’clock to 23 o’clock Beijing time since they are published. In total, 2083 papers were collected. The visiting data for each of these papers were recorded and updated daily for 100 consecutive days ever since they were available on PLOS website. Since the PLOS ALM data for articles published in December 9, 13 and 14 were not available for a period of time, they are excluded from this study. Therefore 1588 papers were left for our study. According to PLOS classification criteria, the 1588 papers are grouped into 2 categories, medicine (1205 papers) and non-medicine (383 papers).

The bibliographic data for all these papers were collected from Web of Science, including titles, abstracts, addresses, references and number of pages, etc.
Methods

Article level metrics

Four kinds of ALM scores are used in this study (Table 1). They are Twitter, Mendeley, PMC, and Counter.

<table>
<thead>
<tr>
<th>PLOS ALM</th>
<th>Meaning</th>
<th>Category</th>
</tr>
</thead>
<tbody>
<tr>
<td>Twitter</td>
<td>Number of tweets which share an article on Twitter, a social networking and microblogging service</td>
<td>Social Shares</td>
</tr>
<tr>
<td>Mendeley</td>
<td>Aggregate number of bookmarks of the article added to a Mendeley reader's and group's library.</td>
<td>Academic bookmarks</td>
</tr>
<tr>
<td>PMC</td>
<td>Aggregate pageviews and downloads for the PubMed Central hosted version of the article.</td>
<td>Usage Stats</td>
</tr>
<tr>
<td>Counter</td>
<td>Aggregate pageviews and downloads for an article based on COUNTER 3-compliant collection standards.</td>
<td>-</td>
</tr>
</tbody>
</table>

Characteristic Scores and Scales

A similar method to Characteristic scores and Scales (Glänzel, W., 1988), was used to classify papers into different categories according to Counter scores. The classification procedures are as follows:

- **Step 1**: the mean Counter scores for all the medicine papers are calculated (mean_1).
- **Step 2**: papers with Counter score below mean_1 are classified as “poorly followed” papers.
- **Step 3**: The mean Counter score are calculated for papers with Counter score above mean_1 (mean_2).
- **Step 4**: papers with Counter score below mean_2 are classified as “fairly followed” papers.
- **Step 5**: papers with Counter score above mean_2 are classified as “remarkably followed” papers.

Results

The trend of ALM scores over time

We investigated the changes of average ALM scores for medical and non-medical papers for 100 consecutive days after they are published. As shown in Figure 1, different from the findings by (Erdt et al., 2016; Haustein et al., 2014; Li & Thelwall, 2012; Priem, Piwowar, & Hemminger, 2012), non-medical papers received more attentions from twitter and mendeley than medical ones. However, the page views and downloads for medical papers on PubMed Central were greater than non-medical ones. The results indicate that PMC, hosting journal literature in the field of
biomedical and life sciences, is still the main source for medical scientists to keep updated on newly published medical research findings.

</table>

It can also be seen that ALM scores such as Twitter, Mendeley and Counter showed a sharp increase at the very beginning after the papers were published. Then, the increase gradually slowed down. We calculated the every day’s changes of Counter score for each of the 1205 medicine papers. Table 2 lists the frequency that Counter's increase reaches the peak at nth day. Because the ALM data became available 2 days after the papers was published, the first updates for the ALM data should be the sum of the increase for the first two days. We divided this score by 2, and consider the average score as the Counter increases for the first or second day. For example, the paper titled “Do Elite and Amateur Soccer Players Outperform Non-Athletes on
Neurocognitive Functioning? A Study Among 8-12 Year Old Children” was published on December 1, 2016. The ALM score for this paper was firstly updated on December 3, 2016. So we divide the ALM score (Counter: 38) by 2, then we consider that the Counter score increased by 19 for each of the first two days after this paper was published. As shown in table 2, 503 papers’ Counter increase reached the peak 3 days after they were published, accounting for 41.74% of the total. 90.87% papers’ Counter increase reached the peak within a week. This result indicates that these papers received most intensive attention on social media immediately after they were published.

The topic analysis for papers with different diffusion pattern

By using Characteristic Scores and Scales, all the medicine papers in this study are grouped into 3 categories according to the 3rd day’s ALM data: “remarkably followed” papers(75 papers, Counter>476), “fairly followed” papers (374 papers, 219<Counter<=476), and “poorly followed” papers (756 papers, Counter<=219).

Abstract analysis
We tokenized the abstracts of all the papers with NLTK, a leading platform for building Python programs to work with human language data. Stop words were removed from the generated tokens. Common words used in medical research were also removed, such as “Disease”, “Patient”, “Cell”, etc. The top word frequencies of the abstracts for the 3 categories are listed in Table 3. “Mutation”, “Cancer”, “Tumor” and “ctDNA” appears most frequently in the abstracts of the “remarkably followed” papers. “Model”, “Mice”, “Blood” are at the top of the word frequency list for both the “fairly followed” and “poorly followed” papers. This results means that cancer research is still the main focus of the medical scientists’ attention, as the problems of curing cancer have not yet been solved.

</table>

As shown in Table 5, the number of publications by the United States ranked first in all the 3 categories. German ranks 2nd, 3rd, 3rd in “remarkably followed”, “fairly followed” and “poorly followed” papers respectively. China ranks 11th in “remarkably followed” papers, while ranks 2nd in both “fairly followed” and “poorly followed” papers. Both the author analysis and country/region analysis indicate that the medical
research in the United States got the highest degree of public interest, followed by German. The medical research in China got a relatively low degree of public interest, which means that the quality of medical research in China need to be furtherly improved.

Paper length analysis

The average page count for “remarkably followed”, “fairly followed” and “poorly followed” papers are 18.21, 17.38, and 15.75 respectively (Table 4). This means that papers with higher degree of public interest always have more abundant content than those with lower degree of public interest.

Reference analysis

The average reference count for “remarkably followed”, “fairly followed” and “poorly followed” papers are 49.48, 51.15, and 44.21 respectively (Table 6). This means that papers with higher degree of public interest always cite more sources.

</tbody>
</table>

Discussion

In terms of Twitter, Mendeley and Counter, non-medical papers received more attentions than medical ones, but in term of PMC, the page views and downloads for medical papers on PubMed Central were greater than non-medical ones. This may be in part because of the nature of medical research. The information provided by medical paper is hard to understand for those without a medical background, so the dissemination of medical knowledge are restricted within the domain of medical scientists other than the public. For both medical and non-medical papers, Twitter, Mendeley and Counter showed a sharp increase over time at the very beginning after the papers were published. Then, the increase gradually slowed down. This finding was further confirmed by the fact that 90.87% medical papers’ Counter increase reached the peak within a week. One of the best ways to strengthen the medical research infrastructure is by promoting it to the public. So the medical research community should take advantage of the social media to make medical information to be disseminated in a way that is easy to understand for those without a medical background.

We grouped all the medical papers into 3 categories with Counter’s Characteristic Score, that is, “remarkably followed” papers, “fairly followed” papers and “poorly
followed” papers. We compared the most frequent words in the abstracts for the 3 categories, the results shows that cancer research is still the biggest concern for the medical scientists. Both the author analysis and country analysis shows that medical research in China got a relatively low degree of public interest compared to the United States and German. So medical scientists in China should attach great importance to quality of their research. The results of paper length analysis and reference analysis indicate that papers with more content and references tends to have a higher degree of public interest. This provide with the medical scientists a good way to prepare their research papers.

**Conclusion**

In conclusion, this study investigated the diffusion pattern of medical knowledge in social media by using PLOS ALM data. The data provided are informative for the scientists in medical field as well as policy makers and administrators for managing and financing medical research in the future.

Abstract
Microblog is an important medium of communicating public opinions toward public emergencies. Excavating topics and sentiment of microblogs on public emergencies has important practical significance in grasping online public opinions, identifying and predicting potential problems and risks during public emergencies. In this study, we propose an approach to analyse the topical and emotional evolution of microblog public opinions on public emergencies. The Zika outbreak is taken as an example and the life cycle of related microblog public opinions is divided into several phases. Topics are extracted from microblogs by the word2vec technique. The sentiment analysis has been conducted based on dictionaries containing sentiment words and emoticons to categorize the sentiment of microblogs at a fine-grained level. The emotional intensity of microblogs for each topic is also calculated to achieve synergetic analysis of topics and sentiment of microblogs. The proposed method can reveal the topical and emotional features and emotional intensity of microblogs on public emergencies and summarize the synergetic evolution patterns of topics and sentiment of online public opinions.

Conference Topic
Knowledge discovery and data mining

Introduction
With the development of the Internet, microblog, WeChat, and other social media are changing people's way of information dissemination and consumption to a great extent. The functions of newspapers, television, radio and other traditional media have been gradually replaced by social media. Sina Weibo is one of the most important social media platforms in China. As of September 30th, 2016, Sina Weibo has owned 297 million monthly active users and 132 million daily active users, among whom 73.9% of the users are concerned about the real-time news and hot topics (Fan, 2017). Users can freely publish posts and enterprises, institutions and government departments set up official microblog accounts to release authoritative information. Thus, microblog has been an important channel of current public opinions.

As public emergencies have the characteristics of suddenness and uncertainty, online public opinions also have similar features and need to be processed timely. The excavation and analysis of the topics and corresponding emotions of microblog entries about public emergencies can help emergency administrators understand the public's attitude toward a certain event and related policies. Thus, the government, enterprises and other organizations can actively respond to the emergency, effectively ease the social negative emotions, and promote social harmony.
and stability. In this study, we aim to construct the method of analyzing microblog public opinion evolution patterns. The method integrates the topical and emotional characteristics, reveals the synergistic pattern between the topics and emotions of microblog public opinions and provides a scientific and rational basis for decision-making and risk prediction by emergency management departments. The purpose of this study is 1) to construct an updated emoticon dictionary and combine the emoticons with short texts to capture the micro-blog’s hidden emotions accurately; 2) to extend the affective tendency analysis from positive, neutral and negative attitudes to a more fine-grained emotion classification; and 3) to capture topics with their related emotions at each stage, analyze and visualize their evolution pattern.

Related research

Topical analysis of microblogs
In recent years, researchers have paid much attention to the analysis of the topical evolution of microblogs, in which the Latent Dirichlet Allocation (LDA) model is frequently used. The LDA model considers a topic as a set of flat probabilities and does not take into account the position relationship between words. The resulting topics are isolated from each other. Thus, it often misses some key features, e.g. the position correlation between topics. In addition, the effectiveness of the LDA model is largely influenced by the length of the document. Microblog entries are often very short with scattered contents and formats. Thus, the performance of the traditional LDA model on microblog is often very poor.

In recent years, with the breakthrough application of deep learning in the field of natural language processing, more and more studies have shown that the word2vec model (Mikolov et al, 2013) which is based on the deep learning thought is significantly better than the LDA model. Word2vec expresses words in word vectors, and the similarity among the word vectors is used to measure the similarity among the texts. It can overcome the deficiency of the bag of words and mine the association among words to obtain abundant semantic information. Studies that apply the word2vec model to analyzing and clustering topics are emerging. A number of studies have shown that the word2vec model is more suitable for extracting topics from short texts, such as microblog entries than the LDA model (Zhu, 2014; Li et al., 2015; Chen et al., 2015).

Sentiment analysis of microblogs
Sentiment analysis includes subjective and objective analyses of emotions, sentiment polarity analysis and sentiment classification. At present, related studies often classify emotions into positive, negative and neutral emotions. However, Internet users’ emotional attitudes in microblogs are often not of a simple type and need more fine-grained sentiment classification instead, such as pleasure, anger, sorrow and joy. This kind of studies is at their early stage. Due to the correlation and combination of various emotions, multiple sentiment classification is regarded as one of the most complicated tasks (He et al, 2017).

The commonly used sentiment analysis methods include the sentiment dictionary-based approach and supervised machine learning (Tang et al., 2016). Sentiment dictionaries can be used to extract subjective vocabularies and their emotional tendencies in different contexts with high accuracies. As supervised machine learning methods depend on labeled training sets and have limited applicability in different fields (Mikolov et al, 2013), in this study we employ the sentiment analysis method based on the sentiment dictionary.
In the traditional text analysis, pictures and emoticons are often seen as noise data. However, in the sentiment analysis of microblog entries, they are likely to become an important source of emotional expression. Some researchers have studied the purpose of use, characteristics, effect and distribution of emoticons. However, most of the existing emoticons dictionaries are labelled based on their official definitions by microblog platforms. Actually, with the development of network cultural, the meanings of emoticons become gradually different from their original definitions. Therefore, in this study we construct an updated emoticon dictionary which is synchronized with the current network culture.

**Time series analysis of microblog public opinions**

The evolution process of public emergencies has a certain life cycle. Extensive research has been done on the spreading process of public opinions. These studies divide public emergencies into several stages based on the sequence of events, such as the three-phase model, the four-stage model (Robert, 2004). A recent study by Jia et al. (2015) divides the life cycle of public emergencies into the initial stage, the outbreak stage, the decline stage and the settling stage. Combined with the characteristics of public emergencies, in this study we adopt the life cycle division method by Jia et al. (2015).

In this study, we construct a topical and emotional evolution analysis framework to mine the microblog public opinions on public emergencies. The topics in microblog entries are extracted by the method based on word2vec and sentiment analysis is conducted based on the constructed emoticon dictionary, in which emotional words, emoticons and other sentiment source are introduced. Fine-grained emotions are identified for each topic and the corresponding emotional intensities are calculated. Combined with the life cycle of the public emergency, the hidden topics and emotions of microblog entries are detected simultaneously.

**Research framework and methods**

**Research framework**

To construct the evolution model of topics and emotions of microblog public opinions on public emergencies, the overall research framework is shown in Figure 1, which consists of three procedures, i.e. life cycle division, topic clustering and sentiment analysis. First, we crawl the microblog entries together with their comments on a certain public emergency, e.g. the Zika outbreak, and preprocess the microblog corpus. As different public emergencies may have different number of peaks, their life cycle of public opinions is divided accordingly. The evolution period of public opinions is shown as follows.

\{\text{the initial stage, the outbreak stage, the decline stage, the settling stage}\}, N=1
\{\text{the initial stage, the outbreak stage, the first recession stage, the second growth stage, the second recession stage, the settling stage}\}, N=2
\{\text{the initial stage, the outbreak stage, the first recession stage, the second growth stage… the N-1}^{\text{th}} \text{ recession stage, the N}^{\text{th}} \text{ growth stage, the N}^{\text{th}} \text{ recession stage, the settling stage}\}, N>2

where N is the number of peaks for public opinions. When N equals 1, the public emergency is defined as a unimodal event. When N equals 2, it is defined as a bimodal event. When N is larger than 2, it is defined as a multimodal event.

Second, the word2vec model is used to cluster the topics in the microblog corpus of each stage. Third, the mutual information method is employed to construct emoticon dictionary, which is combined with the emotion dictionary by Dalian University of Technology (Xu et al.,
We classify the comments of the blogs and calculate the emotional intensity. Finally, we get the trend of micro-blogging theme and emotion of different stages of the life cycle and visualize it.

**Figure 1 Research procedures of topical and emotional evolution of microblogging public opinion**

*Research methods and procedures*

*Theme extraction based on word2vec*

The word2vec model is a tool that converts words into word vectors proposed by Mikolov et al. (2013) which belongs to one of the shallow neural network language models. Word2vec can be used to map the processing of text content to vector operations in K-dimensional vector space, so the similarity of text semantics can be expressed by the similarity of space vector. Word2vec uses CBOW and Skip-gram to construct the vector representation of words, the CBOW model predicts the probability of the current term based on the context, while Skip-Gram is the opposite: the probability of predicting the context according to the current term. This paper is based on the Skip-gram model, using Python's genism (Řehůřek et al., 2011) module to provide the Word2Vec toolkit for training.

In this paper, we use the method of word2vec and K-means clustering to analyze the blog data set of each stage of the evolution of public opinion. Word2vec will express the words in the blog into a word vector containing semantic relations based on blog data set, while K-means uses the word vector as the clustering data sets, and Euclidean distance standardized by Z-score
will be used to calculate word similarity between two words, namely the smaller the European distance, the greater the similarity. In this way, the theme of the evolution of public opinion in each stage is obtained by clustering results.

The construction of the emoticons dictionary

This paper refers to the Dalian University of Technology’s affective lexicon ontology library (Xu et al. 2008) (happy good, anger, sadness and fear, evil, surprise) to classify the emoticons. According to the characteristics of the microblog of the public health emergencies, we combine "happy" and "good" to "happy", "anger" and "evil" to "anger", and finally we get five categories of emotion: "happy", "anger", "sadness", "fear", "surprise" and classify the emoticons. Microblog’s comments are short, different emoticons in the same emotion expression tend to have strong association (Li et al., 2016), therefore, the feelings expressed by emoticons in one comment always have a positive correlation, so the emoticons dictionary is constructed by mutual information calculated method. Based on the probability of co-occurrence of two different emoticons, a certain category of emoticons (seed emoticons) is used to determine the emotional categories of the other emoticons to classify emotions.

According to Ma et al. (2016), microblog emoticons have a long tail effect, the frequency of emoticons in the top 10% can cover the most of the emotion. In order to generate a seed emoticons table, we marked the categories and intensities of these top 10% high frequency emoticons. The results are shown in table 1.

Table 1 Seed emoticons (part)

<table>
<thead>
<tr>
<th>emoticons</th>
<th>category</th>
<th>intensity</th>
<th>emoticons</th>
<th>category</th>
<th>intensity</th>
</tr>
</thead>
<tbody>
<tr>
<td>[doge]</td>
<td>surprise</td>
<td>5</td>
<td>[心]</td>
<td>happy</td>
<td>5</td>
</tr>
<tr>
<td>[笑 cry]</td>
<td>happy</td>
<td>9</td>
<td>[挖鼻]</td>
<td>surprise</td>
<td>3</td>
</tr>
<tr>
<td>[哈哈]</td>
<td>happy</td>
<td>7</td>
<td>[偷笑]</td>
<td>happy</td>
<td>5</td>
</tr>
<tr>
<td>[微笑]</td>
<td>anger</td>
<td>5</td>
<td>[哀]</td>
<td>fear</td>
<td>7</td>
</tr>
<tr>
<td>[赞]</td>
<td>happy</td>
<td>7</td>
<td>[生病]</td>
<td>sadness</td>
<td>5</td>
</tr>
</tbody>
</table>

Note: The emotional intensity is divided into 1, 3, 5, 7, 9, 9 for the maximum strength, 1 for the minimum strength.

Microblog integrated affective computing

In this study, we analyze the comments of the microblogs, select the emotional words, emoticons, commonly used adverbs of the Internet (Han et al., 2012), and extract the negative words from HowNet (CNKI, 2017) to calculate the comprehensive emotions of the comments.

The relationship between the emotional intensity of the emoticons and the emotional intensity of the emotional word will directly affect the final emotional trend analysis. This paper holds that the emotions expressed by the emoticons are as important as the emotional words. Since the annotation (category and intensity) of the emoticons refers to the annotation system of the text emotion dictionary, so the same type of emoticons and words can be calculated together.

Traditional sentiment analysis methods only consider the polarities of emotions. Negative words tend to reverse the polarities. However, the emotions in this study are divided into five
types so that the treatment of negative words is more complicated. We refer to the negative lexicon proposed by Du. (2013), which is supplemented by the corpus of this study, and forms the subdivided emotional conversion table after the negative word modification, as shown in Table 2. The emotional correction formula of the emotional word with an odd number of negative words is shown in equation (1). When there are even negative words to modify the emotional word, the emotional word is not adjusted.

$$\Psi(\omega_i) = \frac{1}{2} \sqrt{S(\omega_i)} \quad (1)$$

Where \(\Psi(\omega_i)\) represents the emotional word intensity after the negative word modification, and \(S(\omega_i)\) is the initial emotional intensity of the affective word \(\omega_i\).

**Table 2 Conversion of emotional category after negative words’ modification**

<table>
<thead>
<tr>
<th>Original emotional category</th>
<th>Negative modified emotional category</th>
</tr>
</thead>
<tbody>
<tr>
<td>happy</td>
<td>sadness</td>
</tr>
<tr>
<td>anger</td>
<td>--</td>
</tr>
<tr>
<td>sadness</td>
<td>a*happy</td>
</tr>
<tr>
<td>fear</td>
<td>--</td>
</tr>
<tr>
<td>surprise</td>
<td>--</td>
</tr>
</tbody>
</table>

Table 2

Note: A is the real number of \([0,1]\), which indicates that the intensity of emotion is weakened, and the accuracy of emotion recognition is highest when measuring \(a=0.1\).

In addition, the degree of adverbs have different degree of adjustment, the emotional word will be modified by the degree of adverbs and obtains a new emotional intensity value, \(Value_{adv}\) represents the adjustment of adverbs around emotional words \(\omega_i\), the calculation is shown in equation (2). According to the statistical comparison, it is found that the degree adverbs and negative words in the range of no more than three words can be recalled well. Therefore, the sliding window value is set to 3, and the emotional word and the corresponding degree adverb, Negative words are matched.

$$\Phi(\omega_i) = Value_{adv} \cdot s(\omega_i) \quad (2)$$

In one comment, the emotional words and emoticons of the same emotional category are summed up, and the emotion categories are \(p, p \in \{\text{happy, anger, sadness, fear, surprise}\}\). The emotional calculation of the comments based on the emotional words and emoticons are shown in equation (3).

$$Value(E_p) = \sum_{i=0}^{n}[f(\omega_i) + g(e_i)] \quad (3)$$

Where \(Value (E_p)\) represents the emotional value of the comment, \(g(e_i)\) represents the emotional value of the emoticons, the final emotional category of the comment and the emotional value are determined by the most significant value of the emotional category and its corresponding value, \(n\) is the sum of the same kind of emotional features (emotional word and emoticons) in the same comment.

**An Analysis of theme and Emotional Evolution of Microblogging Public Health Emergencies**

**Data collection and preprocessing**

We set “Zika” as key word to retrieval blogs from Sina microblog platform. The data set is all relevant microblog and its corresponding comments (direct comment and Forward the...
comments) from "2016-1-1" to "2016-12-31", After data cleaning such as removing the link in the text, @ other users and the stop words, we get 108,997 data.

4.2 Data analysis
We divide the data of Zika microblog as the method provided by Jia et al. (2015). As shown in Figure 2.

![Figure 2 The life cycle of Zika microblog spreading](image)

In this paper, we use word2vec to summarize the theme of different stages of topics, and summarize the theme of each stage as shown in Table 3.

</tbody>
</table>
According to the law of the time sequence of the public opinion propagation, we carry on the sentiment analysis of the corresponding comment of microblog in the life cycle. As shown in figure 3. From the public opinion of the evolution of the entire life cycle, the initial stage and the outbreak stage of public opinion mainly led by the "fear" and "anger", indicating that public opinion has been the phenomenon of emotional agglomeration. The intensity of the "anger" in the initial stage has reached the highest value of this emotional category throughout the evolutionary period, which means the reports of the epidemic abroad have aroused the intense boredom and hatred of the domestic netizens (TopicI-1, TopicI-2, TopicI-4). In the stage of the outbreak, the intensity of "fear" is the highest value of this emotional category in the entire evolutionary cycle, this also means that the epidemic spread from abroad to China (TopicII-5), internet users' emotions have been changed from "anger" to "fear", netizens’s position is gradually converted from the outsider to the party. However, in the first recession, the intensity of the emotions was lower than the previous stage, the proportion of emotional composition is relatively uniform, "anger" "fear" "happy" three emotions cross, the situation of public opinion has eased. There are two main reasons for this phenomenon: On the one hand, the spread of the epidemic in the country caused panic and anger, on the other hand is due to the patriotic health movement throughout the country, various measures are conducted to prevent the spread of negative emotions, which means emergency management has been effective. In the second growth stage, "anger" and "fear", as negatively dominant mood in the previous stage, have been greatly reduced, "happy" has become the dominant emotion, the wind of public opinion began to reverse. Due to the hosting of the Rio Olympics, news media’s reports have shifted the attention from epidemic to the sports event. In the second recession, "fear" compared to the previous stage began to rise, due to the fact that Henan province reported the first Zika(TopicV-1) in the province and Southeast Asia begins to erupt Zika(TopicV-2), the situation of crisis management has intensified again. In the subsidence stage, "happy" and “sad" become the dominant categories of emotion, the reason is that domestic and foreign research has made a breakthrough in the development of Zika vaccine, the majority of people maintain an optimistic attitude toward the treatment of Zika. However, it can not be ignored that the intensity of the "sad" in this stage has reached the highest value of this emotional category throughout the evolutionary period, so the conciliation after the epidemic is of critical importance.

Therefore, the analysis of the emotional evolution of public emergency at different stages has brought a new perspective for crisis management. Throughout the evolutionary cycle, the crisis management department should provide accurate information on the cause and reasonable consequences of the incident in the initial stage to resolve the confusion of Internet users, curb the fermentation of rumors, avoid causing a large area of fear. Emergency management departments should promptly analyze the composition of sentiment of Internet users and
observe the fluctuations of the emotional value to look for the reasons of the fluctuations and carry out targeted emotional guidance and intervention through various media reports, so as to avoid or reduce the impact of public opinion when the event broke out; When the event outbreak, the emergency management departments should promptly report on the direction of the emergencies and assess the safety risk of the incident and popularize precautionary measures. The media should follow up the latest measures and responses at home and abroad in real time to lead Internet users to move toward positive emotions; In the first recession and the second outbreak, crisis management department still cannot lower the guard and should monitor the themes and proportion of emotions to prevent the recurrence of public opinion; In the settling stage, crisis management department should carry out psychological aid and post-disaster reconstruction to placate the public mood. In addition, the "anger" has the meaning of anger and censure, it can not only embody public’s attitudes to public emergency, but also reflect the feedback of crisis management of the relevant departments. If the mood continues to be high, it is time to look at themselves and see if the timeliness and effectiveness of crisis management need to be strengthened.

![Figure 3 Emotional types and intensities in different stages](image)

**Conclusion**

In this paper, we proposed a topic and emotion fusion evolution analysis method, taking deep learning into the theme analysis of public opinion in microblog. Based on the word2vec model, the microblog’s content of the each stage of is modeled. The word in the microblog is expressed as word vector which contains the semantic relations, and the theme of the each stage in evolution of public opinion can be obtained by K-means clustering; We adopt more fine-grained sentiment classification and rich emoticons from existing dictionaries, we also make sentiment analysis for the themes in each stage based on emotional words, emoticons and other multiple source of emotion and obtain the map which shows the evolution trend of topic and emotion fusion evolution. A total of 108,997 samples were collected from the blogs and their corresponding comments, which shows that the method can effectively obtain the theme and the emotion trend in the evolution of public opinion. The research results provide reference for the emergency management departments and other stakeholders to obtain real-time public opinion in terms of cognition, attitude, emotion and behavioral tendency of the internet users.
It is also helpful for the related organizations to conduct the accurate prediction and risk control of the network public opinion, and provides efficient information service and emergency management.

Abstract
This paper investigates how and why scientific video articles are communicated on Twitter. Specifically, we study video articles published in the Journal of Visualized Experiments (JoVE). We harvested all of the tweets from October 2011 to November 2015 that contain one or more JoVE links. These tweets “citing” JoVE articles were analyzed both statistically and qualitatively. In this research-in-progress paper, we discuss our preliminary findings on the distribution of these tweets, with a brief description of the affordance use of Twitter such as hashtags and mentions. The content analysis of the tweets is still in progress. We present the coding schemes of both the Twitter user accounts and the tweets’ text formed after two rounds of coding, discussion, and revision. We also briefly discuss issues including the video/visual feature mentioned, the role of Twitter bots, and self-promotion of different stakeholders in the Twitter communication of JoVE video publications.

Introduction
Research and education are increasingly relying on a more diverse array of information sources. Academic uses of videos both in education applications (Jones & Cuthrell, 2011) and for research purposes (Kousha et al., 2012) have been studied. Previous studies have revealed potential benefits that videos could bring to education in the arts and humanities (Brook, 2011; Cayar, 2011; Hoskins, 2009; Muniandy & Veloo, 2011; Rees, 2008); meanwhile, research has demonstrated considerable advantages of using videos in science and medicine education (Clifton & Mann, 2011; Fernandez et al., 2011; Franz, 2012; Kaw & Garapati, 2011; Knösel et. al, 2011; Settle et al., 2011). The pedagogical value of online videos could help enhance researchers’ knowledge and skills, thus promoting the accuracy and efficiency of their work. Therefore, we are particularly interested in how videos are being utilized in the scientific research process.

Previous studies have been mostly focused on Youtube videos as scholarly information sources; Here we investigate a peer reviewed scientific journal specifically publishing curated videos, the Journal of Visualized Experiments (JoVE). JoVE is a 10-year old journal with nearly 7,000 publications to date. Professional videographers and editors assist in producing videos to visualize methods, data analysis and results in both the physical and life sciences. According to
JoVE’s website (JoVE, 2017), it is devoted to helping researchers understand complicated experimental techniques and methods to make them easier to comprehend and reproduce. Pasquali (2007) discussed the benefits of using videos to communicate scientific protocols instead of using verbal descriptions. He emphasizes the important role that human’s visual perception plays in comprehending ideas and feelings, and argues that because a video includes “information such as color, position, duration, shape, and motion,” it is the “optimal format for transmitting the manifold details of new protocols or technical procedures.”

The microblogging service Twitter is one of the most important altmetrics data sources. In recent years, academic activity on Twitter has been extensively studied (Priem & Costello, 2010; Thelwall et al., 2013; Holmberg & Thelwall, 2014; Holmberg et al., 2014; Haustein et al., 2016; Eriksson-Backa, Holmberg & Ek, 2016; Vainio & Holmberg, 2017). This exploratory research-in-progress paper is particularly focused on the communication of JoVE articles on Twitter and is driven by the following basic research questions:

1. Who tweets JoVE articles? (account identify, account gender, and Twitter bots’ role)
2. How do they tweet JoVE articles? (elements included in the construction of tweets, sentiment, and affordance use such as hashtags and mentions)
3. Why do they tweet JoVE articles? (motivation of tweeting, with a special focus on different stakeholders’ self-promotion)
4. Are video/visual elements specifically emphasized in tweets of JoVE articles?

Methods and Data

Altmetric.com provided the full dataset from October 2011 to November 2015 for this research. This dataset contains over 4.4 million records in JSON format. Each record represents one scholarly artifact and encompasses various types of altmetrics data about this artifact. Specifically, these altmetrics include those based on Twitter, Facebook, Blogs, Wikipedia, News, Google Plus, Policies, Reddit, F1000, Peer Reviews, Videos, and Q&As. After learning the structure of this dataset, we established a relational database. In addition, we used a Python script to process the data and were able to successfully extract all of the data of tweets that contain links to JoVE publications.

Overall, 7,500 tweets were extracted, with data about their user names and URLs, as well as the titles and URLs of the JoVE publications they contain. To better understand the content of the tweets, we used another Python script to retrieve tweets’ text from Twitter.com. Considering that the altmetrics data were gathered earlier than we started to work on this project (in September 2016), some tweets were shown to had been deleted. As a result, we further cleaned the data, and excluded 308 “HTTP Error 404: Not Found” ones and 798 “Twitter/Account Suspended” ones. At the end, when we were exploring tweets content related questions, our data consisted of 6,394 tweets. These data were processed one step further using a third Python script, to extract the hashtags and mentions in the tweets’ text.

In order to gain a deeper understanding of the construction patterns of tweets and the motivation behind them, content analysis was conducted by three authors. Considering that one user can post multiple tweets, we coded the Twitter user accounts and the tweets’ text separately. In each process, there were multiple steps. Among the 6,394 tweets, we planned to use stratified sampling based on the activeness of users (the number of JoVE article tweets they created). For coding the tweets, we firstly studied relevant literature. 30 tweets were then coded by three coders. The initial coding scheme was formed after our discussion about the first coding process. In the second step, 90 tweets were coded. Reaching an average agreement rate of 70%, three coders discussed again, with a particular focus on the coding disagreement and potential new categories. The final coding scheme of tweets was formed after that. In the following step, two coders will code 480 more tweets. In addition, we went through a similar process of coding the accounts. An agreement of 76% was reached and the final coding scheme of accounts was
formed. In the following step, two coders will code 185 more accounts. The third coder will review the disagreement if needed. Due to limited space and the work-in-progress nature of this article, we will present our coding schemes in the Results section.

Results

Distribution of Tweets

In total, 2,153 Twitter users have posted 7,500 tweets that contain JoVE article links. Figure 1 shows the skewed power-law distribution of tweets created by users. Specifically, the top 9 most active users (0.42%) have tweeted more than half of the tweets. By contrast, 1,676 users (77.84%) have only tweeted one JoVE article each. Almost 90% (89.13%) of users have either tweeted one or two JoVE articles.

More details of the top 10 most active Twitter accounts are shown in Table 1. According to our coding and discussion, the top 10 most active Twitter accounts include at least six bot accounts. The bots could be impersonated in institution accounts or individual accounts. The rest four accounts are also likely to be combining bot tweeting techniques with manual tweeting.

Most Frequently Used Hashtags and Mentioned Users

In total, there are 3,235 hashtags (#) tweeted in all of these 6,394 JoVE article tweets. In other words, approximately one hashtag is used in every two tweets. Among these hashtags, there are 928 unique ones, with the most frequently used one tweeted 862 times. We coded the top 100 frequently used hashtags into six categories in terms of their purpose of use: 1) to indicate that this tweet is about an article (which contains more information than the 140 words limit), 2) to indicate that this tweet is about JoVE, 3) to emphasize the visual/video feature of JoVE articles, 4) to emphasize the technical feature of JoVE articles, 5) to specify relevant research areas/topics, and 6) to specify relevant experimental techniques/tools/objects. Due to limited space here, we present the top 10 in Table 2 below. With #article, #Jove, #scivideo (scientific video), and #MySciVid (my scientific video) being the top four, the rest six all specify relevant research areas/topics. The next step of our study is to code all of the hashtags to better understand the use of hashtags.

In terms of mentions (@), all these tweets contain 1457 mentions of 483 unique accounts. Due to limited space, we present the top 8 mentioned accounts in Table 3. The most highly mentioned account is JoVE the journal. Evernote’s Twitter account is ranked the second, revealing these Twitter users’ behavior of mentioning @MyEN to save the tweets of the article to their Evernote notebook stacks. In addition, two are university accounts, while four are researchers in disciplines related to JoVE’s publication scope.

**Coding Schemes**

As is described in the Methods and Data section, we are still working on the content analysis. Due to limited space, we are only able to present our coding schemes in bullet points with the codes delimited by commas. The definition of the codes and more results will be presented in our later work.

Twitter accounts coding scheme:

- Account Gender: Male, Female, Not Sure, N/A
- Bot or NOT: Yes, No, Hybrid, Not Sure

Tweets’ text coding scheme:

- Elements Included: Whole Title, Part of Title, Summary of Title, Methodology of Article, Conclusion of Article, Concept in Article, Topic/Discipline of Article, Summary of Article, Comment on Article, Recommendation of Article, Author, Link Only.
- Sentiment: Positive, Negative.
- Self-promotion: Publisher, Individual, Institution, Colleague/Friend, Others.

**Discussion and Future Work**

In this study, instead of collecting tweets posted by a certain group of researchers or those sharing the same hashtags, we harvested our data by retrieving scientific article link citations. Therefore, these tweets “citing” articles from the same journal (JoVE) are not found to be as conversational or topical in terms of timeliness. However, they display their unique features. First of all, video/visual elements are highly mentioned in both hashtags and the tweets’ text. This is an advantage of video publications and could potentially facilitate the online scholarly communication of specific disciplines. In JoVE’s case specifically, the video articles are mostly video protocols that could potentially accelerate experimental biological, medical, chemical and physical research. Secondly, although the act of tweeting is a behavior to disseminate or discuss information, saving behavior (by mentioning @MyEN) has been observed. This demonstrates the possibility of capturing different types of digital traces that researchers leave on one single platform. Meanwhile, it also provides us more train of thoughts about studying how researchers’ information behaviors have been changed as the advent of new technology. Thirdly, bots play an important role in disseminating JoVE articles. However, does the large number of tweets generate impact or just empty buzz? Without further qualitative analysis, it is hard to know. As a result, we will pay specific attention to this aspect in the further content analysis. Last but not least, under the framework of altmetrics, whether and how much Twitter “citations” can reflect scholarly impact and societal impact are undergoing continuous discussion. When this study is done, more patterns of the tweets will be revealed, and the self-promotion behavior of different stakeholders will be better understood. This exploration will provide more evidence to the comprehension of altmetrics and impact.

Normalization of zero-inflated data:
An empirical analysis of a new indicator family

Abstract
Recently, two new indicators (Equalized Mean-based Normalized Proportion Cited, EMNPC, and Mean-based Normalized Proportion Cited, MNPC) were proposed which are intended for sparse data. We propose a third indicator (Mantel-Haenszel quotient, MHq) belonging to the same indicator family. The MHq is based on the MH analysis—an established method for polling the data from multiple 2×2 cross tables based on different subgroups. We test (using citations and assessments by peers, i.e., F1000Prime recommendations) if the three indicators can distinguish between different quality levels as defined on the basis of the assessments by peers (convergent validity). We find that the indicator MHq is able to distinguish between the quality levels in most cases while MNPC and EMNPC are not.

Conference Topic
Indicators

Introduction
Alternative metrics (altmetrics) have been established as a new fast-moving and dynamic area in scientometrics (Galloway, Pease, & Rauh, 2013). Initially, altmetrics have been proposed as an alternative to traditional bibliometric indicators. Altmetrics are a collection of multiple digital indicators which measure activity related to research papers on social media platforms, in mainstream media or in policy documents (National Information Standards Organization, 2016; Work, Haustein, Bowman, & Larivière, 2015). According to Haustein (2016), sources of altmetrics can be grouped into (i) social networks, (ii) social bookmarking and online reference management, (iii) social data (e.g., data sets, software, presentations), (iv) blogs, (v) microblogs, (vi) wikis, and (vii) recommendations, ratings, and reviews.

Recently, some indicators based on altmetrics have been proposed which are normalized with respect to the scientific field and publication year. These indicators were developed because studies have shown that altmetrics are—similar to bibliometric data—field- and time-dependent (see, e.g., Bornmann, 2014). Some fields are more relevant to the general public or a broader audience than other fields (Haustein, Larivière, Thelwall, Amyot, & Peters, 2014). The Mean Normalized Reader Score (MNRS) was introduced by Haunschild and Bornmann (2016) for normalization of data from social bookmarks and online reference management platforms (with a special emphasis on Mendeley readers), see also Fairclough and Thelwall (2015). The Mean Discipline Normalized Reader Score (MDNRS) was tailored specifically to Mendeley by Bornmann and Haunschild (2016b). The MDNRS uses Mendeley disciplines for field normalization. The employed normalization procedures rely on average value calculations across scientific fields and publication years as expectation values. Normalization procedures based on averages and percentiles of individual papers are problematic for zero-inflated data sets (Haunschild, Schier, & Bornmann, 2016). Bornmann and Haunschild (2016a) proposed the Twitter Percentile (TP)—a field- and time-normalized indicator for Twitter data.
The overview of Work, et al. (2015) on studies investigating the coverage of papers on social media platforms show that many platforms have coverages of less than 5% (e.g., Blogs, or Wikipedia). Erdt, Nagarajan, Sin, and Theng (2016) report similar findings in their meta-analysis. They found that former empirical studies dealing with the coverage of altmetrics show that about half of the platforms are at or below 5%; except for three (out of eleven) where the coverage is below 10%. Thus, altmetrics data are frequently concerned by zero-inflation.

Bornmann and Haunschild (2016a) circumvented the problem of zero-inflated Twitter data by including in the TP calculation only journals with at least 80% of the papers having at least 1 tweet each. However, this procedure leads to the exclusion of many journals from the TP procedure. Very recently, Thelwall (2017a, 2017b) proposed a new family of field- and time-normalized indicators for zero-inflated altmetrics data. The new indicators family is based on units of analysis (e.g., a researcher or institution) rather than on the paper level. They compare the proportion of mentioned papers (e.g., on Wikipedia) of a unit with the proportion of mentioned papers in the corresponding fields and publication years (the expected values). The family consists of the Equalized Mean-based Normalized Proportion Cited (EMNPC) and the Mean-based Normalized Proportion Cited (MNPC). Hitherto, this new family of indicators has only been studied on rather small samples.

In this study, we investigate the new indicator family empirically on a large scale (multiple complete publication years) and add a further indicator to this family. In statistics, the Mantel-Haenszel (MH) analysis is recommended for polling the data from multiple 2×2 cross tables based on different subgroups (here: mentioned and not-mentioned papers of a unit published in different subject categories and publication years compared with the corresponding reference sets). We call the new indicator Mantel-Haenszel quotient (MHq). In the empirical analysis, we compare the indicator scores with ratings by peers. We investigate whether the indicators are able to discriminate between different quality levels assigned by peers to publications. Thus, we test the convergent validity of the indicators. Since the convergent validity can only be tested by using citations (which are related to quality), the empirical part is based solely on citations and not altmetrics data. Good performance on the convergent validity test is a necessary condition for the use of the indicators in altmetrics (although for altmetrics, the relationship to quality is not clear).

**Indicators for zero-inflated count data**

Whereas the EMNPC and MNPC proposed by Thelwall (2017a, 2017b) are explained in the following two sections, the MHq is firstly introduced in the section thereafter. The next sections present not only the formulas for the calculation of the three metrics, but also the corresponding 95% confidence intervals (CIs). The CI is a range of possible indicator values: We can be 95% confident that the interval includes the “true” indicator value in the population. With the use of CIs, we assume that we analyse sample data and infer to a larger, inaccessible population (Williams & Bornmann, 2016). According to Claveau (2016) the general argument for using inferential statistics with scientometric data is “that these observations are realizations of an underlying data generating process … The goal is to learn properties of the data generating process. The set of observations to which we have access, although they are all the actual realizations of the process, do not constitute the set of all possible realizations. In consequence, we face the standard situation of having to infer from an accessible set of observations – what is normally called the sample – to a larger, inaccessible one – the population. Inferential statistics are thus pertinent” (p. 1233).

The relationship between CIs and statistical significance (in case of independent proportions) is as follows:
“1. If the 95% CIs on two independent proportions just touch end-to-end, overlap is zero and the p value for testing the null hypothesis of no difference is approximately .01.
2. If there’s a gap between the CIs, meaning no overlap, then p<.01.
3. Moderate overlap … of the two CIs implies that p is approximately .05. Less overlap means p<.05.

Moderate overlap is overlap of about half the average length of the overlapping arms” (Cumming, 2012, p. 402).

**Equalized Mean-based Normalized Proportion Cited (EMNPC)**

Thelwall (2017a, 2017b) introduced the EMNPC as an alternative indicator for zero-inflated count data. The approach of the EMNPC is to calculate the proportion of papers that are mentioned: suppose that publication set $g$ has $n_{gf}$ papers in the publication year and subject category combination $f$. $s_{gf}$ of the papers are mentioned (e.g., on Wikipedia). $F$ is defined as all publication year and subject category combinations of the papers in the set. The overall proportion of $g$’s papers that are mentioned is the number of mentioned papers ($s_{gf}$) divided by the total number of papers ($n_{gf}$):

$$p_g = \frac{\sum_{f \in F} s_{gf}}{\sum_{f \in F} n_{gf}} \quad (1)$$

However, $p_g$ could lead to misleading results if the publication set $g$ includes many papers which are published in fields with many mentioned papers. Thelwall (2017a, 2017b) proposes to avoid the problem by artificially treating $g$ as having the same number of papers in each publication year and subject category combination. The author fixes it to the arithmetic average of numbers in each combination, but recommends not including in the analysis combinations of $g$ with only a few papers. Thus, the equalized sample proportion of $g$, $\hat{p}_g$ is the simple average of the proportions in each combination

$$\hat{p}_g = \frac{\sum_{f \in F} s_{gf}}{\frac{n_{gf}}{|F|}} \quad (2)$$

The corresponding world sample proportion is defined as:

$$\hat{p}_w = \frac{\sum_{f \in F} s_{wf}}{\frac{n_{wf}}{|F|}} \quad (3)$$

In Eqns. (2) and (3), $[F]$ is the number of subject category and publication year combinations in which the group (in case of Eq. (2)) and the world (in case of Eq. (3)) publishes. Thus, the equalized group sample proportion has the undesirable property that it treats $g$ as if the average mentions of its papers do not vary between the subject categories. The EMNPC for each publication set $g$ is the ratio of both equalized sample proportions:

$$\text{EMNPC} = \frac{\hat{p}_g}{\hat{p}_w} \quad (4)$$

CIs for the EMNPC can be calculated as follows (Thelwall, 2017a):

$$EMNPC_L = \exp \left( \ln \left( \frac{\hat{p}_g}{\hat{p}_w} \right) - 1.96 \sqrt{\frac{(n_g - \hat{p}_g n_g) / (\hat{p}_g n_g)}{n_g} + \frac{(n_w - \hat{p}_w n_w) / (\hat{p}_w n_w)}{n_w}} \right) \quad (5)$$
Here, \( n_g \) is the total sample size of the group and \( n_w \) is the total sample size of the world.

**Mean-based Normalized Proportion Cited (MNPC)**

The second indicator proposed by Thelwall (2017a) has been named as Mean-based Normalized Proportion Cited (MNPC). The MNPC is calculated as follows: For each paper with at least one mention (e.g., on Wikipedia), the number of mentions is replaced by the reciprocal of the world proportion mentioned for the corresponding subject category and publication year. All other papers with zero mentions remain at zero. Let \( p_{gf} = s_{gf}/n_{gf} \) be the proportion of papers mentioned for publication set \( g \) in the corresponding subject category and publication year combination \( f \) and let \( p_{wf} = s_{wf}/n_{wf} \) be the proportion of world’s papers cited in the same year and subject category combination \( f \). Then:

\[
 r_i = \begin{cases} 
 0, & \text{if } c_i = 0 \\
 1/p_{wf} & \text{if } c_i > 0, \text{where paper } i \text{ is from year and subject category combination } f 
\end{cases}
\]

Following the calculation of the MNCS (Waltman, van Eck, van Leeuwen, Visser, & van Raan, 2011), the MNPC is defined as

\[
 MNPC = \frac{(r_1 + r_2 + \cdots + r_n)}{n} 
\]

An approximate CI has been constructed by Thelwall (2016, 2017a) for the MNPC. In the first step, the lower limit \( L \) (MNPC\(_{gL}\)) and upper limit \( U \) (MNPC\(_{gU}\)) for group \( g \) in subject category and publication year combination \( f \) is calculated with:

\[
 MNPC_{gfL} = \exp\left(\ln\left(\frac{p_{gf}}{p_{wf}}\right) - 1.96 \sqrt{\frac{(n_{gf} - p_{gf}n_{gf})/(p_{gf}n_{gf})}{n_{gf}} + \frac{(n_{wf} - p_{wf}n_{wf})/(p_{wf}n_{wf})}{n_{wf}}} \right) 
\]

\[
 MNPC_{gfU} = \exp\left(\ln\left(\frac{p_{gf}}{p_{wf}}\right) + 1.96 \sqrt{\frac{(n_{gf} - p_{gf}n_{gf})/(p_{gf}n_{gf})}{n_{gf}} + \frac{(n_{wf} - p_{wf}n_{wf})/(p_{wf}n_{wf})}{n_{wf}}} \right) 
\]

In the second step, the group-specific lower and upper limits are used to calculate the MNPC CIs:

\[
 MNPC_L = MNPC - \sum_{f \in F} \frac{n_{gf}}{n_g} \left( \frac{p_{gf}}{p_{wf}} - MNPC_{gfL} \right) 
\]

\[
 MNPC_U = MNPC + \sum_{f \in F} \frac{n_{gf}}{n_g} \left( MNPC_{gfU} - \frac{p_{gf}}{p_{wf}} \right) 
\]

The MNPC cannot be calculated, if any of the world proportions are equal to zero. Furthermore, CIs cannot be calculated if any of the group proportions are equal to zero. Thus, Thelwall (2017a) proposed to remove the corresponding subject category publication year combination from the data or to add a continuity correction of 0.5 to the number of mentioned and not mentioned papers in these cases. We prefer the latter (to add 0.5 to the number of papers mentioned and not mentioned, respectively). This approach is recommended by Plackett (1974) for the calculation of odds ratios.
**Mantel-Haenszel quotient (MHq)**

For polling the data from multiple 2×2 cross tables based on different subgroups (which are part of a larger population), the most commonly used and recommended method is the MH analysis (Hollander & Wolfe, 1999; Mantel & Haenszel, 1959; Sheskin, 2007). According to Fleiss, Levin, and Paik (2003) the method “permits one to estimate the assumed common odds ratio and to test whether the overall degree of association is significant. Curiously, it is not the odds ratio itself but another measure of association that directly underlies the test for overall association … The fact that the methods use simple, closed-form formulas has much to recommend it” (p. 250). Radhakrishna (1965) demonstrate that the MH approach is formally and empirically valid against the background of clinical trials.

The MH analysis results in a summary odds ratio for multiple 2×2 cross tables which we call MHq. For the impact comparison of units in science with reference sets (the world), the 2×2 cross tables (which are polled) consist of the number of papers mentioned and not mentioned in subject category and publication year combinations \( f \). Thus, in the 2×2 subject- and year-specific cross table with the cells \( a_f, b_f, c_f, \) and \( d_f \) (see Table 1), \( a_f \) is the number of mentioned papers in subject category and publication year \( f \), \( b_f \) is the number of not mentioned papers in subject category and publication year \( f \), \( c_f \) is the number of mentioned papers published by group \( g \) in subject category and publication year \( f \), \( d_f \) is the number of not-mentioned papers published by group \( g \) in subject category and publication year \( f \). Note that the papers of group \( g \) are part of the papers in the world.

**Table 1. 2×2 subject-specific cross table**

<table>
<thead>
<tr>
<th>Group g</th>
<th>Number of mentioned papers</th>
<th>Number of not mentioned papers</th>
</tr>
</thead>
<tbody>
<tr>
<td>World</td>
<td>( a_f )</td>
<td>( b_f )</td>
</tr>
<tr>
<td></td>
<td>( c_f )</td>
<td>( d_f )</td>
</tr>
</tbody>
</table>

We start by defining some dummy variables for the MH analysis:

\[
R_f = \frac{a_f d_f}{n_f} \quad \text{and} \quad R = \sum_{f=1}^{F} R_f, 
\]

(13)

\[
S_f = \frac{b_f c_f}{n_f} \quad \text{and} \quad S = \sum_{f=1}^{F} S_f, 
\]

(14)

\[
P_f = \frac{a_f + d_f}{n_f} \quad \text{and} \quad Q_f = 1 - P_f 
\]

(15)

Where: \( n_f = a_f + b_f + c_f + d_f \)

The MHq is simply:

\[
\text{MHq} = \frac{R}{S} 
\]

(16)

The CIs for MHq are calculated following Fleiss, et al. (2003). The variance of \( \ln \text{MHq} \) is estimated by:

\[
\tilde{V} \text{ar}[\ln(MHq)] = \frac{1}{2} \left\{ \frac{\sum_{f=1}^{F} P_f R_f}{R^2} + \frac{\sum_{f=1}^{F} (P_f S_f + Q_f R_f)}{RS} + \frac{\sum_{f=1}^{F} Q_f S_f}{S^2} \right\} 
\]

(17)

The confidence interval for the MHq can be constructed with

\[
\text{MHq}_L = \exp \left[ \ln(MHq) - 1.96\sqrt{\tilde{V} \text{ar}[\ln(MHq)]} \right] 
\]

(18)
\[ MH_{q_0} = \exp \left[ \ln(MHq) + 1.96\sqrt{Var[\ln(MHq)]} \right] \]  

(19)

Similar to the EMNPC and MNPC, it is an advantage of the MHq that the world average has a value of 1. It is a further advantage of the MHq that the result can be expressed as a percentage which is relative to the world average, e.g.: \( MHq = 1.30 \) means that the paper set under study has achieved an impact 30% above average.

Data sets used

Data sets used

We used the papers of the Web of Science (WoS) from our in-house database – derived from the Science Citation Index Expanded (SCI-E), Social Sciences Citation Index (SSCI), and Arts and Humanities Citation Index (AHCI) provided by Clarivate Analytics (formerly the IP and Science business of Thomson Reuters). All papers of the document type “article” with DOI published between 2010 and 2013 were included to study the indicators. Citations with a three-year citation window are retrieved from our in-house database (Glänzel & Schoepflin, 1995). For field classification, we used the overlapping WoS subject categories (Rons, 2012, 2014). In order to avoid statistical and numerical problems, we include only fields in the analysis where (1) at least 10 papers are assigned to and (2) the number of cited and uncited papers is non-zero. In total, these restrictions lead to a dataset including 4,490,998 papers.

We matched the publication data with peers’ recommendations from F1000Prime. F1000Prime is a post-publication peer review system of papers from mainly medical and biological journals. Papers are selected by a peer-nominated global “Faculty” of leading scientists and clinicians who then rate the papers and explain their importance. Thus, only a restricted set of papers from the papers in these disciplines covered is reviewed, and most of the papers are actually not. The Faculty nowadays numbers more than 5,000 experts worldwide. Faculty members can choose and evaluate any paper that interests them. The papers are rated by the Faculty members as “Recommended,” “Must read”, or “Exceptional” which is equivalent to recommendation scores (RSs) of 1, 2, or 3, respectively. Papers can be recommended multiple times. Therefore, we calculated an average RS (\( \bar{FRa} \)):

\[ \bar{FRa} = \frac{1}{i_{\text{max}}} \sum_{i=1}^{i_{\text{max}}} RS_i \]  

(20)

The papers are categorized depending on their \( \bar{FRa} \) value:

- Not recommended papers (Q0): \( \bar{FRa} = 0 \)
- Recommended papers with a rather low average score (Q1): \( 0 < \bar{FRa} \leq 1.0 \)
- Recommended papers with a rather high average score (Q2): \( \bar{FRa} > 1.0 \)

We only included fields where a paper with an F1000Prime recommendation is assigned to, following Waltman and Costas (2014). This reduces the total paper set included in the analysis to 2,873,476 papers.

Empirical analysis

The comparison of indicators with peer evaluation has been widely acknowledged as a way of investigating the convergent validity of metrics (Garfield, 1979; Kreiman & Maunsell, 2011). Convergent validity is the degree to which two measurements of constructs (here: two proxies of scientific quality), which should be theoretically related, are empirically related. Thelwall (2017b) justifies this approach as follows: “if indicators tend to give scores that agree to a large extent with human judgements then it would be reasonable to replace human judgements with them when a decision is not important enough to justify the time necessary for experts to read the articles in question. Indicators can be useful when the value of an assessment is not
great enough to justify the time needed by experts to make human judgements” (p. 4). Several publications investigating the relationship between citations and Research Excellence Framework (REF) outcomes report considerable relationships in several subjects, such as biological science, psychology, and clinical sciences (Butler & McAllister, 2011; Mahdi, d’Este, & Neely, 2008; McKay, 2012; Smith & Eysenck, 2002; Wouters et al., 2015). Similar results were found for the Italian research assessment exercise: “The correlation strength between peer assessment and bibliometric indicators is statistically significant, although not perfect. Moreover, the strength of the association varies across disciplines, and it also depends on the discipline internal coverage of the used bibliometric database” (Franceschet & Costantini, 2011, p. 284). The overview of Bornmann (2011) shows further results on journal peer review, that a higher citation impact of papers is to be expected with better recommendations from peers.

In recent years, the correlation between the F1000Prime RSs and citation impact scores has already been targeted. The results of the regression model of Bornmann (2015) demonstrate that about 40% of publications with RS=1 belong to the 10% most frequently cited papers, compared with about 60% of publications with RS=2 and about 73% of publications with RS=3. Waltman and Costas (2014) found “a clear correlation between F1000 recommendations and citations” (p. 433). The previous results on F1000Prime allow the prognosis, therefore, that citation-based indicators differentiate more or less clearly between the three RSs. In other words, the validity of new indicators can be questioned if the ability to differentiate is not given.

Against this backdrop, we investigate in the current study the ability of the three indicators for zero-inflated count data to differentiate between the RS groups. We start with the newly introduced MHq indicator. Figure 1 shows the MHqs with CIs for the three groups (Q0, Q1, and Q2) across four publication years.

Figure 1. MHqs with CIs for the three groups and four publication years. The horizontal line with MHq=1 is the worldwide average.

It is clearly visible that the MHq values are very different for the three groups which speak for their convergent validity: The mean MHq across the years is close to (but below) 1 for Q0. The mean MHq for Q1 is about eight times and that for Q2 is about 15 times higher than the...
mean MHq for Q0. It seems that the MHq indicator significantly separates between the different quality levels.
However, let us take a closer look at the MHq differences between the groups on the basis of their CIs following the rules of Cumming (2012) and Cumming and Finch (2005). If there is a gap between two CIs in the figure, then the difference is statistically significant ($p<.01$). This is the case for the years 2012 and 2013. Here, the indicator differentiates clearly and statistically significantly between the three groups ($p<.01$). In 2010 and 2011, there is also a statistically significant difference between Q0 and the other two groups. However, the CIs for Q1 and Q2 overlap in 2010 and 2011. If the overlap between the CIs is less than 50%, then the difference is statistically significant on the $p<.05$ level. This rule is reasonably accurate, however, when the two margins of error (length of one arm of a CI) do not differ by more than a factor of 2. The calculation of the overlaps yields an overlap of 43% in 2010 and 57% in 2011. Thus, the difference between the MHqs is statistically not significant in 2011 ($p>.05$). Although the difference is statistically significant in 2010 ($p<.05$), we cannot assume that the rule works accurately, because the two margins of error differ by a factor of 2.1.
The reason for the better result of the MHq in 2012 and 2013 than in 2010 and 2011 might be that 2012 and 2013 contain more uncited papers than 2010 and 2011. As MHq is designed for zero-inflated count data, a better performance can be expected for 2012 and 2013.

Figure 2. MNPC with CIs for the three groups and four publications years. The horizontal line with MNPC=1 is the worldwide average.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure2.png}
\caption{MNPC with CIs for the three groups and four publications years. The horizontal line with MNPC=1 is the worldwide average.}
\end{figure}
Figure 3. EMNPC with CIs for the three groups and four publications years. The horizontal line with EMNPC=1 is the worldwide average.

Figure 2 and Figure 3 show the results for the three groups for MNPC and EMNPC – the two indicators proposed by Thelwall (2017a). For both indicators, it is striking that all values in the graphs are very close to 1 – independent of the group. This is very different to Figure 1, in which the MHq values significantly differ from 1 for the two groups with recommendations (Q1 and Q2). This can be interpreted as a first sign that the MNPC and EMNPC do not differentiate between the quality levels in terms of FFa values.

The CIs in Figure 2 further reveal that the differences between the MNPCs for the different RS values are statistically not significant. There are clear and substantial overlaps for all CIs. The results in Figure 3 are very heterogeneous. In 2010, the mean value of Q2 is lower than the value of Q1. In 2013, the situation is reversed and in the expected direction then. In 2011 and 2012, the mean values are also in the expected direction, but there is a substantial overlap of the CIs (52% in 2012). According to the rules of Cumming (2012) and Cumming and Finch (2005), the differences between the CIs in in both years are statistically not significant.

Discussion

Although the empirical analyses in this study are based on citation data, the objective of the study is on developing indicators for sparse altmetrics data, i.e., zero-inflated altmetrics data. According to Neylon (2014), much of the data we have in altmetrics is sparse. An indicator with many zero values is unlikely to be informative about a scientific unit (e.g., a researcher or institution) in the first place (Thelwall, Kousha, Dinsmore, & Dolby, 2016). Thus, Thelwall (2017a, 2017b) proposed a new family of (meaningful) field- and time normalized indicators which are especially designed for the use with sparse data. The family consists of the EMNPC and MNPC indicators. Basically, the indicators compare the proportion of mentioned papers of a unit with the proportion of mentioned papers in the corresponding fields and publication years (the expected values).

The indicators of the family differ from most of the other indicators which have been proposed in bibliometrics and altmetrics hitherto. The other indicators are calculated for single publications and the user of the indicators can aggregate the indicator values (by averaging, summing, etc.). The indicators of the new family are not calculated for single
publications, but publication sets of groups (e.g., single researchers or institutes). Thus, these indicators cannot be used as flexible as the other bibliometric and altmetric indicators. However, we think that it will never be possible to develop reliable indicators with values for single publications for zero-inflated count data.

In this study, we analyzed the new indicator family empirically and added a further indicator variant – the MHq. We did not include altmetrics data in the empirical part of the study, although the indicator family focusses on them. Before the indicators can be used with altmetrics data, they have to be validated and this can only be done on the basis of citation data. Citation data allows formulating predictions which can be empirically validated with the new indicators. In this study, we tested with citation data whether the indicators are able to differentiate validly between three quality levels – as defined by F1000 RSs (FFa). Thus, we compared the indicator values with ratings by peers: Are the indicators able to discriminate between different quality levels assigned by peers to publications?

For the study, citations with a three-year citation window are retrieved from our in-house database as a compromise between having a significant correlation with quality (in the sense of post-publication peer assessments) and having a data set with rather many not mentioned papers. The results for the EMNPC and MNPC show that they cannot discriminate validly between the different quality levels. The scores for all quality levels are close to 1 (the worldwide average) and the CIs substantially overlap in many comparisons. Thus, the results point out that the convergent validity of the EMNPC and MNPC is not given. In this study, we further introduced the MHq to the new indicator family which is based on the established MH analysis. Since the MHq was able to discriminate empirically between the different quality levels – in most of the cases statistically significant – the convergent validity of the new variant seems to be given.

This study follows the important initiative of Thelwall (2017a, 2017b) to design new indicators for sparse data. Our study was the first independent attempt to investigate this indicator family empirically. Since this family is important especially for altmetrics data, we need further empirical studies which focus, e.g., on more sparse data than we used. Future empirical studies should investigate the new indicator family in other disciplines than biomedicine. F1000 focuses on the biomedical literature only.

M-Score: An Indicator Quantifying Individual's Scientific Research Output

Fei Shu

Abstract
This study introduces a new bibliometric indicator, m-score, quantifying individual’s scientific research output. m-score is based on the initiative of h-index using a single number to measure research performance but overcome its inconsistency in measurement. Comparing with the h-index, the m-score can measure research performance more consistently and accurately with the combination of the productivity and the quality.

Introduction
The h-index (Hirsch, 2005) was introduced by American physicist Jorge E. Hirsch in 2005. The index h is defined as “the number of papers with citation number ≥ h, as a useful index to characterize the scientific output of a researcher” (Hirsch, 2005, p. 16569). It is undoubtedly popular to use a single number to represent both the productivity and the quality of research (Bornmann, 2014) so that the h-index has been a popular research front in bibliometrics and scientometrics since its birth. As Figure 1 shows, Hirsch’s paper has been highly cited in the past 10 years; and a lot of variants of the h-index have also been developed (Alonso, Cabrerizo, Herrera-Viedma, & Herrera, 2010; Egghe, 2006; Jin, Liang, Rousseau, & Egghe, 2007; Lando & Bertoli-Barsotti, 2014; Ruane & Tol, 2008; Todeschini, 2011; Wan & Liu, 2014; Yan, Ding, & Sugimoto, 2011). On the other hand, it has been questioned by bibliometricians whether this single number could measure the research performance consistently and accurately (Bornmann, 2014; Bornmann, Mutz, & Daniel, 2008; Waltman & van Eck, 2012). The interest in the h-Index as well as its other derivatives has been declining since 2010 in Library and Information Science (LIS) as the proportion of citing papers from LIS literature has been decreasing as also shown in Figure 1.
Research Problem

Although Hirsch declares that the h-index could measure the impact of an individual’s research performance combining the productivity with the quality, and avoid the disadvantages of some existing indicators (e.g. total number of citations is too sensitive to few highly cited papers), the h-index does not take account of the disciplinary bias in terms of the citation rate and the influence of the academic age (Bornmann, 2014). In addition, it has been proved that the h-index might produce inconsistent ranking due to its arbitrariness (Waltman & van Eck, 2012).

As Waltman and van Eck (2012) argue, the h-index could be defined as “a scientist has an h-index of h if h of his publications each have at least 2h citations and his remaining publications each have fewer than 2(h+1) citations” or “A scientist has an h-index of h if h of his publications each have at least h/2 citations and his remaining publications each have fewer than (h+1)/2 citations” (p. 408), but these alternative definitions may lead to inconsistent results when calculating the h. As Figure 2 shows, scholar A has more publications (P) and receives more citations (C) compared with scholar B, but A’s h-index (11) is lower than B’s (12). Meanwhile, a contrary result may be returned when using either alternative definition mentioned by Waltman and van Eck as indicated in Figure 2. Indeed, every definition regarding calculating the h is arbitrary because the number of publications and the number of citations are two independent entities.

The purpose of this study is to try to develop a new indicator that use a single number use a single number to represent both the productivity and the quality of research. This new indicator could address all inconsistent issues of h-index and provide a more consistent and accurate measurement.

Figure 2. The inconsistency of the h-index in an example
**m-score**

For consistently and accurately measuring the research output, I propose a new indicator, m-score (m), defined as the maximum value of $m = \log_{10}(P) \times \log_{10}(C)$ where the number of publication (P) each has at least C citations.

As Figure 3 shows, for each scholar, we can present her/his research output in a citation-publication curve; every point on the curve represents that the scholar has P publications that were cited at least C times. In each given point B on the curve, the rectangle CBPO represents her/his research impact when the scholar has P publications that were cited at least C times. Based on the rectangle CBPO, we also can present a triangle 2C-2P-O that is exactly twice as big as the rectangle CBPO. The triangle 2C-2P-O can cover most of the research impact except for the two tails of the citation-publication curve that represent those highly cited papers and lowly cited or uncited papers, which may inflate the measurement of research output when simply counting the number of citations or publications (Hirsch, 2005). Since the m-score is calculated based on the area of the rectangle CBPO, it can avoid this inflation by excluding the both tails of the citation-publication curve.

**Figure 3. m-score and citation-publication curve**

In addition, comparing to the h-index arbitrarily requiring that P should be equal to C in calculation, m-score tries to reflect the maximum research impact with the combination of P and C as calculating the maximum value of the area of the rectangle CBPO. Even so one or

---

1 Please note that m-score is different from m-index, which is a variant of h-index where the lengths of academic careers was taken into account.
several extreme highly cited papers still could inflate the measurement. To avoid the inflation due to the outlier(s), we use the logarithms of both P and C instead of the absolute numbers when computing the m-score. All in all, the m-score measures the research impact based on a large group of frequently cited papers.

The computing of m-score is as follows: 1) rank the scholar’s publications based on the number of citations received in descending order; 2) assign the P value and C value representing the scholar has P publications that were cited at least C times; 3) produce the m as $m = \log_{10}(P) \times \log_{10}(C)$; 4) select the maximum value of m as the m-score. For example, 28 out of 32 papers published by Howard White (Drexel University) receive at least one citation. We ranked these publications in terms of the number of citations received and get the P value and C value representing the scholar has P publications that were cited at least C times as shown in Table 1. We also calculated the m as $m = \log_{10}(P) \times \log_{10}(C)$. The maximum value of m is 2,463 representing White has 16 papers that were cited at least 20 times.

Discussion and Conclusion

A test comparing the m-score with the h-index was conducted. Ten top LIS scholars were selected from the list provided by Cronin and Meho (2006) using the h-index to rank influential information Scientists. The number of their publications, the total citations they received, and their h-indexes were retrieved from the Scopus database. As Table 2 shows, although the rank by m-score is similar to the rank by h-index, the m-score could differentiate their research performance better than the h-index while there are three tie in the h-index of 23 and two tie in the h-index of 19. Also, the m-score favours scholars with a large set of frequently cited papers rather than a small number of highly cited papers. For example, McCain has more publications and receives more citations than Fidel but her m-score is lower than Fidel. McCain’s advantage in citation comes from a highly cited paper receiving 532 citations while Fidel’s most highly cited paper were cited 225 times. When the influence of the highly cited papers was excluded, Fidel has 11 papers receiving at least 46 citations while McCain only has 10 papers that were cited at least 33 times. Thus, Fidel’s m-score is higher than McCain’s.

In summary, this study proposes a new indicator, m-score, based on Hirsch’s initiative using a single number to measure research output. As the preliminary test indicate, compared with the h-index, the m-score could measure the research output more consistently and accurately with the combination of the productivity and the quality. In the future, the m-score should be tested in large and various data sets for its validity and reliability.

Abstract
In this paper observes discrimination of the well-known indices, H-index and G-index. There are many
definitions of impact of the researchers in the literature, such as citations, patents, books, source codes of the
open source, and social media. H-index is an alternative tool to measure performance of the researchers. Because
most of the database indexers use H-index to provide the figure of the researcher performance, so that H-index
many used for comparing the study progress among students or for considering research funding. On the other
hand, it was found that H-index has some weaknesses for calculating the researchers who have a few papers with
the high number of citations, and those with more papers but few citations. Many proposals suggested index
variants to improve the H-index calculation method. No other indices substitute the H-index, because the
 correlation of the other indices to the H-index is still relatively high. In this work, we propose a
discrimination tool to show the discriminate of the H-index. The discrimination tool method based on Jain’s
fairness index. Two indexing methods H-index and G-index are used as samples to compare the discrimination.
To prove the effectiveness of the propose method uses the citation set data of 1,000 researchers gained from
Scopus by application programming interface (API). We find that the discrimination of the H-index has the
average of 23.16% and 14.66% for G-Index for H-index range 1-216. We find that the discriminator tool as an
alternative tool for accommodating the discrimination calculation of the indices.

Keywords: discrimination, indices, H-index, G-index.

Conference Topic
Indicators

1. Introduction
The use of the citation records of research results has grown rapidly. This condition is a
portion of the contribution of the database indexers such as Thomson Reuters Web of Science
(WoS), Scopus, Google Scholar, Microsoft Academic Graph, Directory of Open Access
Journals (DOAJ), Connecting Repositories (CORE) and others. The Indexing system is to
identify papers in journals, conference proceedings, and institutional repositories. Scopus,
WoS, and Google Scholar use H-index to measure the productivity of researchers. Hirsch in
2005 proposed the combination of paper number and citation number to calculate the index
value of the researcher widely known as H-index (Hirsch, 2005). Despite a lot of proposals
have been submitted for improving the H-index calculation method, at the 10th anniversary of
the H-index, this method it is still used to measure the performance of researchers (Bornmann,
2011). H-index is also used to measure the credibility of a journal (Schubert & Glanzel, 2007)
(Science & Leuven, 2006)(Torra & Narukawa, 2008). H-index is as well used to justify
research funds granting and compare students' progress (Kreiner, 2016).

H-index has been identified with some weaknesses. In 2011, Lutz Bornmann stated that those
beginners in research are having difficulty to get citation. On the other hand, for senior
researchers with a lot of publications will have their citation number continue to grow
although they are no longer producing paper (Bornmann, 2011). Radko Mesiar in 2016, stated
that H-index was not sensitive to the condition in which the researcher has the large number
of papers with a small number of citations namely big produce researchers (Gagolewski & Grzegorzelowski, 2009). This is also the case with researchers with a small number of papers with a huge number of citations namely perfectionist researchers (Mesiar & Gagolewski, 2016). Alonso in 2009 stated that H-index could not be used to compare a senior researcher with a new one. For beginner researchers, the addition of citations will not significantly raise their H-index (Alonso, Cabrerizob, Herrera-Viedmac, & F.Herrera, 2009). Egghe in 2006 stated that to measure the performance of a researcher, one could consider the overall number of citations obtained, especially for highly cited papers (Egghe, 2006). Quentin L. Burrell in 2013 used a standard size–frequency distribution to compare H-index and G-index. They also showed that the top cited paper is not significantly contributed to the H-index value (Burrell, 2013). Bornman, in 2011 compared the H-index and their varians by using meta-analysis study. He stated that the H-index, and its family have the mean correlation coefficient that varies between 0.8-0.9 (Bornmann, 2011).The H-index method is based on the number of citations and the number of papers. Another index is G-index method, which is based on the Lotka’s Law. Both of methods became calculation index useful tools to indicate the achievement of researchers' performance.

The definition of fairness in Cambridge Dictionary is “the quality of treating people equally or in a way that is right or reasonable” (Cambridge, 2017). In this work, the fairness of the indices method based on Jain’s fairness index method. The definition of fairness index was introduced by Raj Jain in 1984, which is a function to calculate the fairness value.

Objectives and Method
From literatures, we found that the H-index is insensitive to calculate authors who have a few papers with a high number of citations, and those with more papers but fewer citations. So we need to measure the fairness index for the H-index and variants method.

The aim of this work is to find parameters and a method to measure the discrimination index of H-index and variants, based on the fairness using Jain’s method. We performed some experiments using data, which is gained from Scopus for selected researchers' data. The list of the author name gained from the webometrics of the ranking of researchers page.

To provide the figure of the discrimination for this work, we used the calculation comparison sample of the H-index calculation value. The parameters to be compared are citation, geometric area, and the number of the papers.

For example, we have citation set data of two researchers A and B. The researcher A has higher index than the index of the researcher B, although the geometric area of the citation set of A is lower than the citation set of B. The discrimination index of B will a higher than the discrimination index of A, because the index result of B is lower than the index of A. Figure 2 shows the comparison of H-index from the citation set data. Data set is gained from the Scopus database 9 February 2017.

Figure 2. shows that Egghe has the H-index of 24 which is lower than that of Sangwal's H-index (26), although the top cited papers and the number of papers of Egghe more than Sangwal. So that is the term of the discrimination is used. Therefore, it is important to measure the level of discrimination of the indices' method. Finally, we can say that the discrimination index is the difference tolerance degree on the index calculation method. On the occasion where index value has a smaller discrimination index, meaning that is closer to
the fairly index value. In Figure 2, we can see the bias that the top cited paper of citations set data of Egghe is more than Sangwal, but the H-index of Sangwal, which is 26 is higher than index of Egghe (24). The first hypothesis is that the highest citation number of paper of an author does not correlate directly with the high value of H-index. The second hypothesis is that the number of indexed papers on the lower side of the H-index-line does not contribute to the increase of the H-index.

Figure 2. H-index Comparison of the citation set data of the Sangwal and Egghe publications.

Bornmann in 2011 stated that a paper with no citation cannot increase the H-index value (Bornmann, 2011). Formerly, Egghe in 2006 expressed that the top cited paper is important to calculate the researcher performance (Egghe, 2006). Furthermore the performance of an author should consider the area of the lower and higher side of the H-index-line. This work describes the important aspect of the discrimination measurement to provide the fairness for researchers performance calculation. Calculation method has been considered for calculating the top cited articles. We noted some problems in the calculation of an author index. Condition in which new papers are not cited and therefore have a low citation number. Afterwards, for improving the sensitivity of the indices on the next research, firstly, we require to design a measurement tool to calculate the level of discrimination.

The discrimination index value is obtained from some vectors such as the absolute and real vector obtained (Jain et al., 1984). It has a value between 0 and 1. The discrimination index is the opposite of the fairness index (Jain et al., 1984).

\[
\text{Discrimination Index} = 1 - \text{Fairness Index} \quad (1)
\]

The definition of fairness index here is perceived as a factor of fairness received and represented into a number of properties (Jain et al., 1984). Fairness index can be calculated as follows:

\[
f(x) = \frac{\sum_{i=1}^{n} x_i}{N \sum_{i=1}^{n} x_i^2} \quad \text{where} \quad x_i \geq 0 \quad (2)
\]
H-index Method
To calculate the H-index value, we use Choquet and Sugeno integral approach. The method explain as follows. The membership function expressed the degree of membership in a set. The value of this function is the interval \([0,1]\), and is expressed as \(\mu_A\).

\[\mu_A: x \rightarrow [0, 1]\] (3)

The membership function expressed as \(\mu_A(y)\) valued as 1, if \(x\) is a full member of the set \(A\). Meanwhile if the degree of membeship is in the interval of 0 and 1, for example \(\mu_A(y) = \mu\), and \(y\) expressed as the member of the set \(A\) with the membership degree of \(\mu\) (Zadeh, 1965). Fuzzy integrals are defined as a function at a reference value of \(X\), where \(X = \{y_1,y_2,...,y_n\}\), is a finite reference set of the papers (Torra & Narukawa, 2008).

Then the pair is set sequentially stating the fuzzy sets of:

\[A = \{(x_1, \mu_A(x_1)), (x_2, \mu_A(x_2)), ..., (x_n, \mu_A(x_n))\}\] (6)

Vicence Torra in 2008 defined that the h-index can be approximated by the Fuzzy equation the Sugeno and Choquet Integral approaches (Torra & Narukawa, 2008).

**H-index** is a function of \(X : S \rightarrow \mathbb{R}\), so that

\[X(y_1, ..., y_n) = \{\max\{h = 1, ..., n: y_h \geq h\} \text{ jikai } y_1 \geq 1, \} \text{ otherwise} \] (7)

The number of citation (JS)-index is defined as the number of citation of author \(p\). \(Y_p\) is a set of papers owned by \(p\) while \(f(y)\) is the set of citations of paper \(x \in Y_p\). Therefore \(JS_p\) is defined as (Torra & Narukawa, 2008):

\[JS_p = \sum_{x \in Y_p} f(x)\] (8)

a researcher has an h-index \(h\), if \(h\) is the number of papers cited as a number as \(h\) per paper. Using \(Y_p\) and \(f\) definition above, the h-index calculation of the researcher \(p\) can be written as:

\[h_p = \max_i \min_j (f(x_{\partial(i)}), j)\] (9)

where \(\{\partial(1), ..., \partial(N)\}\) is a permutation of \(\{1, ..., N\}\), therefore \(f(x_{\partial(1)}) \geq f(x_{\partial(2)}) \geq \cdots \geq f(x_{\partial(N)})\). Algorithm 1. shows the H-index calculation algorithm which is defined based on the Choquet and Sugeno integral approaches. The result calculation of the H-index method based on the methods approaches significantly same as the H-index result of the Scopus.

G-index Method
The g value on the G-index method is the highest number of papers with the number of citations. This is greater than the square of the paper numbers, that is ordered by the sequence number of the papers sorted from those with the largest to smallest citation (Burrell, 2009). G-index theory was introduced by Leo Egghe in 2006, to fix the h-index of Hirsch (2005). The measurements are taken from the G-index of citations is obtained, “g-index is the largest number of citations of articles \(g\) with papers that has been highly cited at least \(g^2\)”. It has been demonstrated that the value of \(g\) is unique for each set of articles, and therefore it is obtained that \(g \geq h\) [9]. G-index method has been applied to the data of the work of researchers, and the result comparison of the g of the G-index is correlated with the h of H-index (Bornmann, 2011)(Egghe, 2006). G-index takes into account the number of papers, which have the top citation.

```

The general formula Lotka’s Law used in g-index is shown in equation (10):

\[
g = \left( \frac{\alpha-1}{\alpha-2} \right)^{\frac{\alpha-1}{\alpha}} \frac{1}{T^{\alpha}}
\]  

(10)

The calculation results of the algorithm was compare the result in the Egghe method (Egghe, 2006) that the result is same value.

Figure 3. shows the representation of the G-index calculation based on Lotka’s Law. Lotka’s Law in which \( \alpha > 2 \) is the exponent of Lotkaian and \( T \) is the number of data sources. G-index method has been applied to the data of the work of Nobel laureates, and the comparison result that the \( g \) of the G-index has the correlation with the \( h \) of H-index (Bornmann, 2011)(Egghe, 2006). G-index takes into account the number of papers, which have the top citation. The G-index has a strong correlation with the H-index. Therefore, G-index is used for comparing the H-index in order to make the measurement tools of fairness index to this work. Algorithm 2. shows the G-index calculation algorithm which is based on the Lotka’s Law.

Our discrimination index method can be explain as follows:

1. Getting list of the author name from the webometrics site.
2. Querying Scopus ID of the authors from Scopus database using application
programming interface (API).
3. Parsing the data.
4. Querying the authors’ paper id of each author id.
5. Querying the number of citation of each paper id of the authors.
6. Calculating the H-index and G-index.
7. Obtaining the default value of the author H-index area. For example an author within an index of 7. It means that the default value of the total number of papers cited is 7, and the citation number 7 for each papers.
8. Calculating the geometric area of each author data,
9. Calculating the total number of the paper cited.
10. Calculating the discrimination index of authors.
11. Representing the result.

Table 1. shows the comparison of the calculation the H-index and G-index from the citation set data of the author name Egghe (accessed 9 December 2016 from Scopus). H-index value of 21 and G-index value of 36 for Egghe citation set data. Jain’s method measure the fairness index of resources allocation. The resources to evaluate the researcher performance is the total number of paper citation, the total number of paper indexed and area of the author data in the H-index graph. Jain method is chosen because it has advantages that it can be implemented on unlimited data and have an independent scale as the unit of measurement, bounded value of 0 and 1, It also has the continuous characteristic that can be presented by the percentage. The method can detect the slightest changes (continuous) that is appropriate to be applied to measure the discrimination value.

Algorithm 2. The G-index calculation algorithm based on Lotka’s Law

```plaintext

TC = Total Citation, the number of citation
r = the number of paper (ordered by highest to lowest citation)
ΣTC = Sum of TCᵢ + TCᵢ₋₁, r² = square of r
Range numbers of 3 – 18 and 25 – 33 are not written to shorten the table.

The source data of the citation set data gained from the Scopus databases of 1000 world top scientists of the webometrics (February 2017). Each query maximum 200 counts and default 25 maximum query. The quota of the maximum query 20,000 each 7 days on the Scopus Data. The data used in this work is 1000 world top scientists of the webometrics version, and 500 papers of each. We make a query program for querying by Python language. The index fairness can be defined as:

Discrimination index is provided by:

\[
discrimination = (1 - fairness \ index) \times 100\%
\]  

(11)

Resources allocation in this work are defined as resources as 1) the index value, 2) the number
of the cited papers, and 3) the Geometric area. The Geometric Area (GA) is the sum of the papers and citations multiplication. The areas identified as number as figure 1 are used as the base of our calculation. Fairness is an important performance criterion in all resource allocations (Jain, Chiu, & Hawe, 1984). Figure 1 shows the sample of the geometric area of a researcher. The GA is sum of the areas a,b,1,b,1,b,2,c,1,c,2,d,1,d,2,e,1,e,2,f,1,f,2,g, and h.

\[ GA = a + (b_1 + b_2) + (c_1 + c_2) + (d_1 + d_2) + (e_1 + e_2) + f_1 + f_2 + g + h \]  

(4)

Figure 1. The geometric area (GA) of the citation data set of the researcher.

The Geometric area of the researchers can be written as follows:

\[ GA = \sum_{i=1}^{n}(x_i + (0.5 * y_i)), \text{ where } y_i = x_{i-1} - x_i \]  

(5)

in which \( x_i \) = the number of citation of the paper-i

We proposed the parameters for calculating the discrimination index as follows:

1. \( \alpha_t \) is the geometric area (GA) of the author data. While the default of the GA of the index value is \( \alpha_\circ \).
   The \( \alpha_t \) value is the GA of the citation set data of the authors, and the \( \alpha_\circ \) is the value of the default GA or the square of the H-index. For example the \( \alpha_\circ \) H-index of 7 is 49 and. Each the default GA depend on the H-index value.

The Geometric are of the researchers can be written as follows:

\[ GA = \sum_{i=1}^{n}(x_i + (0.5 * y_i)), \text{ where } y_i = x_{i-1} - x_i \]  

(12)

\( x_i \) = the number of citation of the paper-i

2. \( \beta_t \) is the H-index or the other indices value of the authors and \( \beta_\circ \) is the index value of the H-index from the citation set data of the authors.

3. Total number of the paper cited is \( \gamma_t \) and the default number of paper cited is \( \gamma_\circ \). The default number of paper cited depends on the H-index value, for example \( \gamma_\circ \) =7, if the number cited of the paper of 7. Likewise \( \gamma_\circ \) = 10, for the number of the cited papers of 10.

Discrimination index can be calculated as:
\[ \text{Discrimination index} = 1 - \left( \frac{|\alpha + \beta + \gamma|^2}{3 + (\alpha^2 + \beta^2 + \gamma^2)} \right) \]  

\[ \alpha = \alpha_t / \alpha_o \]  

\[ \beta = \beta_t / \beta_o \]  

\[ \gamma = \gamma_t / \gamma_o \]  

For sample case of the discrimination index calculation of two researcher A and B explain as follows. For example, the citation set data of author A with 6 papers with citation set \((6,5,4,3,2,1)\), the citation set data of author B with 4 papers with citation set \((4,4,4,4)\). The authors has same H-index of 4.

The default citation set for each paper of H-index 4 is \((4,4,4,4)\).

1. Discrimination index calculation Author of A:

\[ \alpha_t = (6 + (5 + 0.5) + (4 + 0.5) + (3 + 0.5) + (2 + 0.5) + (1 + 0.5)) = 23.5 \]

\[ \alpha_o = 4^2 = 16 \]

\[ \beta_t = 4; \beta_o = 4 \]

\[ \gamma_t = 6; \gamma_o = 4 \]

\[ \alpha = \frac{23.5}{16} = 1.47 \]

\[ \beta = \frac{4}{4} = 4 \]

\[ \gamma = \frac{6}{4} = 1.5 \]

\[ \text{discrimination index} = (1 - \left( \frac{(1.47 + 4 + 1.5)^2}{3 + (1.47^2 + 4^2 + 1.5^2)} \right) = 1 - 0.79 = 0.21 = 21\% \]

Therfore discrimination Index for author A = 21\%.

2. Discrimination index calculation Author B:

\[ \alpha_t = (4 + 4 + 4 + 4) = 16 \]

\[ \alpha_o = 4^2 = 16 \]

\[ \beta_t = 4; \beta_o = 4 \]

\[ \gamma_t = 4; \gamma_o = 4 \]

\[ \alpha = \frac{16}{16} = 1 \]

\[ \beta = \frac{4}{4} = 1 \]

\[ \gamma = \frac{4}{4} = 1 \]

\[ \text{discrimination index} = (1 - \left( \frac{(1 + 1 + 1)^2}{3 + (1^2 + 1^2 + 1^2)} \right) = 0 = 0\% \]

Therefore discrimination Index for author B = 0\%, or absolutely fair.

**Result and Discussion**

We find that the discrimination index of the H-index ranges from 1-80 and 181-216 of H-indexes are higher than the range 81-161 of H-index. Table 1 shows that the discrimination index range 1-80 and 181-216 have 25-36\%. It means that the H-index method insensitive for the researcher with small number of papers with huge number of citations (Bornmann, 2011)(Torra & Narukawa, 2008)(Egghe, 2006).

It was found that the measurement of the discrimination related with higher value for the H-index range 1-80 and 182-216 than the H-index range 81-180. The results demonstrated that the lower and upper areas of the H-index for researcher usually has a fairly wide area.
However this is not contributing to the H-index. The mean index of discrimination for the H-index are 25% and 19% for the G-index. The H-index discrimination is higher than the G-index. The research result of the index value discrimination of G-index is lower than for H-index. The discrimination index of the G-index is lower than H-index, this finding correlated with the G-index that has considered those top cited papers of the authors.

</tbody>
</table>

Figure 4. shows that both indices have the same pattern that is relatively high on the range of the H-index 1-80, this mean the measurement method for the calculation index should be improved to get more sensitive for author that has more paper and low citation.
Conclusion
It was found that the discrimination occurs especially in terms of the citation set data of the big produce researchers and perfectionist researchers. The data processed involves three parameters, namely: the index value obtained, the geometric area, and the number of the cited papers. The method can be used to measure the level of fairness for the H-index and G-index. This approach of the discrimination index can be used to compare the insensitivity and discrimination of those well known indices. The mean values from the H-index discrimination calculation from the existing data are 23.16 % for H-index and 14.66 % for G-Index. Therefore the G-index and H-index should be improved to get a fairer result.

Abstract

Based on some heuristic methods, this study improved the credit allocation in three aspects. For one thing, combining the authors' self-citation with the co-cited publications; secondly, employing different allocation rules to different range of authors' number; lastly, comparing the research experience of authors with the content of the target article. The improved model has been compared with several methods by statistical analysis. The main conclusions are as follows: 1) considering the co-citation, the methods based on the signature order are greatly improved at a confidence level of 90%; 2) self-citation can make up for the lack of the co-citation; 3) the content matching has a significant impact on the credit allocation at a confidence level of 97%. Therefore, under the premise of reasonable results, the "co-citation + self-citation + research content matching” model can effectively improve the credit allocation method.

Conference Topic

The application of informetrics on evaluation; co-authorship credit allocation; content matching; co-citation.; self-citation.

Introduction

Allocating credit among co-authors of a publication is a basic issue to many scientometric studies, such as the academic impact of researchers, and the capacity evaluation of institutes or countries. However, there are some problems that cannot be overlooked, which making the research challenging:

(1) Differences in authors’ signature rules. In some disiplines, the authors who sign in the first place tend to receive more attention(Van Praag M & Van Praag B M S,2007), and the order of the authors' signature usually determines how much the author earns, and in other disiplines, the authors' signature is only in alphabetical order, such as high-energy physics(Blaise Cronin,2001). Besides, even in the same displine that may be different (Joseph K & Laband D N & Patil V, 2005). Therefore, although there are many credit allocation algorithms developed based on the signature order, no one can cover all the rules.

(2) "Hyperauthorship" phenomenon. In recent years, the number of articles more than 50 authors has been significantly increased, especially greater than 1000, which is common in the field of biomedical and high-energy physics. Blaise Cronin (2001) has proposed a new concept on this phenomenon - "hyperauthorship", which means massive authorship levels. The emergence of this new phenomenon has changed authors’ cooperation mode (Birnholtz J P, 2006): the contribution unit is no longer a single author, but the group - institutions or country. Cronin pointed out that it is very difficult to assess the contribution of a person to an
article under this phenomenon, as we cannot figure out which author is dominant. Now for "hyperauthorship" article, credit is generally based on the average allocation, such as SCOAP3’s method (Krause J & Lindqvist C M & Mele S, 2007). But this distribution is also biased. Birnholtz J P (2006) stated that there are many authors in the "hyperauthorship" articles but are not involved in specific work in the researchers' interview, in this case, give the same credit to all people is obviously unfair. So it needs to explore a new way to measure the contribution in the case of "hyperauthorship".

This issue keeps undetermined currently. Some studies heuristically mapped the contribution of authors to their signature order. Yet there is no agreement on the signature rule in different disciplines or even in one discipline. Some used the citing relation to evaluate the author. But not all the citation is valid for the discussed article. Some highlighted the credit of the authors of an article who had publications on similar subjects. Yet these publications were usually located by the citing articles of the discussed article. If the citing articles may not thoroughly cover the similar publications, or the discussed article was newly published, the method would not work well. So how to find a more reasonable and universal method to allocate the authors’ credit is discussed in the following.

Related work

In the study of credit allocation, two main factors are considered and discussed.

The signature order of author

(1)Some scholars have pointed out that the authors' signatures are now usually arranged in terms of the contribution to the research. This view has been proposed and elaborated by Hodge and Greenberg (1981). Van Praag (2007) elaborated on the benefits of the author who is the first in signature, so people are more willing to put the author of the greatest contribution to the first one. Ludo Waltman (2012) has proved that the majority of the authors are willing to decide the signature order depending on the contribution of authors and authors’ number with such rule presenting an increasing trend, combined with the practical experience and the actual statistics. In addition, there are many algorithms which are based on this rule: Proportional Counting, which was proposed by Hooydonk (1997), in which the credit of each author decline in equal difference by the order; later, Abbas (2011) proposed another method, and this algorithm is more flexible than the Proportional Counting because it adds a mediation parameter that can adjust the decreasing disparity. Such linearly algorithms have its inevitable flaw, for the same order r of the author, the credit will increase first and then decrease with the number of authors increase, which is clearly not consistent with the actual experience. In addition, there are some nonlinear algorithm: Eghe (2000) put forward the Geometric Counting, he believed that this model is more in line with the actual situation than the Arithmetic method; Hagen (2010) proposed Harmonic Counting, which was verified to be the most practical algorithm (without adjustable parameters).

(2)In addition to the rule that signature is ordered by contribution, some scholars (Hodge S E, 1996; Huang M H, 2011; Tove Faber Frandsen & Jeppe Nicolaisen, 2010) mentioned that signature with alphabetical order is also common. This rule is more prominent in certain fields, such as the economy (including finance), high-energy physics and other fields (Ludo Waltman, 2012). Based on this point of view, some of the classical methods are Total Counting and Fractional Counting (Lindsey D, 1980), the former method will cause a significant expansion problem.

(3) In addition, there are many methods which don’t adopt the above two theoretical assumptions. For example, First-author counting, which takes into account only the contribution of the first author and allocates all the credit to the first author, which is clearly unfair to other authors. In CCS (Lukovits I& Vinkler P, 1995), Trueba & Guerrero (2004), and Zhang (2009), the first author and the corresponding author are calculated separately and considered to be same important.
This article has summarized several algorithms based on signature orders, which are often discussed at present, see Table 1:

</tbody>
</table>

**The authority of authors**

The authority of an author in one research field can determine whether he or she has the capability to contribute to the target research. The indicators include the author's output in this field and the citations the target article gained:

1. The output of the author is a very straightforward measurement. Kosmulski M (2012) believe that the higher the output is, the more qualified the author can be. But the rule is unfair to authors who were not productive yet had high quality papers.

2. Compared with the simplicity of the output metrics, citation reflects the impact of an article. Garfield (1972) initially counted the citation for the evaluation of articles or researchers. Later, h-index (Hirsch, 2005) was put forth, which is now quoted in some literature database, such as Web of Science, Scopus, etc. The variants of h-index includes g-index (Egghe L, 2006), c-index (Bras-Amorós M, 2011), s-index (Silagadze Z K, 2009), etc. Besides, there is an algorithm (Pradhan D, 2016) similar to PageRank, the citation by other authors in this field can indirectly reflect author's authority. However, the above method is
more suitable for the evaluation of the authors’ scientific achievements in the whole domain, not in a single article. Wang H, Shen HW, Cheng XQ et al. (2016) pointed out that the authors' credit allocation of an article could be considered in two aspects: the author network and the article network. The difference of them is that an article will be given corresponding gross value according to citation by article network, and equal distribution by author network. They argued that using author network may lead to misallocation of contributions, especially for the authors whose articles are high quality but small quantity.

(3) The co-citation is the extension of the unidirectional citation relation. The utility of co-citation has been mentioned early (Garfield E, 1972; White H D & Mccain K W, 1998), which could be the tools of journal evaluation, or find the experienced author in some domains, and so on. Author co-citation analysis can be used in lots of research, author assessment is one of that, Ding Y & Yan E. (2009) used the co-citation network to rank the authors. Hua-Wei Shen et al. (2014) identified the highest credit author using the co-citation of Nobel candidate articles, the special part of which is the assessment in a single article, and the combination with the methods based on the signature order. For convenience, we call it co-cited model.

**Model based on co-cited articles**

**Model description**

The co-cited model was proposed by Hua-Wei S et al. (2014). In this model, one author will be given a basic value basing on Fractional Counting in the discussed article, then the final value will be the sum of the credits in the co-cited articles of this author. Finally allocate the credit depending on the proportion of each author’s final value. They validate the method by identifying the authors of Nobel-winning articles that are credited for the discovery. The method’s accuracy achieved about 75%.

**Model analysis of advantages and disadvantages**

(1)The advantage of using co-cited articles: firstly, co-citation can aggregate the literature with similar content; secondly, it can expand the time of relevant document, reference or citation can only appear on the unilateral side of the target document (before the target document or after), and the co-citations can cover the entire time axis.

(2)The co-cited model adopted Fractional Counting as the basic credit calculation. Although this algorithm can reduce the burden of calculation to a certain extent and avoid the extremely uneven distribution when it cannot judge the ranking intention. So how to adopt fit algorithm needs further consideration.

(3)The co-cited articles play a role of the aggregation of similar content literature. But the model only uses its co-citation "Frequency", apart from that, is there any other properties can be used to measure the importance?

(4)The primary condition of co-cited model is that there are a certain amount of citations. When the number of citations of the target literature is insufficient, the model cannot work well. So for the literature with less co-citations, what methods can make up for this defect?

**The improvement to co-cited model**

Based on the articles with different range of authors' number in the field of high energy physics, this research developed the co-cited model, and compare with the original co-cited model and several algorithms based on signature order, for convenience, algorithms solely based on signature order can be called as traditional methods.

The main research questions are as follows:

**Question-1** How should the order of authors' signatures be applied to the allocation of contributions, where the articles have different number of co-authors?

**Question-2** How to measure the author's authority over the content? Is there any other ways more reasonable than the original citation model?
Exploration of authors’ signature rules

In order to explore the relationship of authors' signature and the number of authors, this article analyzed 10046 papers from the SCOAP3 open access platform. The data involved a total of 61513 authors, and the largest number of co-authors is 2951 in a single article.

This article compares the real signature order with the simulated order generated by other permutations, like author's alphabetical order, country's alphabetical order, etc. If it is consistent with the real order, it is more likely to be arranged in accordance with the rule. But, the more the number of co-authors, the higher the likelihood of anastomosis:

1. The number of co-authors less than 5: for these articles, most authors’ institutions and countries are the same, and the articles in accordance with the author's alphabetical order take up 72.91% (except for only one author's article). But it may be accidental due to the small number of authors. In this case, the signature law is more difficult to be reflected from the data. It is relatively clear in task allocation, and the gap between the authors should not be so obvious.

2. The number of co-authors is between 5 and 10: 13.21% of the articles that meet the national alphabetical order; 54.19% meet the alphabetical order of the name. In this case, the rule is more pronounced, and the articles by alphabetical order and none is close in number, so we must judge the order rule first and then decide the distribution method. For such literature, leading contributors are relatively significant but not too much, and the gap between non-leading contributors should not be too large.

3. The number of co-authors greater than 10: these articles almost follow the order of a certain type of alphabet, for example, the national order, the name order, the organization order and so on. In this case, the law is clear and single, basically alphabetical order. Because the number of people is too high, this law can be explained. The uniform distribution is a more reasonable algorithm for them in traditional algorithms.

According to the signature rule, the three types of literature are suitable for different traditional algorithms. The rationality is weak if solely depends on signature rules, so it should be supplemented with content correlation.

Principle of model improvement

This article have analyzed the merits and demerits of the original co-cited model. Therefore, our study maintains the advantages of co-cited model and improves its shortcomings. There are still some problems in current methods, the authors proposed some solutions to the following phenomena:

**Phenomena-1** “Hyperauthorship”.

Problem The contribution can’t be allocated to individuals.

Solution Increase the weight of the target author according to co-cited articles; compare the content of the article with the author's research experience.

Basis The phenomenon changes the research mode of cooperation from individuals-individuals to groups-groups; the traditional methods are based on empirical rules, which is not suitable for all situations.

**Phenomena-2** The diversity of signature rules in the articles with medium number of co-authors.

Problem This kind of articles cannot be treated with one method.

Solution In the basic contribution calculation, to judge whether the order of the signature follows the author's name, if it is, adopt the Fractional Counting, otherwise adopt the Harmonic algorithm.

Basis Features of such articles are obvious, easier to judge. (Seen in “Exploration of authors' signature rules”); Harmonic Counting has been proved to be the most realistic in the traditional algorithms without adjustable parameters.

**Phenomena-3** Uncertainty in the signature rules of minor authors' articles.
**Problem** It is difficult to determine the actual rule of signature by the order of the author.

**Solution** In the basic contribution calculation, adopt the Proportional Counting, a typical linearly decreasing algorithm.

**Basis** The contribution and task distribution is rather clear in these articles; most scholars agree that the signature is sorted by the contribution from high to low; compared with the linearly decreasing algorithm, the gap between the authors in the nonlinear algorithm is relatively large, which is not suitable for too few and too many authors.

**Phenomena-4** Not all the citation relationship is valid for the target article.

**Problem** Some citation which has nothing to do with the target content will be included, which led to the allocated contribution in the current literature is not fair and reasonable.

**Solution** After choosing the related articles by co-citation firstly, compare the target content and the authors’ research experience.

**Basis** The citation can aggregate articles roughly, and the content match will make a more detailed distinction between the articles.

**Phenomena-5** Most of the articles have less citations.

**Problem** The total amount being cited is less, or even zero, making the co-cited model’s effectiveness cannot be achieved.

**Solution** On the basis of the co-citation, consider the author’s self-citing relationship.

**Basis** If the other study of the target author can provide reference for the discussed study, the author should be more likely to make a greater contribution to the target article; the number of citations is not influenced by the publication time of the article or the quality of the article, so the source of the reference is more stable for all documents.

**Data collection and description**

The data used in this study was from the Web of Science database, the authors first selected two journals in HEP field, whose article number is large, from the journals obtained by SCOAP3(https://scoap3.org). They are Journal of High Energy Physics and Physics Letters B.

Considering the use of citation data and time lag of citing, so the authors selected the papers with citation times more than 150, published during 2000-2010. The sample capacity of 528, then according to the number of co-authors stratified sampled the seed literature, among which there are 20 for 1 to 4 co-authors, 14 for 5 to 10, 11 for 10 +.

This study involved four sets of data: the seed literature, the citation of the seed literature, the co-citation of the seed literature, and the reference literature of the seed literature. There are 1367 authors in seed sets, and the total citation of seed literature is 14080 times; 973,185 times co-citations, in which there are 105,880 articles.

The downloaded data was involved in the nine fields and explained in Table 2:

**Table 2. The field identifier of WOS data.**

<table>
<thead>
<tr>
<th>Identifier</th>
<th>Description</th>
<th>Identifier</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AF</td>
<td>Full name of the author (by signature)</td>
<td>C1</td>
<td>Address of authors</td>
</tr>

</tr>
<tr>
<td>ID</td>
<td>Additional keywords</td>
<td>DI</td>
<td>Digital object identifier (DOI)</td>
</tr>
<tr>
<td>AB</td>
<td>Abstract</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

DI is the unique identifier of an article, and CR is used to obtain the citation literature of the seed literature. AF and C1 can show the order of the authors’ signature, and the attribution
of organization and nationality(state), and the RP points out the corresponding author, besides, the content of the article can be explained by TI, DE, ID, AB.

This study has used RegexBuddy 4, java programming to preprocess the data. RegexBuddy is widely used for regex expression editing, which is combined with java for the extraction of the required information. Besides, if ID and DE are both missing, from the TI field and AB field to obtain the representative words using TextRank.

The implementation steps of the improved model

(1)First part: The basic contribution’s superposition basing on the co-citation and self-citation.

This part is an improvement to the basic credit of the original co-cited model, and take the self-cited relationship into consideration.

The improved model involves four types of literature sets: T-the seed articles; D-the articles citing T; G-the articles co-citing T; F-the articles cited by T. And the basic term symbolic keep consistent with original co-cited model.

∀t ∈ T:

\[ M_t \] is the set of all authors in t, |\( M_t \)| = \( p \), for \( p_0 \), \( M_{p_0} = \{a_1, a_2, a_3, a_4\} \), |\( M_{p_0} \)| = 4; \( D_t \) is the set of articles citing t; \( G_t \), the terms of which have the similar content with s; \( P_t = D_t \cup G_t \cup F_t \), |\( P_t \)| = q, all literature of \( P_t \) determine the weight of authors in \( M_t \).

Step1 Count citation times of \( P_t \) by \( G_t \), then get s.

Step2 Calculate the basis credit in a single article. The following logical judgments are made for the literature in the \( P_t \), for \( p_0 \):

IF \( \forall p_i \in P_t \) , the author of \( p_i \) is one of the author in \( M_{p_0} \), \( a_k \in M_{p_0} \), r is the order, N is the number of authors in \( p_i \).

IF \( 1 \leq N \leq 4 \)

\[ A_{a_kpi} = C_r = \frac{2 \times (1 - \frac{r}{N+1})}{N}, 1 \leq r \leq N \]

ELSE IF \( 5 \leq N \leq 10 \)

IF signature is ordered by alphabetic

\[ A_{a_kpi} = C_r = \frac{1}{N^r}, 1 \leq r \leq N \]

ELSE

\[ A_{a_kpi} = C_r = \frac{1}{\sum_{i=1}^{N} r}, 1 \leq r \leq N \]

ELSE

\[ A_{a_kpi} = C_r = \frac{1}{N}, 1 \leq r \leq N \]

ELSE

\[ A_{a_kpi} = 0 \]

As for corresponding author, the credit of which should not affect others’ credit, if the basic algorithm is average allocation, the credit of corresponding is double of original, else the credit directly equivalent to the one ranked second (if the first author is corresponding, the credit maintains).

Step3 \( c = A \cdot s \), c is the proportion of credit allocated to every author in \( p_0 \).

(2)Second part: The content matching based on co-citation and self-citation.

This part is to compare the similarity of author’ research experience and the content of target literature. Then according to the similarity allocate the credit:
Step 4 For \( p_{0} \), the set of keywords is \( d_{p_{0}} \), \( a_{k} \in M_{p_{0}} \), the keywords set of \( a_{k} \) is \( b_{a_{k}} \), the keywords of which can be got from \( P_{p_{0}} \);

Step 5 To compress \( b_{a_{k}} \). In order to reduce the cost of the program processing, compress should be carried out before the similarity calculation. The purpose is to remove the similar words in the set, so that the words in the collection cannot replace each other. If \( |b_{a_{k}}| > 50 \), do the compress, \( MIN_{sim} \) was set to be 0.6 at first, the first term of \( b_{a_{k}} \) was added to set \( f_{a_{k}} \), then compare the next term with all the terms of \( f_{a_{k}} \), if one of the similarity of \( b_{a_{k}}[i] > MIN_{sim} \), then add sim to the weight of \( b_{a_{k}}[i] \). If the \( |f_{a_{k}}| > 50 \) after a round, then set \( MIN_{sim} = MIN_{sim} - 0.1 \) and do compress again.

Step 6 To compare the terms of \( f_{a_{k}} \) and \( d_{p_{0}} \), then sum the similarity \( SIM_{a_{k}} \), for \( p_{0} \) \( g_{p_{0}} = \langle SIM_{a_{1}}, SIM_{a_{2}}, SIM_{a_{3}}, SIM_{a_{4}} \rangle \), that is the proportion of allocation.

In this article, the method used in the comparison is based on the semantic similarity of WordNet2.1 dictionary.

(3) Third part: Get the final contribution credit.

This part is to sum the score of former two parts, and get the final credit.

Step 7 for \( p_{0} \), the final credit proportion of \( a_{1}: a_{2}: a_{3}: a_{4} = (c_{p_{0}}[1] + g_{p_{0}}[1]): (c_{p_{0}}[2] + g_{p_{0}}[2]): (c_{p_{0}}[3] + g_{p_{0}}[3]): (c_{p_{0}}[4] + g_{p_{0}}[4]) \).

Result of state contribution based on the improved model

Summing up the authors’ contributions by the state attribution of each author. In order to compare these methods fairly later, the authors standardized the original state contribution value: \( s_{a_{k}} = \frac{MIN_{a_{k}}}{MAX_{a_{k}} - MIN_{a_{k}}} \). See Table 3 for details:

The original co-cited model takes the Fractional Counting and co-cited articles into consideration; the improved model considers the self-citation and co-citation relations in the calculation of the basic contribution, and segmented traditional algorithm, besides, it introduces the thought of content match. Fractional Counting, Harmonic Counting, and Proportional Counting are three typical pure author signature algorithms. The segmented traditional algorithm is a combination of the fractional counting, harmonic Counting,
proportional Counting, which classifies the basic contribution calculation under different situations.

In order to compare the similarity of the results of these algorithms, the authors calculated the national contribution based on different algorithms, and uses the spearman correlation coefficient to measure (using R language).

According to Table 4, the correlation between the new model and several other methods is relatively low, of which thought has a relatively large impact on the results of the national contribution calculation, especially relative to the four traditional algorithms; The results of the Fractional Counting present a line parallel to the x-axis, the Proportional Counting is linearly decreasing line, and the Harmonic Counting is a curve line. The results of the authors’ contributions are different in a single article. However, the correlation between the three algorithms is higher than 96%, which show that although the choice of traditional algorithms is different, the impact to the contribution of states is relatively small, and the impact of the segmentation of traditional algorithm is small too; In general, the difference of the algorithms based on the signature order would be diluted in the process of states’ contribution calculation, but the inclusion of citation and content match can have a greater impact.

(2)Single factor analysis of the contribution to individual authors

1)Self - citation

According to statistics, the target literature involved a total of 1367 authors, the number of self-cited is 2709 times, and an average of 1.98 per author, that is, self-cited relationship can bring the superposition of two articles’ contribution to each author for average, which takes an increase in the original contribution of 36.71 (not a standardized contribution to each document), compare to the pure co-cited model, it brings a total of 5% contribution credit. In conclusion, just refer to the number and additional contribution of self-citation, the self-citation can make up for the lack of co-citation, but in our experiment, because the co-citation of sample is too many, so the effect of self-citation is not obvious.

2)Co-citation

In order to verify the influence of this factor on the allocation of individual authors, the t test (using SPSS) of pair of samples was used to calculate the contribution of 500 random authors based on the results of fractional counting and original co-cited model. The results of the test showed that p = 0.053 <0.1, which shows that co-citation factors have a significant effect on the authors’ distribution of individual documents at a confidence level of 90%.

3) Classification of Three Classification Basic Algorithms

The basic contribution algorithm in the new model is based on the different algorithms of the sub-case. We also select 500 random authors as samples, and set two control variables in the test group (using SPSS): (A) Fractional + Proportional + Harmonic, (B) Fractional + Proportional and (C) Fractional + Harmonic. The test results show that the p value of (A) vs (B) is 0.687, and the p value of (A) vs (C) is 0.998. Therefore, the participation of Proportional and Harmonic algorithms has little effect on the contribution credit of single literature.

4) Research content matching

500 random authors are selected. These two parts contribute to the distribution of the results of the t-test of the paired samples (using SPSS):
Table 5. The t-test of the paired sample in the improved model.

<table>
<thead>
<tr>
<th>Experimental group and control group</th>
<th>Controlled variable</th>
<th>P-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>The improved model(including two parts) VS The improved model(basic contribution superimposed)</td>
<td>The content matching</td>
<td>0.017</td>
</tr>
<tr>
<td>The improved model(including two parts) VS The improved model(content matching)</td>
<td>The basic contribution superimposed</td>
<td>1.000</td>
</tr>
</tbody>
</table>

It can be seen from Table 5 that for the two parts of the improved model, p-value of the content matching factor is less than 0.03, that is, at a confidence level of 97%, content matching can have a very significant effect on the final results of the model. From the comparison of the p-values of the two parts, it can be seen that in the improved model, the content matching factors play a more important role than the basic contribution calculation.

### Conclusion and future work

In this article, 45 articles of high-energy physics field were selected by stratified sampling as the seed set, and the self-cited, citing and co-cited articles were obtained for the seed set. The authors have improved original co-cited model from the following two aspects: first, considering the self-citation and co-citation relations in the calculation of the basic contribution, and classifying the basic contribution calculation under different situations; the second is comparing the research direction of the authors and the subject content of the target document. Finally comparing the similarity and effect of methods.

From the comparison of the methods, each pair of contrast is more than 0.8, we can see that the rationality of these algorithms can be mutually confirmed. The spearman values between the improved model and other methods are the smallest, the impact of the improvement is relatively large; different types of traditional algorithms perform different in a single document, but in the state contribution the similarity of the results is more than 0.96, whose difference is small. Therefore, when the algorithm of national contribution needs to be improved, the effect of traditional algorithm change is not obvious, so it should be more effective in exploring the citation relationship and research content.

As for the single factor analysis: (1) self-citation can bring 1.98 articles to strengthen the author weight in the target article for average. If the article has many co-cited articles, the effect of self-citation would be diluted. But it can make up for the lack of co-citation. (2) The introduction. The matching sample t test shows that the co-citation will have a significant impact on the allocation of authors' contribution at a confidence level of 90%. (3) All traditional algorithms have no obvious effect. In general, the improvement of the algorithm depending the rules of authors' signature is not good, whether for the contribution of state or the single author. (4) Research content matching has a very significant effect on the distribution of individual authors' contributions in the new model, at a confidence level of 97%. The effect of this factor is greater than that the basic contribution calculation.

In conclusion, the experimental results show that the influence of the traditional algorithm on the final effect is not obvious, and the introduction of the common reference is a significant improvement to the traditional algorithm. The self-citation relationship can make up for some literatures. The matching of the research contents has a very significant effect on the author's contribution allocation algorithm. The improved model is able to reflect its own characteristics under the premise of ensuring the rationality of the general trend.

There are some shortcomings in this study hope that future research can be improved: first, to expand the amount of sample data, which can more effectively illustrate the authenticity of the results; second, the universal test in other fields, not limited to the field of high-energy physics; Thirdly, in the research content matching, word vector can be combined to calculate the similarity of the text in the field, so that the matching is more accurate and
professional; Lastly, in this article we did not compare the reality, that can be the assessment of professors in HEP, or the origin authors’ self-evaluation. It’s really a pity for the lack of that, hope the future work will rich the study to validate the model’s effectiveness more comprehensively.

Acknowledgments

Thanks Institute of Scientific and Technical Information of China (ISTIC) for providing SCOAP3 data, which was used in the exploration of authors’ signature rules. And the authors are sincerely grateful for the anonymous reviewers’ advices during the process of paper writing.

Do Patent Citations to Conference Papers Differ from Journal Articles? Evidence of Technological Impact through Google Patents

Ashraf Maleki

Malekiashraf@ut.ac.ir
Master Graduate at Scientometrics, University of Tehran, Iran

Abstract
The research presented in scientific meetings are a major way to maintain the connection between science and technology in most engineering-related fields. However, although conference papers constitute predominant proportion of publications in some disciplines, the extent to which they are able to be cited in patents compared to journal articles is less known. In order to examine this, bibliographic information of a sample of 111,108 Scopus indexed papers including journal articles (53%) and conference papers (47%) across 30 disciplines in two years (1996 and 2006) was searched in Google Patents (GP) using Bing search engine. An ordinary least squares regression model demonstrated that conference papers and journal articles were almost equally predictive of patent uptakes in most fields, suggesting that proceeding can be as important as journal articles if technological value is meant to be assessed. Although patent uptake of both journal articles (2.9%) and conference papers (1.9%) was relatively low, disciplinary differences should also be considered since journal articles are acting better in fields such as biomedical engineering and bioengineering, but conference papers are significantly better in geotechnical engineering, automotive engineering and computer science applications. Furthermore, it takes slightly more years for conference papers than journal articles to be cited in patents.

Conference Topic
Patent Citation Analysis, Altmetrics, conference papers, technological impact

Introduction
Conference proceedings tend to be premier venue when publishing innovative knowledge in line with trendy topics (Chen, Song, & Zhu, 2007) or printing theory-changing breakthroughs (Winnink, Tijssen, & van Raan, 2015). However, due to inconsistent acceptance rate and precision attributed to peer review processes in some scientific meetings (Cabanac & Preuss, 2013), they have been relatively undermined in research impact assessment practice compared to formal journal papers. Both Web of Science and Scopus have improved their conference papers’ citation indexes (http://wokinfo.com/products_tools/multidisciplinary/webofscience; Scopus Content Coverage Guide, 2016), although their coverage might be inconsistent across fields (Bar-Ilan, 2010; Meho & Yang, 2007). However, scholarly citations to conference papers are not prevalent (Michels & Fu, 2014), partly due to authors tendency to cite equivalent articles in periodicals (Lisée, Larivière, & Archambault, 2008). On the other hand, it is also argued that conventional citations might fail to demonstrate actual value associated with proceedings because conference paper are sometimes intended to trigger formal publications (Drott, 1995) and aid scholarly communications unlike the way journal articles do. Some studies presented at scientific meetings maintain the connection between knowledge and application for example in biotechnology (Martens, 1993), or the interaction between industrial and academic researchers such as in microelectronics and software engineering (Meyer-Krahmer & Schmoch, 1998); they are also a significant output to measure productivity of science-based technical projects (Breschi & Malerba, 2011; Garg, Gupta, Jamal, Roy, & Kumar, 2005). In consequence, conference papers are sometimes recognised with more ability to measure technical innovation and novel ideas rather than science production (Montesi & Owen, 2008). However, despite the proposed bibliometric indicators for assessing quality of scientific meetings (Martins,
Gonçalves, Laender, & Ziviani, 2009), a measure to recognise likely technological impact of conference papers is less investigated.

Some bibliometric investigations into proceeding publications tried to identify research topics (Hofer, Smejkal, Bilgin, & Wuehrer, 2010) and potential collaborations in science (Boyack, 2009). Online indicators (altmetrics) was also analysed to assess conference papers’ Mendeley readerships compared with journal articles in engineering-related fields (Aduku, Thelwall, & Kousha, 2017). Furthermore, citations in online conference presentation files was used as evidence of research impact (Thelwall & Kousha, 2008) and tweets posted during conference events were also used to assess scholarly communications in scientific meetings (Weller, Dröge, & Puschmann, 2011). However, few have analysed patent uptake of conference papers as evidence of their technological impact and there has been no multidisciplinary evaluation compared with journal articles. This article partly fills the gap by speculating patent citations to both conference papers and journal articles in 30 scientific disciplines mainly constituting from engineering-related disciplines and some other fields with considerable proportion of literature emerged in conference proceedings. The analysis is conducted using webometric method and through Google Patents searches.

Scholarly Impact of Conference Papers

Given the importance of industry and technological connections in conferences, assessing technological impact of conference papers seems to be important, because in some engineering-related disciplines scientific meetings are leading form of scholarly communications (Goodrum, McCain, Lawrence, & Giles, 2001). A study of ISI proceedings in 1997 through 2005 showed that conference papers constituted up to around 55% of publications in engineering (Glänzel, Schlemmer, Schubert, & Thijs, 2006) and over 70% of 2009 publications in electrical engineering and computers (Michels & Fu, 2014). Some countries such as China had significant growth in terms of number of conference papers in computer sciences, though the growth in citation rate tended to be minimal (He & Guan, 2008). As various studies have pointed out, significant proportion of publications in computer sciences are conference papers (Bar-Ilan, 2010; Vrettas & Sanderson, 2015), and assessing their technological impact perhaps can make sense because some conference papers recognized with leading discoveries in computer science were witnessed without formal citations available (Winnink et al., 2015). This poor reflection of impact might be due to partial coverage in conference citation indexes (Meho & Yang, 2007) as well as different nature of their impact (Drott, 1995; Lisée et al., 2008). However, the extent to which conference papers tend to demonstrate technological value compared to formal journal articles is less known. To address this issue, current research aimed at examining technological value associated with conference papers through patent citations as an alternative indicator of research assessment (Wouters et al., 2015).

Patent impact of Academic Research

Numerous studies have discussed commercial value and technological utility associated with public science through evaluating patent citations to academic research (Meyer, 2000; Narin & Olivastro, 1998; Oppenheim, 2000; Schmoch, 1993), as journal and conference references are found as major constituents of non-patent references. One study on two samples of references in granted patents from 1991 to 2001 estimated proportions of citations to conferences and journals as much as 17% and 55%, respectively, in USPTO, and 34% and 64% in EPO (Callaert, Looy, Verbeek, Debackere, & Thijs, 2006). There is also a lower estimation of conference paper references (5.9% vs. 77.7%) for USPTO Chinese patents in nanotechnology between 1991 and
2008 (Wang & Guan, 2011). Another research did a large-scale estimation of patent uptake for Scopus indexed journal articles between 1996 and 2012 using Bing’s Google Patent search results, finding patent uptake of articles not prevalent, ranging between a mere 3.2% in mechanical engineering and approximately 10% in biomedical engineering (Kousha & Thelwall, 2017). A webometric study recognised that extent of Google Patent (GP) indexed URL references outlinking to academia was able to demonstrate technological influence of US universities (Orduna-Malea, Thelwall, & Kousha, in press). Furthermore, journal articles citations in patents seem to be able to recognise a distinct aspect of research impact relative to conventional citations (Sud & Thelwall, 2014) because they are found in very weak correlations with each other (Kousha & Thelwall, 2017; Tijssen, Buter, & van Leeuwen, 2000).

Research Question

In order to be able to identify whether a particular document type advantages more patent citation both conference papers and journal articles are assessed and compared in relation to Scopus citations and over time. Therefore, current research is driven by below questions:

1. To what extent do conference papers have patent impact in relation to journal articles?
2. In which fields are there disproportionate patent citations to conference papers or journal articles?
3. To what extent patent citations to conference papers and journal articles is in relationship with Scopus citations?
4. How long it takes for patents to cite conference papers compared to journal articles?

Method

In response to research questions, 111,801 sample of records indexed in Scopus, including 59,693 (53%) journal articles and 52,108 (47%) conference papers published in two distinct years of 1996 and 2006, were exported across 30 disciplines by August 2016. The sample included about 1000 records for each year and each document type when possible (Table 2), though due to integrating data with pilot investigations there are more papers tested for some fields such as in industrial engineering. Scopus was used to collect proceeding records, due to its broader coverage of peer-reviewed conference papers compared with Web of Science (Meho & Yang, 2007). In addition, the chosen publication years are both distant enough to accrue patent citations and can make appropriate cases to compare significant changes of each document type over time (see more detailed trends in patent uptake of Scopus indexed journal articles in Kousha and Thelwall, 2017).

So far, variety of limitations were associated with gathering non-patent citations for a large-scale analysis, such as inconsistent formulation of references in patents’ content and variety of term specification for journal titles (see more in Kousha & Thelwall, 2017). Therefore, based on the acceptable accuracy level of results acquired through Bing’s Google Patent searches for collecting patent citations (Kousha & Thelwall, 2017), Google Patents (google.com/patents) was used to gather citations information. For this purpose, bibliographic information of papers was submitted to Bing search engine, formulated in queries as below, including first authors surname, three to ten words in title of work and publication year, and Google Patents website’s URL:

Mandal "Image indexing using moments and wavelets" 1996 site:google.com/patents

Due to specifying source titles in various forms in patent reference, journal and conference titles are not included in the search queries. At the time, September 2016, the data was collected via Webometric Analyst software program (lexiurl.wlv.ac.uk) submitting queries to Bing Search
Identifying Patent Families. Google Patents (GP) claims to cover patents from six major offices (google.com/patents); therefore, its citation results tend to find patents from across variety of offices although majority of results represented US patents (Kousha & Thelwall, 2017). Results also sometimes include patents with repeated content from one patent family (for example two patents of www.google.com/patents/US6622470 and www.google.com/patents/US6910335 in Bing search results for one articles had the same titles and priority dates). Raw patent counts can provide an indicator of technological productivity, however, once many patents are extensions of a similar patent family, using the raw counts is criticized for over representing inventions (Trajtenberg, 1990). Some studies have attempted to avoid the problem of over-counting patents by calculating patent family normalized counts of inventions in company and country levels (Dernis & Khan, 2004; Park & Hingley, 2009), particularly in fields with large patent families such as in pharmaceutics (Messinis, 2011). Therefore, in order to normalize Google Patent citation counts to papers in current research, “Priority date” of citing patents was recognised because a “basic patent family” claims an equal priority date across all patent extensions and equivalents in different countries (“Derwent World Patents Index patent family,” 2017). To do this, firstly, all Bing’s recognized Google Patent pages were crawled and saved using SocSciBot crawler software (socscibot.wlv.ac.uk). Then, using the service of “Extract SocSciBot crawl info” in Webometric Analyst the details of patents was extracted from saved web pages including priority date of patents to recognize patent families and normalize GP counts based on unique families referencing them. In response to forth research question, priority date as well as filing and publication dates of patents were also identified to investigate how long it takes for papers to appear as patent references.

Limitations
One limitation of this method is that titles of conference papers could interfere with non-patent references such as journals articles with similar titles and author. Bar-Ilan (2010) and Michels and Fu (2014) pointed out that publication of conference papers in periodicals lead to problem of double counting papers. Authors of conference papers that have provided a primary source of information usually intend to revise and publish in peer-reviewed periodicals (Drott, 1995), such as about 33% of proceedings at International Society for Informetrics and Scientometrics (Aleixandre-Benavent, González-Alcaide, Miguel-Dasit, Navarro-Molina, & Valderrama-Zurián, 2009). This seems to be important since about one-fourth (approximately 2 million in 7.7 million) of Scopus indexed conference proceedings records are published in special issues of periodicals (Scopus Content Coverage Guide, 2016) which could have influenced results in current research, because source title could not be included in search query (more above). Another issue was the overlap of paper titles with similar patent titles. These patents had older priority date (over 4 years older) than publication date of paper, so they could be recognised and after checking discarded as false results (6.5%). Another limitation is that only two years are checked and results can be influenced by particular events on these years. In addition to this, the differences between documents types in each year were rather inconsistent which can be influenced by changes in topics and focuses of conference events.
Findings

The Google Patents’ searches identified 6,571 patents which referenced overall 2,722 (2.5%) papers, including 1,703 (2.9%) journal articles and 988 (1.9%) conference papers. Based on the priority date of retrieved patents 3,070 (60%) and 2,033 (40%) patent families were recognized, which referenced journal articles and conference papers, respectively. Table 1 demonstrates GP uptake of papers across 30 Scopus subjects for 1996 and 2006 together. The least proportion of journal articles with GP citations was 0.4% (5 papers) in Automotive Engineering and the highest was 12.6% (246) in Biomedical Engineering, while the second highest were just below half this proportion (5.4%) in both Biotechnology (107) and Computer Vision and Pattern Recognition (108). In terms of conference papers, this proportions ranged between 0.3% in three fields of Artificial Intelligence (3), Environmental Engineering (4), and Ceramics and Composites (3) and 4.5% in Computer Vision and Pattern Recognition (91). Table 2 makes comparable the means of GP and Scopus citations across fields. Regarding the whole samples, medians of GP citations were all 0, while the mean of citations ranged between 0.01 and 0.48. In fourteen fields, the difference of average patent uptake of conference papers and journal articles were insignificant, with the highest close averages of GP citations (including zero counts) occurring in Computer Vision and Pattern Recognition (0.10 journal article and .11 conference papers) and the lowest close means in Building and Construction (both .01). Consistent with previous findings (Kousha & Thelwall, 2017), Biomedical Engineering had the highest mean patent uptake of journal articles (0.48), which is found significantly more than conference papers’ average patent uptake (0.06) (Mann-Whitney test significant at p < .001). The second most significant difference was in Computer Graphics and Computer-Aided Design, where journal articles received significantly more GP family normalised counts (0.15, p < .001) than conference papers (0.04). Similarly, in 14 other fields average patent uptake of documents was significantly different (Table 2), while in majority of them (9 fields) patent uptake of journal articles were significantly higher than conference papers. In the remaining five fields conference papers advantaged significantly more GP citations, among which the highest significant differences were apparent in Geotechnical Engineering and Engineering Geology (mean 0.06 conference papers vs. 0.01 articles, Mann-Whitney test significant at p < .001), Automotive Engineering (0.05 vs. 0, p < .001), and Computer Science Applications (0.07 vs. 0.03, p < .01). Furthermore, in most fields differences between patent uptake of document types have been erratic over the years, changing superiority of each document type from 1996 to 2006, however, most significant differences were apparent only in 1996.

In addition to testing difference of means using Mann Whitney test (more above) a regression model was also used to assess whether document type is predictive of patent uptake. For citation data, the ordinary least squares regression model was used as it is recommended on transformed data through natural logarithm of citations +1 (Thelwall, 2016) instead of zero-inflated negative binomial regression model, due to capability to return false influences (Thelwall & Wilson, 2014). After regressing transformed data by using ordinary least squares most significant difference shown in Mann Whitney was repeated with almost similar significance level (Table 2); however, in six fields there were variations. In addition to above results, conference papers in Civil and Structural Engineering as well as Industrial Engineering seemed to advantage significantly more GP citations, whereas journal articles in Signal Processing benefited from significantly more patent uptake (all significant at p < .05). In contrast, Information Systems, Safety, Risk, Reliability and Quality, and Atomic and Molecular Physics, and Optics did not
show significant differences in regression analysis. In terms of Scopus citations, however, consistent with finding from Web of Science’s Science Citation Index (Lisée et al., 2008) there was significantly fewer citations to conference papers than to journal articles across all disciplines ($p < 0.001$).

Correlation between Google Patents and Scopus Citations

Correlation between Scopus and GP citations, shown in Table 2, was very low and slightly high in earlier year. The Spearman’s correlation coefficients were slightly higher in conference papers (ranging between 0.06 and 0.279) than in journal articles (between -0.081 and 0.233), despite inconsistencies. Although in one-third of fields the correlations were not significant in both document types, the highest significant correlations in conference papers were in 1996 Computer Graphics and Computer-Aided Design (r = 0.251, p < 0.01) and 2006 Biophysics (r = 0.279, p < 0.01). In terms of journal articles, the highest correlations were in 1996 Computer Vision and Pattern Recognition (r = 0.233, p < 0.01) and 2006 Bioengineering and Biotechnology (in both r = 0.218, p < 0.01).

Age of Papers by Patent Uptake

Figure 1 indicates age of papers when they were cited in patents (deviation of paper’s publication date from patent’s priority date). Priority date of patents citing about 23% of scholarly papers with Google Patents’ citations were in advance of their publication date. Furthermore, proportions of conference papers cited in patents tended to reach its maximum rate (about 0.7%) 2 years after they were published; however, only about 1 year after they formally appeared to journal articles (about 0.8%). Filing dates were not available in 9.4% (647) of Google Patent pages, though they indicated that it took almost 4 years for journal articles and 6 years for conference papers to maximise as patent references. Publication date of patents indicates that it took about 8 years for most citing patents to be published, although there was
a minor peak for both conference papers and journal articles uptake about 18 years later which obviously relate to 1996 papers and might have been influenced by the granting processes and publication periods of office(s).

Figure 1. Age of conference papers vs. journal article in terms of technological uptake

Discussions and Conclusion

RQ1. Regarding first research question, there was very low uptake of both journal articles (2.9%) and conference papers (1.9%) in patents, while the difference in average of citations (0.06 vs. 0.05 patent citations, respectively) was not significant and overall medians (both 0) and geometric means (0.02) were equal. This suggest that although patent impact constitutes a tiny proportion of research impact, conference papers does not generally appear different from journal articles if technological value of public science is meant to be assessed, and this makes an important evidence as in terms of conventional citations conference papers were significantly disadvantaged form of publication compared to journal articles (Lisée et al., 2008).

RQ2. As addressed in the second research question, the number of fields with disproportionately more patent uptake of one document type was of 30 fields only 14: nine fields with journal articles and 5 with conference papers more advantaged. The broadest difference was shown by Biomedical Engineering where journal articles received disproportionately more patent citations that conference papers. The two fields in which conference papers should be sensitively taken into account when patent impact is being assessed are Geotechnical Engineering and Engineering Geology and Automotive Engineering where journal articles was genuinely playing the least role to influence technology, at least in the years assessed. Computer Science Applications is the next field where still there is a significant patent uptake of conference papers, although journal articles also play a role.

RQ3. With regards to third research question, the relationships between GP and Scopus citations to conference papers was all weak, although slightly stronger than journal articles. The correlations were marginally higher in fields with weaker connection to engineering and more scientific nature such as Biophysics and Biochemistry, whereas consistent with prior research (Kousha & Thelwall, 2017) correlation in more engineering-related fields was very week and usually not significant, likely to suggest the broad difference between research with significantly high technological impact and scholarly influence.

RQ4. Regarding the forth question, as Figure 1 illustrates conference paper uptake in patents peaked slightly afterwards journal articles, which is slightly surprising because conference
papers tend to be published relatively sooner than journal articles. However, this evidence probably reflects that most patentable ideas published in journal articles was being processed along with patenting; whereas, the latency in patent uptake of conference papers might be evidence of freshness of ideas offered through scientific meetings. However, any implication about the patent uptake of scholarly research should be made cautiously, because references of academic papers might be made by examiner rather than inventors due mandatory aspects of involving closely related literature (Jaffe, Trajtenberg, & Fogarty, 2000) and might have less direct involvement in citing patent’s innovative idea (Callaert, Pellens, & Van Looy, 2014).

**Conclusion.** Ultimately, findings are providing the evidence that conference papers can be effectively used along with journal articles in order to assess patent uptake of academic research in most fields. However, despite this statistical evidence, another research is required to speculate how much vigorous are the patent cited ideas in conference papers compared with journal articles. It also should be considered that patent impact of conference papers could become apparent slightly later than they do for journal articles.

Abstract
Governmental initiatives capitalising on multidisciplinary (or interdisciplinary) research are growing in number. They are motivated by the increasingly shared view among academics and policymakers that this mode of research, by favouring innovation in firms, will fuel the economic competitiveness of nations through job creation and increased revenues. However, there is an obvious lack of empirical evidence supporting the connection between multidisciplinary research and innovation. This study partly fills this gap by addressing the following question: Is the knowledge disclosed in a scientific publication more likely to be taken up in innovation (i.e. cited in the patent literature) as its multidisciplinarity index increases? The results thus obtained clearly show, in the aggregates, that multidisciplinarity increases the odds of research results being useful to innovation, thereby supporting existing R&I policy interventions or paving the way for new ones. However, because uptake in innovation, as measured through patent citations to scientific articles, remains a relatively rare phenomenon, multidisciplinary research is not an effective predictor of an individual article being useful to innovation; science is experimental, and the innovation outcome of an individual project cannot be guaranteed ahead of time merely through the extent of disciplinary mixing among the participating researchers.

Conference topic
Science policy and research assessment, Citation and co-citation analysis, Patent analysis, Knowledge discovery and data mining

Introduction
The past decade has seen a significant change in the organisation and management of scientific research. Although research has traditionally been organised into specialised disciplines, more and more governmental initiatives are emerging that aim to break the disciplinary silos (Van Rijnsoever & Hessels, 2011; Allmendinger, 2015). Various approaches are reported in the literature to operationalise this mode of research, the most common being interdisciplinary research (IDR) (Sonnenwald, 2007; Wagner et al., 2011).

The underlying rationale motivating IDR initiatives resides in an increasingly shared view among academics and policymakers: by uncovering innovative solutions residing outside the context in which they emerged, partnerships integrating multiple scientific cultures and bodies of knowledge help foster new lines of thought (i.e. the emergence of new disciplines) and help tackle and solve today’s increasingly complex problems (Allmendinger, 2015; Blackwell et al., 2010; Mainzer, 2011). Blackwell et al. (2010) refer to the former application of IDR as being curiosity driven, and the latter application as being outcome driven.

By helping companies to stay ahead, or at least abreast, of the most recent developments in a rapidly changing business environment, outcome-driven IDR is perceived as having the potential to boost the competitiveness of firms and the economic well-being of nations. While the number of initiatives capitalising on outcome-driven IDR to fuel innovation in firms is
increasing, there is a glaring lack of empirical evidence to support the notion that IDR is an effective mechanism to spur innovation and longer-term job creation and competitiveness in the knowledge economy. As laid out by Allmendinger (2015):

While there are plenty of data, insights and lessons on directed research programs and organized research units at universities, we have but next to no empirical evidence on how to best stage interdisciplinarity, about the added value it may produce, and what it may take universities and research organizations to effectively cross narrow disciplinary boundaries, perspectives, and interests. The ironic bottom line is that we need both more interdisciplinarity, and more organizational experiments, to advance it, and to learn more about what is conducive to it, what works and what does not.

This study aims to partly fill this gap by investigating the type of added value that may be produced by IDR. More specifically, the following question is being addressed: To what extent is IDR positively associated with innovation, focusing on outcome-driven/applied research? Because current interventions rely mostly on assumptions derived from rational—but speculative—thinking, it is still pertinent to investigate the above question in furthering our understanding of IDR and its potential outputs/outcomes—this to further assess the relevance of existing and upcoming policy interventions. With this aim, this study’s policy question was converted into the following data mining problem: the extent to which IDR is conducive to innovation is measured by investigating if, and to what extent, the knowledge disclosed in a scientific publication has greater odds of being taken up in the patent literature as its interdisciplinarity increases. Because the study focuses on a specific type of innovation—product/process innovations as disclosed in patents—the findings are not generalizable to the full innovation landscape.

Methods
Briefly, uptake in innovation is inferred by matching non-patent references (NPRs) in patents to a bibliographic database of peer-reviewed scientific literature focusing on science and engineering fields. This variable is referred to as the ‘cited in patent’ indicator throughout this paper. The scientific literature on measuring IDR has been blooming in recent years (Porter & Rafols, 2009; Rafols & Meyer, 2010; Campbell et al., 2015; Cassi, Mescheba, & de Turckheim, 2015; Calatrava Moreno, Auzinger, & Werthner, 2016). Most of these studies attempted to measure IDR using bibliometric data extracted from large bibliographic databases of peer-reviewed literature to quantify the diversity of integrated knowledge within individual research articles. This is typically done by computing the Rao-Stirling diversity index of the material cited in an article. This index integrates the number of different subfields cited, the balance between these subfields, and the intellectual distance between them (Porter & Rafols, 2009). Because one of the main eligibility criteria for researchers applying to funding programmes targeting IDR is almost always the requirement that the project team includes researchers from diverse disciplines—and because IDR measured from co-referencing of multiple disciplines in an article (as in Porter & Rafols, 2009) can result from the work of a single author—it was decided that the Rao-Stirling diversity index would be applied to papers’ contributing disciplines as revealed by the departmental affiliations of their authors, instead of their cited subfields. To differentiate this indicator from those based on cited subfields, as per a paper’s references, it is referred to as the ‘multidisciplinariness’ (MDR) throughout this paper.

Data sources
Two sources of primary data are necessary to match NPRs in patents to individual scientific publications to create the cited in patent indicator: a patent database and a database of peer-
reviewed scientific publications. For this study, PATSTAT was selected as the patent database, limited in this instance to a dataset of USPTO patents. The Web of Science (WoS), produced by Clarivate Analytics, was selected as the database for peer-reviewed scientific publications. The WoS also includes the addresses of all authors on a publication, enabling the computation of the MDR. Only articles published in the domains of Natural Sciences and Engineering (NSE) and Health Sciences (HS) were retained for this study (as defined by Science-Metrix’ classification, see Archambault, Caruso, & Beauchesne, 2011). This is because materials from the Social Sciences and Humanities are unlikely to be taken up in innovation as disclosed in patents. Also, although reviews might be cited in patents, they typically do not disclose original research contributions. Conference papers were not available to perform this analysis.

Cited in patent indicator

The cited in patent indicator is a binary indicator, computed at the paper level. It takes the value of 0 if the publication is not cited in the patent literature and a value of 1 otherwise. A detailed discussion of the matching procedure that was implemented in this study to link the patents’ NPRs in the USPTO to scientific articles in the WoS is beyond the scope of the present paper. For a detailed presentation of this procedure, see Campbell et al. (2016).

Multidisciplinarity (MDR)

Recall that the MDR is measured with the Rao-Stirling diversity index of the disciplines represented among a paper’s author addresses in the WoS. The department names appearing in the author addresses of all papers in the WoS were harmonized to 129 distinct forms representing the disciplines used in computing the MDR. The pairwise similarity matrix between the 129 disciplines is computed using the cosine similarity between the distribution vectors, across scientific subfields as per Science-Metrix’ journal-based classification, of any two disciplines. The distribution of a given discipline across subfields is obtained by counting the papers, in each subfield, that include the corresponding discipline among their author addresses. The index varies from 0 for monodisciplinary papers to 1 for highly multidisciplinary papers. Because it was not feasible to assign a cleaned department name to all author addresses in the WoS, potential biases might arise from this limitation in the data. Although the characterisation of this indicator revealed that robust inference can be performed even in cases where not all addresses have been classified (for more details, see Campbell et al., 2016), the analyses were performed using only those articles that had all their addresses classified by department. This was done to reduce the size of the dataset, and thus allow the computation of the analysis to run (see below).

Analyses

The question to be addressed in this paper can be re-formulated as follows: Is the knowledge disclosed in a scientific publication more likely to be taken up (i.e. cited) in the patent literature as its MDR increases? To address this question, it was decided that a logistic regression would be appropriate for the type of data we are dealing with: logistic regression supports multiple discrete and/or continuous predictors (MDR is a continuous predictor and additional controls are to be added to the model) and is suitable for binary outcomes (a paper being or not being cited in patents).

Three additional variables were created: the subfield of an article, the number of contributing authors, and the number of contributing countries on an article. These were inserted in the model to control for other networking effects that could supplant the effect associated with the

1 http://www.science-metrix.com/en/classification
crossing of disciplinary boundaries in research teams. For example, an increased citation rate in patents could be due simply to the increase in the number of researchers or countries involved in a research project, rather than to the diversity of disciplines represented among them. Another factor that likely influences the citation in patent outcome is related to inter-sectoral cooperation. For example, is the publication resulting from a public–private partnership? At the time of submitting this paper, this variable had not yet been prepared and included in the study’s model. Further, due to space limitations in the current paper, the additional materials related to this analysis will be added to the oral presentation.

In the context of this study, it is important to note that the event to be modelled—the citation of an article in patents—is rare. For instance, only 2% of 2008 articles in the NSE and HS, as indexed in the WoS, have been cited in USPTO patents (see Table 3 in Results section). With dozens of times fewer 1s than 0s (i.e. cited in patents vs. not cited in patents), most logistic regression tools would likely underestimate the probability of citation in patents even in the presence of sample sizes in the thousands (King & Zeng, 2001). An algorithm that provides an accurate estimate of the binary logistic regression’s coefficients in such circumstances is Firth’s biased reduced logistic regression using penalised likelihood (Firth, 1993). The R implementation of this algorithm was selected for this study (see ‘logistf’ package created by Heinze and colleagues, 2015).

Since the algorithm used to estimate the parameters of the constructed regression model is computationally intensive and could not run on the entire dataset, the dataset was reduced using three consecutive steps. First, the analysis was restricted to the most recent publication year of scientific articles (in the WoS) for which a sufficiently long time window was available to capture their citations in US patents (in the USPTO); this was to ensure that the analysis would reveal contemporary effects. Since it can take, on average, about 3.5 years for patents to be granted from their application date at the USPTO, and because relevant references to scientific articles can be added by patent examiners in this period, the time window over which citations can be captured should minimally extend over a five-year period—that is, four years to account for the granting process at the USPTO, and one year to account for the fact that papers can be published late in a given year. As complete data on patents were available up to 2014, this means that the citation windows of articles published after 2010 (citation window of five years; 2010 through 2014) would be too short. To balance data accuracy with the need to focus on contemporary effects, it was decided that a minimum window of seven years would be used, restraining the analysis to 2008 articles. Articles published in earlier years could have also been used, but this would have necessitated including an additional control variable to the model (i.e. publication year) to account for the fact that older papers have had the chance to accumulate citations over a longer period. Since the model was already taking a long time to run, the focus was placed on 2008 articles only. This led to a dataset of 402,916 articles times five variables (subfield, MDR, number of authors, number of countries and citation in patents) for a total of about 2 million data points. Following this restriction, the dataset was still too large to run the selected analysis method.

As a second step, limiting the analysis to only those articles with all their addresses classified by discipline (or department) reduced the size of the dataset by an additional 37% (from 402,916 to 255,372 articles). Filtering using such a criterion also carries the benefit of eliminating a potential source of biases in the measurement of multidisciplinarity at the individual paper level. Conversely, such a filter may bias the population towards papers with fewer authors, and hence towards papers that are less multidisciplinary; the more addresses there are on a paper, the more difficult it is to clean all addresses. To assess the robustness of the conclusions drawn in this study, the analyses presented in this paper could be run again using a random sample of papers that have at least 5 addresses with a cleaned department or that have a cleaned department assigned to at least 50% of their addresses when they have fewer than 10 addresses. That said,
since the analysis was possibly focused on a portion of the population of papers that is less multidisciplinary, it is anticipated that the results presented here are conservative.

With the above filter applied to the dataset, the computer (4 cores/8 threads Intel Xeon CPU E3-1240 v2 processor (3.40GHz) running a 64-bit version of Windows Server 2008 R2 with 32GB of RAM) crashed after a day of computing. Accordingly, as a third step, this restricted dataset was randomly downsampling to 100,000 articles so the analysis could run successfully.

**Global analysis:** In performing the analysis for all 132 NSE and HS subfields combined, the subfield of scientific articles was added to the model as a control (dummy) variable. This was important to control for differences that prevail in the citation practices across technological fields (e.g., some fields generally include more references to the scientific literature than other fields do). As the global model was statistically significant ($p$-value < 0.05), the model was then run again for each subfield separately.

**Analysis by subfield:** Out of the 132 NSE and HS subfields, 44 (one third) that had at least 30 papers cited in patents were retained for analysis. The subfields were filtered since a small number of cases on the rarer of the two outcomes in binary logistic regression can lead to underestimation of the odds ratios. These 44 subfields accounted for 65% of all papers in the combined subfields. All articles with 100% of their addresses classified by discipline (or department) were kept in the analysis (i.e., 164,972 articles out of 255,372; the data were not downsampled). Only the subfields with a statistically significant relationship between the multidisciplinarity of peer-reviewed scientific articles and the event of being cited in patents are reported in the results section.

**Results**

*Global analysis*

When all 132 NSE and HS subfields were combined, the global model was statistically significant ($p$-value < 0.05); its associated parameters are shown in full in Table 1. Note that the lower and upper odds ratios provide the 95% confidence interval of the odds ratio for a given predictor. When the confidence interval does not overlap with 1, it means that the odds ratio is significant ($p$-value of the odds ratio < 0.05).

The odds ratio of a predictor typically shows the multiplicative factor by which the odds of citation (of an article, by a patent) increase with each full unit change in the predictor. For multidisciplinarity only, the odds ratio was re-scaled for a magnitude of change of 0.1 unit since a full unit change for MDR is highly unlikely; in contrast to the number of authors and countries, the MDR score of a paper is bounded between 0 and 1. Also, a variation of 0.1 is commonly observed across all papers; 42% of articles have a deviation from the median MDR score that is greater than or equal to 0.1. For the number of authors and countries, the odds ratio is reported for a 1-unit change, which is more commonly observed for the former relative to a 0.1-unit change for MDR (78% of papers deviate by one or more units from the median), but less commonly observed for the latter (27% of papers). How to interpret the MDR score, to digest what a 0.1-unit increase means in a practical context, is explored at length in Campbell et al. (2016).

As detailed in Table 1, the MDR of an article has a statistically significant effect on the likelihood that its results will be taken up in innovation; for instance, when the MDR score of an article increases by 0.1 unit, its likelihood of being cited in the patent literature increases by 12% (odds ratio of 1.12).
Table 1. Relationship between the multidisciplinarity, as well as the number of authors and countries, of scientific articles (2008) and their citation in the patent literature (patents issued in 2008–2014).

</tbody>
</table>

Note: ǂ The odds ratio was re-scaled for a magnitude of change of 0.1 unit instead of 1 unit (recall that the MDR can only take values from 0 to 1).

This analysis of odds ratios was also conducted on the number of authors listed for a paper and the number of countries participating in the collaboration, to determine whether either of these features exert an effect that could suppress the influence of multidisciplinarity on the uptake of scientific knowledge in innovation. The meaning of such a change is simple to interpret for these predictors: Does having one more author, or one more participating country, involved in publishing a paper increase its likelihood of being cited in the patent literature?

The odds ratio for having an additional author is statistically significant and equals 1.09, meaning that having one more author on a paper increases the chances of citation in the patent literature by 9% (Table 1). Thus, a larger number of collaborating authors does have a positive effect on the uptake of scientific knowledge in innovation and this effect does not override the effect linked to the multidisciplinarity of a research team. International collaboration does not appear to exert a statistically significant effect on the uptake of scientific knowledge in patents.

**Analysis by subfield**

Now that a positive and statistically significant effect of MDR and the number of collaborating authors on the likelihood of being cited in the patent literature has been detected at the global level, it becomes relevant to assess if this effect holds equally well across subfields or if there are any meaningful disparities. The results are only presented for the 44 subfields with at least 30 papers cited in patents; as previously noted, subfields were filtered in this way since a small number of cases on the rarer of the two outcomes in binary logistic regression can lead to an underestimation of the odds ratios.

A summary of results at the subfield level is presented in Table 2. Of the 44 retained subfields, the model was statistically significant in 29 cases (66%). Of those 29 subfields, the odds ratio for MDR scores is statistically significant in 16 subfields (55%) and the effect is always positive in these cases. For the number of authors on a paper, the odds ratio is statistically significant in 22 of the 29 subfields (76%) for which the model is significant and the effect is positive in 95% of these cases. As noted above, international collaboration does not have a statistically significant connection with innovation, a finding that is borne out here at the subfield level: the odds ratio for number of countries is statistically significant in 9 of the 29 subfields (31%) for which the model is significant and the effect is positive in only 44% of these cases.

Focusing on only those subfields where the connections to innovation (positive or negative) are statistically significant for each predictor taken separately, we can once again look at the effects of MDR, number of authors and number of countries. On average across statistically significant subfields for MDR, an increase of 0.1 in MDR score is associated with a 32% increase in the likelihood of being cited in the patent literature (avg. odds ratio of 1.32, Table 2). A paper with one more author (a 1-unit change for number of authors) is associated, on average, with a 13% increase in chance of being cited by a patent. The inclusion of an additional country in
International collaboration is associated, on average, with a 14% increase in the chance of being cited in the patent literature. Although this is similar to the score for the number of authors, the range of the statistically significant odds ratios for the number of countries is broader, with stronger scores on the negative side effect (i.e. odds ratio below 1). The highest (significant) odds ratio for the number of countries is 1.72, but the lowest is 0.62. These values are more extreme than those for MDR (1.13 to 1.54) and the number of authors (0.92 to 1.13), meaning that there is much stronger variation from one subfield to the next in terms of the connection between international collaboration and citation in the patent literature. This finding is unsurprising given that findings presented above suggested that the connection was much weaker between international collaboration and patent citation (in the aggregate and across subfields). Only for multidisciplinarity are the effects consistently on the positive side across subfields where the predictor has a statistically significant effect—that is, multidisciplinarity never appears to lead to important decreases in the likelihood of citation in patents.

Table 2. Comparative analysis of the magnitude of effect of the multidisciplinarity, number of authors and number of countries of scientific articles (2008) on their odds of being cited in the patent literature (patents issued in 2008–2014).

| Note: † The odds ratios were re-scaled for a magnitude of change of 0.1 unit. |

In summary, multidisciplinarity is most consistently connected to patent citation, compared to the other two predictors. This finding holds both in the aggregate and at the subfield level. However, the number of authors has a significant effect in a larger set of subfields with an effect which is nearly always positive. Thus, both multidisciplinarity and the number of authors are significant contributing factor to the uptake of articles in patents. For the 16 subfields in which the multidisciplinarity–innovation link is statistically significant, the odds ratios range from a 13% increase to a 54% increase in the probability of being cited in patents for a 0.1-unit increase in MDR score. In-depth results for each of these subfields are presented in Table 3. More specifically, this table provides information on the number of cited and uncited articles in each subfield (along with the percentage of cited articles), their respective odds ratios for a 0.1-unit increase in MDR score, the upper and lower bounds of those odds ratios, and the share of articles deviating by at least 0.1 unit from the median MDR score in the given subfield. The coefficients of other variables included in the model are not shown here.

Note: OR_{X→X+0.1} = odds ratio re-scaled for a change of 0.1 unit in the MDR score of papers.

Out of the 16 subfields where a positive and statistically significant connection exists between multidisciplinarity and the uptake of scientific knowledge in innovation, 10 (63%) are related to the Health Sciences (Table 3), where the extent of multidisciplinarity research is more pronounced (data not shown). In Table 3, the odds ratio varies from a low of 1.13 in Cardiovascular System & Hematology to a high of 1.54 in Orthopaedics. In Orthopaedics, this means that a 0.1-unit change in MDR translates into a 54% increase in the odds of an article being cited in patents. Of all the articles in this subfield, 46% deviate from the median MDR score by 0.1 unit or more. This indicates that some papers stand out by a sufficient margin in terms of MDR, significantly increasing the likelihood of their results being taken up in patents. The subfields with the most disparate spreads of MDR scores are Organic Chemistry, Biomedical Engineering, and General Chemistry, each of which has at least 50% of its articles with an MDR score 0.1 unit or more away from the median. In turn, it is reasonable to assume that a policy aiming to promote multidisciplinarity as a way to catalyse innovation could lead to a sufficient change in the MDR of supported articles in these subfields to achieve a noticeable increase in the likelihood of their findings being taken up in innovation.

Until now, the odds ratios have only been analysed for 0.1-unit changes in MDR. Although the odds ratio when moving from an MDR of 0.1 to 0.2 is the same as when moving from an MDR of 0.5 to 0.6, it is worth noting that the relationship between an odds ratio and the magnitude of change (e.g. 0.1 unit, 0.2 unit, …, 1 unit) in the predictor (i.e. MDR) is exponential, making it relevant to investigate the magnitude of an effect that can be achieved when doubling, tripling or even quadrupling the MDR of a paper. In doing so, the analysis focused specifically on the subfield of Orthopaedics, which has the largest odds ratio—1.54 for a 0.1-unit change in MDR. Figure 1 shows the change in odds ratio as a function of the magnitude of change in the MDR score of a 2008 article in Orthopaedics. Articles with an MDR score of 0.4 are slightly more than five times as likely to be cited in the patent literature compared to monodisciplinary papers (MDR = 0) in Orthopaedics (odds ratio = 5.57); the magnitude of this effect is 3.6 times larger than for an MDR of 0.1 (odds ratio = 1.54). Taking any baseline, an increase of 0.4 of a unit in the MDR score of an article (e.g. from 0 to 0.4, 0.1 to 0.5, 0.2 to 0.6) will lead to a 5.57 times increase in the odds that the knowledge it contains will be taken up in innovation. This is a non-negligible effect when we note that close to a fifth of 2008 articles in Orthopaedics have an
MDR score of at least 0.4, while the mode of the distribution is at MDR = 0 (see inner chart in Figure 1). For an MDR score of 0.67, the highest score observed in Orthopaedics in 2008, the odds of being cited in patents are nearly 18 times larger than for monodisciplinary papers.

**Figure 1.** Relationship between the increased probability (odds ratio) of an article being cited in the patent literature and a given change in its multidisciplinarity score (for 2008 articles in Orthopaedics, cited in patents issued in 2008–2014).

The preceding analyses of MDR’s effect on the likelihood of uptake in the patent literature, for the subfield of Orthopaedics, has shown that the relationship is exponential, with the likelihood of being cited in a patent growing more and more rapidly as the magnitude of change in MDR scores increases. But an important piece of context is still absent: the relative increases in likelihood of uptake in patents has been discussed, but the likelihoods themselves, as a function of MDR scores, have so far not been quantified. Let us turn to that point now. Because citation by a patent is a relatively rare event, individual articles needed to be sorted into suitably large bins to enable the signal to emerge clearly from the background noise. For the present analysis, Orthopaedics articles were sorted into three bins in ascending order of their MDR scores: one for the ~22% of articles with an MDR score of 0, and then two equally sized bins of ~39% each, each accounting for exactly half of the remaining articles. More bins could not be produced without reducing the number of cited articles found in each bin, which would introduce unwanted noise into the analysis.

The average multidisciplinarity of articles, as well as the frequency of cited articles, was computed for each bin, producing the data points shown in Figure 2. In this figure, the results are showing the actual odds of being cited, not the odds ratio (which quantifies the relative change in odds for a given change in MDR, but not the odds themselves). As detailed in Figure 2, the observed frequency of citation in patents for the three bins prove to be a relatively strong fit to the expected odds of being cited in patents as predicted by the logistic regression model (see the exponential prediction line in the graph), suggesting the overall adequacy of the model. However, because of the rarity of article references in patents, the predictive power of this
model for any individual article will be very low; instead, the model is better suited to predicting overall patterns in the aggregate.

Figure 2. Relationship between the increased probability (odds ratio) of an article being cited in the patent literature and a given change in its multidisciplinarity score (for 2008 articles in Orthopaedics, cited in patents issued in 2008–2014).

Note: The model was fitted using three explanatory variables: multidisciplinarity, number of authors and number of countries. In this graph, the number of authors and countries were held constant using the average number of authors (4.94) and countries (1.17) across all Orthopaedics papers. This is acceptable given the small variability observed in these quantities across the three bins (no. of authors ranges from 4.47 and 5.19; no. of countries ranges from 1.17 to 1.20) and given the non-significance of the odds ratio for these two variables. The effect of these variables is here embedded in the model intercept.

Comparing Figure 1 to Figure 2 can provide a valuable perspective on the effects of MDR on uptake in innovation. For a paper with an MDR score of 0, the likelihood of being cited by a patent is 0.5%—a 1 in 200 chance. Increasing the MDR score to 0.4, which is a significant increase in multidisciplinarity, increases the likelihood more than fivefold. However, even a fivefold increase of such a small value results in a still relatively small value: a paper with an MDR score of 0.4 has about a 2.7% chance of being cited by a patent, still only a little better than 1 in 40.

Accordingly, while it is appropriate to conclude that multidisciplinarity increases the likelihood of research being taken up in innovation, its effect is not large enough to predict with certainty that a given piece of work will contribute to new innovations (i.e. be cited in patents) solely on the basis of the disciplinary diversity of the research team. Far more factors are likely to influence such an outcome, and these would have to be introduced into the model to precisely predict the innovation outcome of an individual research article (or project). Still, the relationship that has been uncovered in this study suggests that, in some scientific (sub-)fields, promoting multidisciplinary research can significantly increase the odds of fuelling new innovations, thereby paving the way for evidence-based R&I policy intervention. Additionally, it should be noted that a rather short citation window has been used, which likely underestimates the longer-term odds of a patent citation. Consequently, policy interventions promoting multidisciplinary research may have more leverage on innovation than is suggested here.
Discussion

The present study has assessed the connection between research that crosses disciplinary boundaries and contributions to innovation through the measurement of multidisciplinarity (assessing the number, balance and diversity of disciplines or departments integrated into a research team) and the resulting chances of articles published by these research teams being taken up in the patent literature, as tracked through citations. The conclusions reached are that multidisciplinarity certainly does contribute to increased chances of uptake in innovation; this finding holds across the aggregated subfields of the NSE and HS, as well as in about 1 in 3 subfields individually. Multidisciplinarity seems to have a more robust connection to innovation than the number of countries (for international collaboration). The number of authors also appears to contribute positively to citation in patents.

Even so, this study has shown that MDR is only valuable as a predictor of general tendencies within a set of cases and cannot effectively predict whether an individual article will or will not be cited by a patent. If one assumes that uptake in innovation is not the result of a chancy system, then the factors that most strongly determine uptake for individual articles have yet to be identified. Further study would be needed to fill out this picture and hopefully identify those strongly determining elements. One such idea would be to examine the sectors in which the collaborating authors are working, seeking especially to see whether collaborations involving private-sector co-authors have a higher likelihood of providing the foundation for subsequent patents. Furthermore, it must be acknowledged that even once these determining factors are identified, the large majority of peer-reviewed publications are never cited by a patent. Uptake in innovation thus remains a relatively rare phenomenon.

Integrating these research findings back into the policy context, then, what lessons may be extracted? First, this study was initially driven by the need for some evidence to support a fundamental assumption underlying a growing number of R&I policy interventions: that crossing disciplinary boundaries helps to fertilise the ground for innovation, tilling the soil for job creation, economic growth and increased competitiveness. The evidence discovered in this study suggests that this baseline assumption is indeed borne out by facts.

It is important to note that the present study has only been a pilot test. It was conducted using a single year of peer-reviewed publications (2008) and a restricted range of years for patents (2008–2014). The cleaning of author addresses by discipline (or departments) could be improved to remove additional noise from the analysis, and the algorithm matching NPRs to scientific articles in the WoS should be improved to increase its recall while maintaining its precision. Currently, it is likely that the citation rate of scientific articles in patents is underestimated, diluting the effects measured in this project. For example, the 7-year citation window used is rather short in the context of patents, possibly underestimating the longer-term odds of a patent citation. Policy interventions promoting multidisciplinary research may thus have more leverage on innovation than is suggested in this paper. Furthermore, only 44 of 132 subfields could be analysed, as the others did not meet a minimum threshold of cited papers to facilitate robust analysis. Thus, while this study’s findings are valuable and shed light on a fundamental policy assumption in need of evidential support, they are also extremely preliminary, requiring much more robust assessment before they should be considered sufficient for the basis of future policymaking—robust both in the sense of repeating these analyses on larger samples and in the sense of approaching these phenomena from other angles.

Acknowledgments

This study was performed as part of a larger project on the development and application of a methodological framework guiding the design and implementation of data mining projects in the R&I policy context. The project was commissioned by the European Commission, DG Research and Innovation, Unit A4 – Analysis and monitoring of national research policies.

Measuring and Forecasting Technology Market Potential

Luan Chunjuan
julielecj@163.com
Dalian University of Technology, Dalian (China)

Abstract
This paper aims at exploring the methodologies and indicators on measuring and forecasting technology market potential, which will benefit us in understanding technology developmental and competitive frontiers and promote patent industrialization and commercialization. Four-quadrant analysis based on patent portfolio data is employed, and two aggregative indicators of disruptive potential and technology maturity are selected, to conduct the study. Empirical study by choosing an emerging technology called cell Immunotherapy in medical domain is investigated from four fields with the filter function embedded in Relecura IP Platform, i.e., Field of Technologies, Field of Sub-Technologies, Field of IPC Codes and Field of CPC Codes. The empirical study help us well understand the situation of technology market potential for a specific technology area from various levels.

1 Introduction
The research objective of this study is to explore the methodologies and indicators on measuring and forecasting technology market potential, via four-quadrant analysis based on patent portfolio data, and two aggregative indicators of disruptive potential & technology maturity being selected. Investigations on measuring & forecasting technology market potential will benefit us in deploying emerging technology strategies and selecting R&D investment areas, and it can also afford significant decision-making references for S&T managers and intellectual property (IP) market dealers.

Studies pertinent to the topic of technology market potential have been paid attention to from 1980s by scholars. An approach for estimating the market potential of new energy-saving technologies is presented (Roberts and Greene 1983). This approach is based on the assumption that consumers implicitly minimize total expected lifetime costs when purchasing new technologies and an important result of this approach is that technologies can have zero market potential and that these technologies can be identified based solely on technology-specific information, not on attributes of the consumer population.

It is recognized that understanding technology market potential is not only the premise and foundation of technology trading activities, such as transformation and potential licensing (Bagchi and Mukherjee 2014, Mukherjee 2014), but also is significant basis for R&D researchers to select whether entering a specific technology domain (Chun and Mun 2014, Duchene, Sen et al. 2015). Technology market potential is a crucial indicator for industrial competitors’ capital operating (Svensson 2013), technology trading (Galasso, Schankerman et al. 2013), and market developing trend forecasting (Bayar, Chemmanur et al. 2011). At the same time, technology market potential analysis is also the foundation for companies to implement IP strategies (Engel 2011), to strengthen patent portfolios (Cockburn and MacGarvie 2011, Ismail, Omar et al. 2011), to develop new products (Schmiele 2012), and to exploit emerging technologies (Jun, Yeom et al. 2014).
A patent portfolio is an aggregation or collection of patents owned by a single owner, particularly a corporation, and these patents might have been developed individually by the owner or might have been purchased from the original patent owner. A patent portfolio can be a valuable asset to its owner (Ernst 1998, von Graevenitz, Wagner et al. 2011). The value of a corporation's patent portfolio can be a significant fraction of the overall value of the corporation (Narin 1995, Grimaldi, Cricelli et al. 2015, Song, Seol et al. 2016). Patent portfolio analysis is a methodology employed to evaluate and forecast the developing trend of an innovator or a specific technology field, by constructing the aggregation indicators which can be used to measure patent potential values, and this methodology can also be applied in IP strategies formulating and implementing (Blind, Cremers et al. 2009, Grimaldi, Cricelli et al. 2015, Tripathi, Jana et al. 2016).

Narin proposed a patent portfolio indicator employed to evaluate companies’ R&D performance based on cross-licensing in 1995 (Narin 1995); Ernst put forward 4 models of patent portfolios, i.e., a patent portfolio on the level of technological field, on the company level, on the inventor level, and on the integration of patent-market portfolios (Ernst 1995, Ernst 1997, Ernst 1998). In addition, such topics as the necessity of patent portfolios (Han 2015), the security of patent portfolios (Risch 2013), the function of patent portfolios (Lichtenthaler 2012) and value evaluation of patent portfolios (Schubert 2011), et al., have also been explored.

Technology disruptive potential represents the revolutionary transformation of emerging technologies comparing to the state of the art, and it can change the current technology developing patterns due to its higher innovative index and impacting upon the subsequently technologies significantly (Dereli and Altun 2013, Relecura 2016). Such subjects as the definition of disruptive potential (Ganguly, Nilchiani et al. 2010), future-oriented technology disruptive potentials (Cagnin, Havas et al. 2013), assessment procedures on disruptive potentials of candidate technologies (Dereli and Altun 2013), et al., have been investigated.

Technology maturity can be measured from such dimensions as developing period of a specific technology field, the amount of patents, global progress of the technology field and the extent of its applications (Roussel 1984, Relecura 2016), et al.. Related topics have been investigated, such as the evaluation modes of technology maturity (Rocha 2012, Waring 2015), assessment methods (Nogales-Bueno, Hernandez-Hierro et al. 2014, Nogales-Bueno, Ayala et al. 2015), various risks in the maturation process (Mishra, Das et al. 2016), and the technology maturity of a specific domain (Roussel 1984), et al..

The extant studies have formed the essential foundation of this paper, and have significant referring values for us. Existing indicators in the current four-quadrant analysis tend to be unicity, such as patent activity is represented only by R&D expenditure in a specific technology field. If more factors, such as patent applications, patent citations, and even innovative index, et al. could be taken account into a measuring indicator, the aggregative indicator will be much more convincing, and the analyzing results concluded will be much closer to the real technology competitive market.

Two aggregative indicators including technology disruptive potential and technology maturity will be employed in measuring technology market potential in this study. Relevant influence factors have been taken account into the two indicators. The emerging technology domain of cell immunotherapy is selected as an empirical study, and Relecura IP Platform is selected to conduct the study, exploring the methods and indicators of technology market potential.
measurement, expecting this study support decision-making in the area of emerging technology developing strategy and the S&T achievements transformation.

2 Methodologies & indicators, data source

2.1 Methodologies & indicators

Four-quadrant analysis based on patent portfolio data which is designed by Relecura innovation team (Relecura 2016), is employed in this study. Relecura is a new generation patent search tool. It uses a knowledge discovery framework to simplify patent searches and patent portfolio analysis. Its intuitive interface and unique features provide valuable insights into patents and patent portfolios. This methodology provides an indication of the relative position of the competitors in graphical form. The position of the bubbles in the graph helps us determine how much potential a technology has in the market. The size of the bubble represents the number of all patents worldwide for a specific technology. The Relecura IP Professional Platform analyses the position of the competitors with respect to Technologies/Sub-technologies/Class codes, and positions the values in a four-quadrant format. Four-quadrant analysis is typically applied to display a visual comparison of various parameters, positioned along appropriate X-Y axes, to give an intuitive comparison snapshot of the chosen parameters.

Two indicators, disruptive potential along with X-axis and technology maturity along with Y-axis (Fig. 1), developed by Relecura innovation team (Relecura 2016), are selected to measure technology market potential for a specific technology area.

![Figure 1. Analyzing Model of technology market potential](image_url)

The X-axis, Disruptive potential, indicates the potential of a technology with respect to the IP portfolio at hand (Relecura 2016). It takes into account patent filings, citation counts and innovation index that are indicative of the novelty of a technology. A positive disruptive potential indicates the capacity of the technology to impact the current IP portfolio.

The Y-axis, Tech maturity, indicates the extent to which the technology is prevalent in the IP market (Relecura 2016). It measures the development stage of the technology with respect to the current IP portfolio and includes the number of patents in the technology area, the amount of time the technology has been addressed by the IP portfolio, the global reach of the technology and the implementation or usage measure for the technology.

When a specific technology positions in the first quadrant like T1, it indicates that this technology has a positive disruptive potential and its technology maturity reaches a certain degree. In such a situation, it can be concluded that this technology has a strong market potential with an advantage value in IP business market. If a specific technology locates in the
second quadrant like T2, it indicates that this technology has no disruptive potential, though its technology maturity has reached some degree. Such technologies have little market potential and business value. T3 locates in the third quadrant, shows that such a technology has neither disruptive potential nor technology maturity, and it probably won’t have any market potential. Technologies as T3 have little market potential and business value. Technologies position in the fourth quadrant as T4, reveal that they have technology disruptive potential, and simultaneously, they are still in initial, even infancy developing phase. Such technologies have some uncertainty in their developing process: one possibility is that they can develop gradually and will have great market potential and business value; another possibility is that they cannot develop gradually, or even in the infancy phase for a comparative long period.

2.2 Data source

Cellular immunotherapy is an emerging technology in the medical area. It offers novel, safe and effective routes to treating cancer (Qian, Wang et al. 2016). It is recognized a promising therapy in treating cancer in the recent years (Hochberg, El-Mallawany et al. 2014). The developing trends both of patent filings and granted patents worldwide are shown in Figure 2.

![Figure 2. Developing trends of patent filings and granted patents of Cellular Immunotherapy.](image)

The earliest two patent filings in the technology area of Cellular immunotherapy can be dated back to the year of 1988 with priority in 1987. Only a few patent filings at the beginning phase, 10 patent filings totally before the year of 1993; no patent grants are found before 1991; the first granted patent appears in 1992. The number of total patent filings is 3104 and the total granted patents are 1168, up to our searching date of April 20, 2016. There are 853 patent assignees total, and the top five ones are University of Texas with 114 patent filings, US National Institutes of Health (NIH) with 101 patent filings, Synta Pharmaceuticals with 100 patent filings, US Health and Human Services, abbr. as HHS hereafter, with 90 patent filings, Celera Corp. with 68 patent filings, respectively.

Empirical study: measuring & forecasting technology market potential

Four-quadrant analysis can be employed to conduct the analytic work from the perspectives of assignees, technologies, sub-technologies, and technology class codes including IPC Codes / CPC Codes and US Classes. Here, the filters embedded in Relecura Platform of technologies, sub-technologies, IPC Codes and CPC Codes are selected to do the empirical study.

3.1 Field: Technologies

Firstly, the Field of Technologies has been selected to measure and forecast technology market potential in the area of Cellular immunotherapy by employing four-quadrant analysis embedded in Relecura IP Platform, and we got the map of Fig. 3.
Fig. 3 reveals that in the Field of Technologies, as far as the indicator of Disruptive potential is concerned, the technology of Medicinal Preparations with 2712 patent filings has the strongest disruptive potential, indicating this technology is of absolute synthetic competition advantages in terms of patent filing activities, patent citations and technology novelties. Another three technologies have some degree disruptive potential when it comes to their patent portfolios: Micro organisms/Enzymes with 1,893 patent filings; Therapeutic activity of chemicals and medicinal preparations with 1,469 patent filings; Peptides with 1,461 patent filings, respectively. Technologies locating in the third quadrant, such as Heterocyclic Compounds, et al., nearly have little technology disruptive potential.

![Figure 3. Four-quadrant analysis of technology market potential in the Field of Technologies.](image)

When it comes to the indicator of Tech maturity, it is pretty high of the technology of Medicinal Preparations, indicating that this technology is comparatively prevalent in the current IP market, and it has progressed into a higher developing stage in terms of its amount of patents, the amount of time the technology has developed in the IP portfolios, the global reach of the technology and the implementation or application measure for the technology.

Synthesizing the two indicators both disruptive potential and technology maturity, the technology of Medicinal Preparations has not only stronger technology disruptive potential, but a pretty higher technology maturity, so it can be concluded that this technology has the most promising technology market potential. Though another three technologies, such as Micro organisms/Enzymes, Therapeutic activity of chemicals and medicinal preparations, Peptides, have some extent disruptive potential, they are still situated in a comparatively early developing phase, far away from technology maturity, so they will probably have a long progressing space. Technologies such as Heterocyclic Compounds, et al., having neither disruptive potential nor technology maturity, are of little technology market potential at present.

3.2 Field: Sub-Technologies

Secondly, the Field of Sub-Technologies has been selected to measure and forecast technology market potential in the area of Cellular immunotherapy. It can help us well understand the disruptive potential and technology maturity of various sub-technologies from a perspective of comparative micro level, and further insight their technology market potential. Selecting the field of sub-technologies of Cellular immunotherapy, also by applying four-quadrant analysis embedded in Relecura IP Platform, and we got the diagram of Fig. 4.

The sub-technologies appeared in Fig. 4 have various degree of disruptive potential, with different developing phases in terms of technology maturity. The sub-technology of
Medicinal preparations containing antigens or antibodies with 1,809 patent filings appears to be of comparative advantages for the two indicators, both disruptive potential and technology maturity, so it can be considered the most promising market potential among all. Other sub-technologies, such as undifferentiated human/animal or plant cells with 1,260 patent filings, Antineoplastic agents with 1,224 patent filings, have some degree disruptive potential whereas still being in the initial developing phase, and they will probably have a promising developmental space and even a strong market potential. Still some sub-technologies, such as Medicinal preparations with genetic material-gene therapy with 517 patent filings, et al., they are of some extent disruptive potential yet being with a comparative undeveloped phase in terms of technology maturity, their future are of a certain degree of uncertainty.

![Four-quadrant analysis of technology market potential in the Field of Sub-Technologies.](image)

3.3 Field: Technological Class Codes

1) Field: IPC Codes

The International Patent Classification (IPC), established by the Strasbourg Agreement, provides for a hierarchical system of language independent symbols for the classification of patents and utility models according to the different areas of technology to which they pertain. The appropriate IPC symbols are indicated on each patent document, of which more than 1,000,000 were issued each year in the last 10 years. Choosing the field of IPC Codes of Cellular immunotherapy, also by employing four-quadrant analysis embedded in Relecura IP Platform, and we got the diagram of Fig. 5.

Fig. 5 reveals that the IPC Code of A61P 35/00, representing Antineoplastic agents with 1,201 patent filings, has both a stronger disruptive potential and a higher technology maturity, so it can be concluded that this IPC Code is of stronger market potential among all appearing in Fig. 5. Another two IPC Codes, A61K 39/00 representing Medicinal preparations containing antigens or antibodies with 779 patent filings, A61K 39/395 representing Antibodies; Immunoglobulins; Immune serum with 618 patent filings, respectively, have some degree disruptive potential, yet they just step into the infancy developing stage, still need a comparative long time to technology mature phase, and it is supposed that such IPC Codes could probably get a stronger market potential after a period of development. Still some IPC Codes locating in the fourth quadrant, such as A61K48/00 representing Medicinal preparations containing genetic material which is inserted into cells of the living body to treat genetic diseases / Gene therapy with 468 patent filings, they are of some extent technology disruptive potential, yet they are in the very immature developing phase, existing some
uncertainties, and some of them will probably be of great market potential after a comparative long period of development.

Figure 5. Four-quadrant analysis of technology market potential in the Field of IPC Codes.

2) Field: CPC Codes
Cooperative Patent Classification, CPC, is the new classification system introduced since January 2013 in order to standardize the classification systems of all major patent offices (Montecchi, Russo et al. 2013). CPC has been jointly developed by the European Patent Office (EPO) and the United States Patent and Trademark Office (USPTO). The CPC is substantially based on the previous European classification system (ECLA), which itself was a more specific and detailed version of the International Patent Classification (IPC) system (Angue, Ayerbe et al. 2014, Leydesdorff, Alkemade et al. 2015, da Silva, Pinheiro et al. 2016). Here, we choosing the field of CPC Codes of Cellular immunotherapy, also by employing four-quadrant analysis embedded in Relecura IP Platform, and we got the diagram of Fig. 6.

Figure 6. Four-quadrant analysis of technology market potential in the Field of CPC Codes.

Fig. 6 shows that the CPC Code of A61K 39/0011, representing Cancer antigens with 594 patent filings, has a stronger disruptive potential with some degree technology maturity, so this CPC Code is of a comparative stronger market potential among all appearing in Fig. 6. A piles of other CPC Codes, such as CPC=A61K 2039/5158 (Antigen-pulsed cells e.g. T-cells with 408 patent filings) et al., are gathering around X axis, revealing that these groups of technology domains denoted by the CPC Codes have a certain of disruptive potential, yet most of them are still in a situation of initial developing phase, even just in a infancy stage. Some of them will probably develop into a mature stage gradually and will be of disruptive
potential, and some of them may be not. Another CPC Code, A61K 35/17, denoting Lymphocytes; B-cells; T-cells; Natural killer cells; Interferon-activated or cytokine-activated lymphocytes with 263 patent filings, positioning in the fourth quadrant, nearing original point, neither has it disruptive potential nor technology maturity at present, and it needs time to predict its market potential.

4 Conclusions and discussions

4.1 Conclusions

This study has shed light on how to measure and forecast technology market potential. It will promote technology commercialized if the information of technology market potential could be measured, forecasted and understood. We proposed the two aggregative indicators, disruptive potential and technology maturity, embedded in the IP Professional Platform Relecura, an international intellectual property Platform, to measure and forecast technology market potential. These two indicators are designed based on patent portfolio data, and each of them is a combination of multiple factors taken into account. The indicator of disruptive potential has been designed by considering such factors as innovators’ patent activities, patent citations and innovative index representing technology novelty, et al.; the other indicator of technology maturity has been designed according to the factors, such as the amount of patents in a specific technology domain, the duration of a technology has been developing, and the level of a technology reach and its implementation, et al..

We also conduct an empirical study on measuring and forecasting technology market potential of an emerging technology named cell Immunotherapy in medical domain, by employing the four-quadrant analysis based on patent portfolio data, and selecting the two aggregative indicators, disruptive potential and technology maturity, from four fields with the filter function embedded in Relecura IP Platform, that is, Field of Technologies, Field of Sub-Technologies, Field of IPC Codes and Field of CPC Codes. The empirical study help us well understand the situation of technology market potential for a specific technology from various levels.

Finally, further research is necessary to investigate technology market potential from a comparatively micro level, for example, individual patent level, instead of a technology area. It will help patent assignors or assignees much if they can get the information of technology market potential of their patents pending to be commercialized or industrialized.

4.2 Discussions

The innovation of this study lies in, the two aggregative indicators, disruptive potential and technology maturity, taking account into multiple factors, are of much stronger functions in measuring and forecasting technology market potential, comparing to the extant results. It affords us a big inspiration that the analysing four quadrant model based on patent portfolio analysis proposed by previous researchers (Ernst 1998, Santiago, Martinelli et al. 2015). The design of the indicator of disruptive potential, considering not only patent portfolios of assignees, but synthesizing technology impacts on sequent technology developments, and even more, this indicator combines the analysis of technology novelty characteristics by adding innovative index. More disruptive potential, more destructive force, more challenging power for the existing technology market, and such disruptive potential technologies are likely to transform the current technology market developing patterns.
The indicator of technology maturity, taking into account a series of factors including the amount of patents and its developing time, also the level it reaches and the usage globally (Relecura 2016). In such a four-quadrant analysis model, we can predict a specific technology will have a promising market potential in the future, if it is of a strong disruptive potential, and simultaneously it still locating in a very beginning stage, or even in a infancy phase. A technology will probably step into a declining phase next, if it has strong disruptive potential and already it is in a comparative technology developing mature stage, then its advantageous market potential probably won’t last long. If a technology has little disruptive potential, then it is supposed to be of little market potential, either, regardless of its technology maturity.

Indicators employed in this study, not only can be applied by the national planning department in deploying emerging technology developing strategies, but also can be adopted by corporations in selecting R&D projects. At the same time, the indicators could be chosen by business investors for decision making. It will help us understanding the developing trend and direction of the frontier technologies, improve our decision-making quality in selecting new technology and implementing intellectual property strategy, and also promote patents commercialization. It can be easily imagine that if an innovator chooses a technology with great disruptive potential, and it is still in infancy stage, then such a technology is probably developed successfully in the near future, and it will have great market competitive advantages, further it will be easily commercialized for its great market potential. Due the limit of pages, the rationale on constructing the indicators will be illustrated in the future studies.

Acknowledgments
I do appreciate Mr. George Koomullil, the CEO of Relecura IP Professional Platform Inc. and the Director Sheena Mathew, for their facilitating me much in my employing the program of Relecura. This work was supported by the National Natural Science Foundation of China (NSFC) under Grant 71473028; Project of the National Social Science Fund under Grant No. 14BTQ030. Fundamental research funds for the central universities under Grant No. DUT17RW224.

Abstract
As one of research funding providers, private company will influence development of science and technology throughout its support. While funded papers are mainly used to test their impacts of funding in recent researches, it can be expanded to detect the intellectual structure and scientific frontier of this provider. This study examines the co-word network of scientific papers funded by Lockheed Martin Corporation. We explore the dynamics of this network from 2009 to 2016 based on publication records collected from Web of Science. In our analysis, we firstly divide records into three main clusters according to disciplines, using HCA and SPSS. Secondly, we use the mixed strategy to select each cluster’s keywords, which are extracted by BibExcel before. Lastly, we map the network to detect keywords’ communities and core sub-network in each cluster, using Gephi and K-cores decomposition method. The analytical results demonstrate that what this corporation funded is related to their business and research areas, and detailed scientific fields are founded.

Conference Topic
Social network analysis, Co-occurrence analysis

Keyword
Funded paper; Co-word analysis; Hierarchical cluster analysis; Social network analysis; BibExcel; SPSS; Gephi; intellectual structure; scientific frontier

Introduction
As a key resource in current academic community, research funding has an irreplaceable function in research development (Vardakas et al., 2015; Ebadi and Schiffauerova, 2016; Zhao et al., 2016), as well as fulfills researchers’ hope to expedite and disseminate high-quality research (Zhao, 2010). Common sources of research funding include the researchers themselves, their home institutions in the form of salary and research infrastructure, and grants internal to the researchers’ institutions or, more importantly, by public or private funding agencies outside the researchers’ institutions (Zhao, 2010). Besides financial support, research funding sometimes would be seen as physical support, such as device and facility, especially from company or laboratory.
On the other hand, research funding is not an act of kindness (Li, 2011). Researchers are confronted with an environment of decreasing funding resources (Hoyla et al., 2016), because funders make detailed demands on the target, the purpose of the project and the attribution of research achievements, as well as lead to discussion of how to make financial resources go further, and to the concern that some researchers take more money from them for a particular project than needed (Rigby and Julian, 2014). Taking the National Natural Science Foundation of China (NSFC) as example, it had an acceptance rate of 22.87% in General Program and 22.00% in Key Program in 2016 (National Natural Science Foundation of China, 2016). In other words, more than 75% of the proposals were rejected. They just did not conform to what NSFC preferred, or rigorous competition-based funding policy, consisting of procedures, practices, stipulating grant conditions and regulatory criteria (Braun, 1998; Wang and Shapira, 2011). To put it another way, with limitations, a funder can indirectly affect development of science and technology (S&T).

Since funder can influence the development of scientific fields, funded papers, one of the most important outcome of researches, may contain information of what funder see development of S&T as. However, these papers are usually used to evaluate the efficiency of financial support in scientometrics, ignoring this information. Considering co-word analysis may be a good way to map the intellectual structure of academic researches, as well as find frontiers of S&T, we take co-word analysis to detect the information of funder.

Public funding agency, private foundation and company are common research funding providers. In this paper, we chose Lockheed Martin Corporation (Lockheed) as our example. As an US corporation with worldwide interests, this corporation organizes or participates in numbers of individual research programs and joint projects, providing researchers financial support. In addition, Sandia National Laboratories (Sandia), one of the national laboratories of US Department of Energy, operated by Sandia Corporation, a Lockheed Martin company, also provides financial or physical support. As a part of Lockheed from 1993-2017, it is no wise to exclude Sandia and its funded researches. Therefore, we treat Lockheed and Sandia as an integrated whole (LMT), and funded paper includes which paper receives financial or physical support.

This paper investigated the co-occurrence network of keywords form scientific journal articles funded by LMT, attempting to map the intellectual structure of researches and find frontiers of S&T supported by this corporation. We explore the funded articles of this network from 2009 to 2016 based on large data derived from Web of Science, Science Citation Index Expanded (WoS). It is organized as follows: after giving a brief review of assessment in funded researches, we describe in section “Data and Methodology”. Then, we present and analyze the detailed results in ‘Results and discussion’ section, followed by a conclusion section including the major findings and limitations.

Literature

With the help of quantitative tools provided by bibliometric and scientometrics, analysis of funded researches has become a hotspot in recent years.

Firstly, Acknowledgement is the main source to identify which research is funded, and collect funding information, such as funding program, agency, and grant number. Wang and Shapira
(2011) used a novel bibliometric approach in the context of nanotechnology research, to undertaking funding acknowledgement analysis which links research outputs with their funding sources.
Secondly, it is usually to find out difference between funded and non-funded researches in the same field, as well as funding effect in different countries. Zhao (2010) compared grant-based funding of research with non-grant-based research, both published in library and information science journals. And compared Canada with the United States in terms of the impact of public grants and scientific collaborations on subsequent nanotechnology-related publications, Tahmooresnejad et al. (2015) found that while research funding had a significantly positive linear impact in Canada and a positive non-linear impact in the United States on the number of papers, and it just only yielded a positive impact in the US in terms of citations.
Also, funded paper can be used to evaluate an academic journal, such as Sun (2010) evaluated Information Science, by the ratio of funded paper, the scale of the grant, subjects, collaboration, and institution the authors belong to, and Wei (2011) investigated funded papers in Library Tribune published from 2006 to 2009 by quantitative methods.
Thirdly, choosing funding agency and program is another point. For example, Gaughan and Bozeman (2002) examined effects of funding from the National Science Foundation (NSF), Gaughan (2009) chose the National Institute of Health (NIH) to compare impact on the paper publication rate adjusted by age, Ida and Fukuzawa (2013) investigated the 21st Century Centers of Excellence (COE) Program in Japan, and then Rigby and Julian (2014) indicated that papers achieved a higher citation count, funded by European Molecular Biology Organization (EMBO) and the Human Frontier Science Program (HFSP) at the same time.
Based on assessment results of funded researches, mainly using the number of papers and citation per paper as indicators, agency can watch on the situation and patterns of these investments and related outputs (Zhao et al., 2016), as well as decide on subsidizing potential domains, institutions, or individual, which thus enhances the efficiency of research resource allocation to achieve maximum production results (Liaw et al., 2014). What’s more, canonical funding agency or program, established by government, is the most popular choice for academia.
In addition, besides methods of scientometrics, there are some other ways to analyze funded research. Hoyla et al. (2016) used Proposal-Evaluation-Grant System (PEGS), an agent simulation system that models individual researchers in their activities related to getting funding, aiming for promotions and making science, to simulate different research funding allocation policies. Comins (2015) applied a data-mining approach to dig up technological importance of government-funded patents in the private sector.
Last but not least, co-word analysis were used to map the intellectual structure, or identify topics of the research denoted by funding agency or program, such as NOAA’s Office of Ocean Exploration and Research (OER) (Belter, 2013), and “The impact of economic transition on Central and Eastern European enterprises” (Topalli et al., 2016). However, they just studied on public program, not a company, especially scientific and technological enterprise which denote much to and participate in government researches or university studies. Therefore, with co-word analysis, this study can be extended to private company.
Data and Methodology

Data Collection

WoS was used as source of data, which catches attention of scientific and technological academia in the world and is the approach to top level and high quality of basic science fields (Kang and Su, 2008). It has started implementation of Funding Acknowledgements since August 2008. The funding acknowledgement fields contain data on research funding agencies, grant award numbers and associated funding acknowledgement text reported by paper authors (Thomson Reuters 2010; Wang and Shapira, 2011). In order to collect scientific journal articles produced with LMT funding from 2009 to 2016, we searched the “FO = Funding Agency” field tag.

The first search string was “Lockheed Martin”, receiving 855 records. Analyzing their detailed funding agencies, we found that there were some articles also funded by Sandia, which belongs to LMT until May 1, 2017.

The second search string “Sandia Co* OR Sandia National Lab*” was executed and we collected 2,012 records.

Considering some affiliations of Lockheed Corporation or Martin Marietta, the predecessors of Lockheed, may still exist, we respectively searched both of them in next. Compared with the first search string, string “Lockheed” received another ten records. And analyzing the string “Martin Marietta”, only “Martin Marietta Energy Systems” belongs to Lockheed Martin.

The ultimate search string used in this method was followed:

“FO = ((Lockheed OR Martin Marietta Energy Systems) OR (Sandia Corp* OR Sandia Com* OR San Cor* OR Sandia National Lab*))”

This search was executed and obtained 2,758 records. We downloaded and examined them in full-text format. In these records, some are lack of “DE (Author Keywords)” or “ID (Keywords plus)” fields. The situation of articles per year is shown in Table 1. Reducing those lack of both DE and ID, 2,690 articles were finally selected.

Methods and Tools

In this paper, we use the co-word analysis, including cluster analysis and social network
analysis. Co-word analysis is a technique that uses pattern of co-occurrence of words and phrases in a corpus (Ravikumar, 2015). Combining the bibliometrics and text mining techniques, it can reflect the relation between terms in order to mine the deeper meaning of the literatures (An and Wu, 2011). Especially, occurring of two keywords within the same paper indicates a relationship between the topics to which they refer (Cambrosio et al., 1993). With the co-word analysis, it is possible to map the intellectual structure of academic researches, as well as find frontiers of S&T, focused on by LMT.

Cluster analysis refers to a class of data reduction methods used for sorting cases, observations, or variables of a given dataset into homogeneous groups that differ from each other (Yim and Ramdeen, 2015), and facilitating comparison among similar entities and support decision making (Tahmooresnejad et al., 2015). From cluster analysis, as a powerful tool for comparison of entities and for high-lighting inequalities (Tashobya et al., 2016), hierarchical cluster analysis (HCA) is used to divide records into several subgroups based on disciplines, carried out by the SPSS statistical software (version 22).

Compared with other approaches, social network analysis are better for conducting co-word analysis (Ding et al., 2001; Hu et al., 2013). From social network analysis, we use both BibExcel and Gephi (version 0.9.1) with the former providing a file with co-word matrix for the latter. As an application software that can analyze information from WoS publication records (Jiang and Chen, 2010), BibExcel extracts keywords form the publication records, counts their times of occurrence, puts in numerical order, and finally generates Pajek NET files with co-occurrence matrices of keywords. Gephi is an open-source dedicated network analysis software used in data visualization (Calma and Davies, 2016), supporting Pajek NET files in after mapping network of keywords.

Step wise procedures of analyses are mentioned below as it is shown in Figure 1:
Preliminary measurement and normalization

The selected records contained two kinds of keyword fields, “DE” and “ID”. We merged “DE” with “ID” into a new field, named “R-DE”. Extracting keywords in “R-DE” with BibExcel into Excel, we found three problems:

P1. In one article, there are several terms for the same thing. “DE” is a field that author pluses into the article, while “ID” is produced by WoS, based on the article. The combination makes it likely that the same thing may have more than one term in one article. For example, “microelectromechanical systems” and its abbreviation “mens” occurred simultaneously at the times in one record.
P2. The same thing has different spellings among different articles. It includes singular and plural, American English and British English, phrases with and without hyphen, as well as popular name and its scientific name or chemical formula.

P3. The keywords are too scattered as a whole. Different form articles with the same subject, articles selected in this paper just have the same funding agency, LMT, and belong to several different disciplines. Therefore, keywords in this paper gather on several subjects.

In order to resolve P1 and P2, we firstly created a keywords table (see Table 2) to normalize the extracted keywords with Excel. After unifying terms and spellings of the identical thing, deleting duplicated terms in the same article, and then modifying “R-DE” fields in the original records, we finally got new modified records with 11,169 keywords, less than 18,386 originally had.

</tr>
</tbody>
</table>

Cluster analysis of disciplines

The P3 forced us to divide the whole modified records into several subgroups. There were two fields related to disciplines, “SC” and “WC” in the records. In SCI-Expend, “WC” referred to Web of Science Category, including 176 categories of subjects (Thomson Reuters., 2017). By contrast, “SC” was like first level disciplines, while “WC” was secondary level disciplines. We extracted disciplines of “SC” and “WC” separately with BibExcel, building Table 3. It was shown that there were 137 disciplines in “WC”, divided into 80 disciplines in “SC”. The latter was more general and easier to process than the former. Therefore, with 2,489 publication records, accounting for close on 93% of the whole modified records, the top 15 “SC” disciplines were took to build a co-occurrence matrix (see Table 4).

However, the co-occurrence frequency was absolute value, so it was difficult to reflect real interdependence between words, in the use of statistical software for cluster analysis (Lu, 2016). For this, the matrix was converted to correlation matrix with Ochiai coefficient (see Table 5), and then dissimilarity matrix, using the method of subtracting elements of 1 converted it to dissimilarity matrix (see Table 6) (Li and Wu, 2011).

Ochiai coefficient could numerate as the following:

\[ Ochiai = \frac{c_{ij}}{\sqrt{c_{i} \times \sqrt{c_{j}}}} \quad (1) \]

\( c_{ij} \) is regarded as time of co-occurrence between keyword i and keyword j, \( c_{i} \) is regarded as time of keyword i and \( c_{j} \) is time of keyword j.

In dissimilarity matrix, bigger the element was, farther the distance and the lower correlation between the keywords were (Zhang and Ma, 2007). The matrix was imported into SPSS to conduct HCA, using Ward’s method and squared Euclidean distance (Dehdariad et al., 2014),
with no standardization. Finally, HCA was illustrated using a dendrogram (Figure 2).

Figure 2. Dendrogram of top 15 disciplines showing clusters

Social network analysis of keywords

After clustering, we divided 2,489 publication records into three groups. Cluster “MSCP” had 1,626 publication records, extracted 6,426 keywords with BibExcel, while “ET-EMCM” had 903 records with 5,098 keywords and “IEAPO” had 454 records with 2,455 keywords. With so many keywords, it was no wise to put all of them in Gephi, which might make visualization of network deprived of conciseness and readability. Therefore, a strategy of keyword selection was needed. Yang (2014) had introduced a new strategy that the same number of keywords was selected respectively based on two strategies, one was word frequency threshold and the other was co-occurrence intensity threshold, and then the two selected keyword collections were merged into the final selected keyword collection, which proved to have a better effectiveness of co-word analysis. However, it was difficult to select the same number of keywords in these publication records, so it was compromise to use similar number. Co-occurrence intensity thresholds of three clusters were all set at 3, while word frequency thresholds of “ET-EMCM” and “IEAPO” were 5 but “MSCP” was 6. Finally, three combined keyword collections (see Table 7) came out respectively in Pajek Net file.

Next, keywords of the three clusters were visualized in social networks separately. In Gephi, a
node was a keyword, and an edge showed the relationship between two or more keywords, which referred to co-occurrence of keywords. Importing Pajek Net files, directed graphs set by “Force Atlas” layout algorithms were generated. Counting average path length and modularity, we could get all nodes’ betweenness centrality and closeness centrality, as well as detect communities of keywords. Each cluster has two types of graph. One was communities of keywords, the other was core sub-group of keywords with degree centrality and betweenness centrality. The former interpreted the structure of topics represented by keyword communities, identified by node’s color. The latter was filtered by K-cores decomposition method, which was used for exploring the hierarchy of social network and detecting core sub-groups (Baxter et al., 2012). Setting the highest K-core value, it visualized the lastly filtered nodes and edges. The K-core value of a node, defined as \( k \), described that this node had at least \( k \) interconnections, as well as referred to the core degree of node (Xiao et al., 2016; Zhang et al., 2014). Color of node in latter graph showed the degree, while size of node presented the betweenness centrality in both graphs. The darker color meant the higher degree, and the bigger size meant the higher betweenness centrality.

Table 8 lists the three clusters with number of nodes and edges, modularity, number of communities, average path length, and the highest K-core value in Gephi.

Results and discussion

Clusters of disciplines

Figure 2 presents an output of the clustering process for the top 15 disciplines as a dendrogram, showing how the disciplines were successively grouped into clusters until they formed a single cluster. A line has been drawn through the dendrogram to illustrate the point at which three clusters were determined. The three clusters are as follows:

“MSCP”: The cluster includes 4 disciplines, such as Physics, Materials Science, Chemistry, and Science & Technology. In addition, except Physics, the rest can be merged into a more
homogeneous sub-cluster, which infiltrate mutually and develop crosswise. MSCP may be the most significant scientific fields LMT payed attention to, which has almost 65% of 2,489 publication records.

“ET-EMCM”: It can be separated into three sub-clusters. The first is composed of Energy & Fuels and Thermodynamics, the next is Engineering and Mechanics, and the last is Computer Science and Mathematics.

“IEAPO”: As the more heterogeneous cluster, it is formed by Optics, Astronomy & Astrophysics, Instruments & Instrumentation, Polymer Science and Electrochemistry. Although the determining point could be located closer to the left side of the plot, illustrating that the clusters being merged became more homogeneous (Yim & Ramdeen, 2015), and they had a number of duplicate recorders with each (see the Venn diagram in Figure 3), it was reasonable for this paper. The number of the clusters was modest for later co-word analysis, and the proportion of duplicated records with another two was less than 35% in each cluster, except IEAPO up to more than 45%. It was still a successful clustering process.

![Figure 3. Venn diagram of relation among three clusters’ records](image)

_Gephi files of MSCP_

There are 7 communities of MSCP in Figure 4, with 0.284 of modularity. Connected with “growth”, most of nodes from Group 0 and Group 1 gather together, and almost all nodes with high betweenness centrality from Group 2, Group 3, Group 4, Group 5 and Group 6 connected with Group 0 and Group 1 (see Figure 5).

1) Group 0 and Group 1 are related to Materials Science. The former is about Coatings & Films, while the latter is Composites. In Group 0, “thin-films”, “graphene”, “chemical-vapor-deposition” are included, which are obviously about thin film, a layer of material ranging from fractions of a nanometer (monolayer) to several micrometers in thickness, playing an important role in the development and study of materials with new and unique properties (Wikipedia, 2017b). Chemical vapor deposition (CVD) is a chemical process used to produce high quality, high-performance, solid materials, which is often used in the semiconductor industry to produce thin films (Wikipedia, 2017a), while Graphene is one kind of thin film. Group 1 has keywords about composite, such as “mechanical-properties”, “carbon nanotubes”, “nanocomposites”, “hybrid composites”.

2) Group 3 and Group 5 are related to the application of molecular dynamics, a computer
simulation method for studying the physical movements of atoms and molecules (Zhou et al., 2016), because “molecular-dynamics” has high betweenness centrality behind “model” in Group 3, and “molecular-dynamics simulations” in Group 5.

3) Group 2 is closely related to study of nanowires, especially its application of battery, with “nanowires”, “ion batteries”, “cathode “, “energy-storage”.

4) Unlike the groups noted above, Group 4 and Group 6 are too decentralized to have unique theme. Group 4 can be divided into two parts, one is centered on “interface”, gathering in the center of Figure 4, while the other takes “plasma” as center, in the edge of Figure 4. Unlike Group 4, Group 6 is also divided into two parts: all nodes with high betweenness centrality flock together, linking to “growth”, and the rest just located on the edge.

Figure 6 shows the core sub-network of $k = 29$ in MSCP, with 102 nodes, and Table 9 lists the top 10 nodes with frequency, betweenness centrality and modularity class. “thin-films” is the node with the highest degree centrality, and “growth” and “nanoparticles” are nodes with the highest betweenness centrality. Obviously, thin-film is the main study object in MSCP, which relates to Materials Science, Physics, and Nanoscience & Nanotechnology. Especially, the growth of thin film, and thin films in nano-scale maybe the major research areas.

*Gephi files of ET-EMCM*

Keywords in ET-EMCM are divided into 9 communities (see Figure 7), while the modularity is 0.409. Ignoring the control function of “model” in the network, the communities in Figure 7 are demonstrated as follows, based on their nodes with high betweenness centrality:

1) Group 8 can be divided into three sub-groups. Two groups are mainly related to Energy & Fuels and Thermodynamics, such as study of electrode, and the energy of chemical reaction. For example, the first includes “hydrogen-production”, “electrodes”, “thermal boundary conductance” and so on (see Figure 8), while the second takes “energy” as center connecting “hydrogen”, “heat transfer”, “thermodynamic analysis” (see Figure 9). The last focuses on microelectromechanical systems (MEMS), the technology of microscopic devices widely used in high and new technology industry, merged at the nano-scale into nanoelectromechanical systems (NEMS) and nanotechnology (Wikipedia, 2017c), having “microelectromechanical systems” and “microfluidics” (see Figure 10). Microfluidics is a new development of MEMS, as a multidisciplinary field intersecting engineering, physics, chemistry, biochemistry, nanotechnology, and biotechnology (Wikipedia, 2017d).

2) Group 3, Group 0 and 6 reflect scientific methods. For example, Group 3 is obviously related to the method of fluid dynamics, having “finite element”, “navier-stokes equations”, and “computational fluid dynamics”, especially Navier–Stokes equations describes the motion of viscous fluid substances. And, Group 0 has “model predictive control”, “nonparametric regression”, as well as Group 6 includes “posteriori error analysis”, “sensitivity analysis”, etc.

3) Groups 1, Group 2 and Group 5 are about molecular dynamics, especially molecular dynamics simulation, studying on the growth, strain, crack, plasticity, propagation, elasticity, and degradation of metals or alloys. For example, Group 1 takes “deformation” as center, linking to “molecular-dynamics simulations”, “strain” and “crystal plasticity”, etc. With the node of “molecular-dynamics”, Group 2 also has “propagation”, “elasticity theory”, “crack-growth”, etc. Group 5 has nodes connected to Group 2, such as “shape optimization”, “damage tolerance”, “finite element analysis”, which are connected with Group 2’s “finite-element method” and “elasticity” (see Figure 11). The shape optimization is related to molecular dynamics simulation.

4) Phase, as a physically distinctive form of a substance, such as the solid, liquid, and gaseous states of ordinary matter, is the main theme of Group 4, which is consisted of “isoenergetic-isochoric flash”, “phase-equilibria”, “phase stability”, “liquid equilibrium”, etc.

5) Group 7 also can be divided into two main sub-groups. One is related to Computer Science, Hardware & Architecture, with “memristors”, “resistive random access memory (rram)”, “electrical characteristics”, “resistive memory” (see Figure 12). The other is bound up with the...
application of artificial material, taking “metamaterial” as center linking to “artificial magnetic conductors” and “horn antennas” (see Figure 13). For example, metamaterial is a material engineered to have a property that is not found in nature (Kshetrimayum, 2004), and artificial magnetic conductors is one of them, which is used in antenna.

Figure 14 shows the core sub-network of \( k = 16 \) in ET-EMCM, with 66 nodes, and Table 10 lists the top 10 nodes with frequency, betweenness centrality and modularity class. Keywords with high betweenness centrality over 1,000 are mostly about methods, such as “finite-element method”, “finite element”, “equations”, “simulation”, “optimization”, and, “formulation”. It is obviously that the core network is about scientific methods. One of the most typical methods in this field is molecular dynamics, detecting the property of given materials.

</table>
As shown in Figure 15, with 0.347 of modularity, there are 4 sub-groups as follow:

1) In Group 0, most keywords are related to Astronomy & Astrophysics, especially research of the sun, including structure and investigative techniques, such as “dynamics”, “magnetic-field”, “sun: activity”, “corona”, “sun: chromosphere”, “magnetohydrodynamics”, “dynamics-observatory sdo”, etc. Solar corona is an aura of plasma that surrounds the sun, as well as Solar Dynamics Observatory (SDO) is a satellite observing the sun launched by NASA. What’s more, as one of the Magnetohydrodynamics (MHD) systems, the sun is focused on by the study about magnetic properties of electrically conducting fluids.

2) Related to MHD, Group 1 has “magnetic reconnection”, “coronal mass ejections”, “flux”, “sun: magnetic topology”, “sun: surface magnetism”, “turbulence” and so on.

3) Compared with the two former subgroups, Group 3 and Group 2 are less homogeneous, and keywords of them belong to Optics, Polymer Science, Electrochemistry and Instruments & Instrumentation.

Figure 16 shows the core sub-network in IEAPO, with the K-core value set by 18, as well as Table 11 lists the top 10 nodes with frequency, betweeness centrality and modularity class. Compared with Figure 15, the core sub-network is similar to the mixture of Group 0 and Group 1. The keywords with high betweeness centrality over 300 are likely to concern with the study about MHD of the sun and its activity, such as coronal mass ejections and sunspot.

Conclusion and limitations

The conclusion presented here are based on SCI-Expanded articles funded by LMT and published from 2009 to 2016. Although research funding is being more and more significant in academic research, it cannot meet all researches’ demand, and this is why funder has set regional laws to examine and verify application from research communities, selecting the most valuable project they thought. This behavior not only indirectly influences the development of S&T, but also reflects which science field or technology funding provider focuses on, especially private company. Throughout funded papers, it is possible to detect
funding agency’s intellectual structure, as well as scientific and technological frontier. This paper shows a feasible way to map the intellectual structure and find frontiers of S&T. The top 15 disciplines and three main clusters are completely conform to what area LMT engages in. Besides Aeronautics, Missiles and Fire Control, Rotary and Mission Systems, and Space Systems, the four main business areas, Lockheed has business in the energy and emerging technologies. And Sandia is home to a wide variety of research including computational biology, mathematics, materials science, alternative energy, psychology, MEMS, and cognitive science initiatives. In cluster analysis, the top 15 disciplines were divided into three main clusters, MSCP, ET-EMCM and IEAPO. Compared all of them, it is obvious that MSCP is much more homogeneous than the rest, and has a large number of papers. Materials Science, Chemistry and Nanoscience & Nanotechnology are the fields that develop crosswise recently, and are the academic areas LMT focused on. Besides, Energy & Fuels and Thermodynamics, Engineering and Mechanics, as well as Computer and Mathematics are also the areas LMT pays attention to, which are related to Lockheed’s business and Sandia’s research areas. With business of space systems, LMT shows interest in Astronomy & Astrophysics.

Some detailed science fields and technologies funded by LMT are founded. In social network analysis, thin film in nano-scale and its growth are the core study in MSCP, while ET-EMCM is specifically about scientific methods in these subjects, such as molecular dynamics simulation used in special material, and IEAPO is focus on the sun’s structure and activity, especially MHD. Except the major parts above, there are some special fields detected, such as nanowires applied in battery, microfluidics, phase as well as metamaterial used in artificial implements.

The method in this paper is feasible to detect information of S&T in LMT. However, there are four limitations to this paper. First, the datasets in this paper are collected in the WoS, other databases are ignored. Second, we just used corporation name as search string to collect datasets, ignoring funding program manipulated or supported by LMT. Thirdly, we just chose the main part of samples we collected and did not explored the whole datasets, which might contain less but more valuable information of LMT. Lastly, we viewed Sandia and Lockheed as a whole, which ignored difference between them. They should be separately further elaborated in future research.

Abstract
We investigate the similarities of pairs of articles which are co-cited at the different co-citation levels of the journal, article, section, paragraph, sentence and bracket. Our results indicate that the following similarities rise monotonically as the co-citation level gets lower (from journal to bracket), in order of importance: textual similarity, intellectual overlap (shared references), author overlap (shared authors), proximity in publication time. While the main gain in similarity happens when moving from journal to article co-citation, all levels entail an increase in similarity, especially the paragraph and sentence/bracket levels. We compare results from three journals over the years 2010-2015, Cell, the European Journal of Operational Research and Physics Letters B, with consistent general outcomes.

Conference Topic
Citation and co-citation analysis, Natural Language Processing.

Introduction
The co-citation relation is used extensively in both information retrieval and bibliometrics. Applications include the identification of topically-related publications for search engines and clustering of publications to understand the structure of science. If two or more publications are co-cited by a third one, they are generally assumed to be related to some extent. Normally, this assumption is considered to be valid at a relatively coarse co-citation level, most often at the publication (e.g. article) level. In addition, recent work suggests that the similarity between co-cited publications might increase with increasing proximity of two publications within the full text of the citing publication, and that improvements in maps of science or document retrieval can be obtained by taking textual proximity into account. Indeed, it makes sense to assume that if two publications are co-cited in the same sentence or bracket in a publication, they typically will be in some way more related than two publications barely co-cited at the more general section or publication levels. Yet open questions remain and we know little about the ways in which related, co-cited publications are similar. This proof-of-principle study was designed to provide answers to these questions.

The recent increase in availability of full text data is beginning to impact the areas of research of bibliometrics and the retrieval of scientific publications by enabling the exploration of topics such as those listed above at a finer grained level. In this study we explore the implications of co-citations at different levels of granularity, and we do so by: a) considering different measures of similarity: textual similarity, reference overlap, shared authors, and publication time; b) comparing articles from three journals as representing different fields and possibly different citation practices and behaviors. The three journals considered in this study
are *Cell*, the *European Journal of Operational Research* and *Physics Letters B*. After discussing related literature in the following section, we define our dataset and methods, discuss empirical results, and then conclude with implications and suggestions for future research.

**Related Work**

Co-citation relations have been used in a variety of contexts. Originally introduced in 1973 independently by Small (1973) and Marshakova Skaikevich (1973), co-citation analysis has most often been used to study the structure of science from the perspective of cited publications. A pair of publications is considered to have been co-cited if they appear together in the reference lists of one or more citing publications. The more often a pair of publications has been co-cited together, the more related they are assumed to be. The notion of co-citation has been extended to cited authors (White and Griffith 1981) and journals as well (McCain 1991; Ding, Chowdhury & Foo 2000). While it was originally used only on very small data sets, in recent years it has been used to cluster sets of over two million publications (Boyack & Klavans 2014).

The increasing availability of the full text of scientific publications has enabled a rising interest in its use in bibliometrics and related areas of research (Jha et al. 2016). Recently, it was also shown using a set of nearly four million publications from Elsevier journals that full-text features can sensibly enhance the prediction of the future impact of a publication, and more broadly that “it is well worth the effort to obtain the full text of scientific articles and to exploit the power of natural language analysis” (McKeown et al. 2016).

Recent analysis has also been using sentences from full-text publications. For example, pairs of articles that are cited within the same sentence have been shown to be more similar than pairs of articles that are cited within the same article (Tran et al. 2009), which has obvious applications in information retrieval and document clustering. Liu et al. (2014), using several hundred thousand articles from PubMed Central, found that queries against citing sentences do very well at finding highly relevant older articles, but not for newer ones. Doslu and Bingol (2016) used citation contexts (text surrounding the reference marker) to improve the ranking of items in a retrieval context using data from CiteSeerX. Citation contexts have also been used for sentiment analysis (Small 2011) and for identifying biomedical discoveries (Small, Tseng and Patek 2017).

More closely related to our study are a number of works aimed at improving measures of publication relatedness using their full text. The majority of these have investigated co-citation proximity, while a couple are based on bibliographic coupling.

Nanba et al. (2000) were the first to test if co-citation proximity was related to increased textual similarity. Using a small set of citation areas (typically a couple of sentences) extracted by hand, they reported a rise in the textual similarity of two articles as their co-citation proximity increased. Elkiss et al. (2008) explored a set of nearly 2500 full-text articles from PubMed Central, finding that the cosine similarity of articles increased if they were co-cited at closer granularities, considering both their abstracts and body texts. Gipp and Beel (2009) suggested weighting the links between pairs of articles in a co-citation network according to their co-citation level, using full weight for the sentence level, half weight for the paragraph level, etc. They found that this weighting scheme performed twice as well at retrieving relevant publications than when not accounting for link weights. As mentioned above, Tran et al. (2009) found that pairs of articles that are co-cited within the same sentence
were more similar than pairs of articles that are co-cited only at the article level. Callahan et al. (2010) suggested using the structure of the citing publication to establish co-citation relations among publications, albeit without assessing their method with more than anecdotal evidence. Liu and Chen (2012) examined a large dataset of publications and resulting co-citation pairs from BioMed Central (BMC), analyzing the sentence, paragraph, section and article levels. They found that in general lower co-citation levels are correlated with higher co-citation frequency, supporting the use of co-citation level information if available, and suggesting that co-citations at the sentence level form the basic structure of the general co-citation network. Boyack et al. (2013) used co-citation proximity information, as mapped by character offset, in order to improve co-citation clustering of articles. Their results on nearly 300,000 full-text articles published in Elsevier journals in 2007 show that the textual coherence of resulting clusters can increase by up to 30%, at the price of a decrease in the size of clusters. Finally, in a work using Wikipedia entries rather than scientific articles, Schwarzer et al. (2016) found that citation proximity analysis improved recommendation quality as compared to a simple co-citation approach.

Despite the above efforts, and the evidence in support of the idea that lower co-citation levels entail an increased similarity between publications, not much is known on what kind of similarity is involved, nor if the effect is similar in different fields of research.

**Methods and Data**

**Definitions**

We consider a co-citation to be a relation established between a pair of publications which are both cited at a certain level within scientific text. In this study we consider articles as publications, our hierarchy therefore starts at the journal level, where articles are published. The levels at which a pair of publications can be co-cited are, from high to low:

1. **Journal**: publications co-cited within the same journal. In our analysis, we consider articles as co-cited within the same journal if they are cited in the journal in the same year.
2. **Article**: publications co-cited within the same article.
3. **Section**: publications co-cited within the same section – a logical unit of the publication identified by some header – in an article.
4. **Paragraph**: publications co-cited within the same paragraph in an article. Paragraphs are usually identified with some layout expedient such as indentation or interlinear space.
5. **Sentence**: publications co-cited within the same sentence in an article.
6. **Bracket**: publications co-cited at the same location in an article. These are often delineated with brackets or parentheses.

Note that a pair of publications co-cited at a given level is also to be considered as co-cited at any higher level. For instance, if two publications are co-cited at the paragraph level, then they are also considered as co-cited at the section, article and journal levels. In the literature co-citation proximity often, but not always, entails considering the textual distance between co-cited publications, such as character offset (e.g. Boyack et al. 2013). In our case, we do not take this approach. Instead, we use meta (e.g. publication), logical (e.g. section) or syntactic (e.g. sentence) textual units to identify different co-citation levels. The two approaches are related but not identical. We therefore refer to co-citation levels instead of co-citation proximity. We order co-citation levels from high (journal) to low (bracket). In this study we only consider journal articles as co-cited publications for analysis.
Data

Our analysis considers three Elsevier journals: Cell, the European Journal of Operational Research (EJOR), and Physics Letters B (PLB). Our analysis includes journals from three very different disciplines, possibly with quite different citation practices. Cell is a prominent life sciences journal. EJOR can be seen as a journal at the interface between the social sciences, computer science, and mathematics. PLB is a physical sciences journal. The three journals have also been chosen because they are all quite large and because they all have at least a moderately high citation impact. We analyze co-citations in the three above-mentioned journals in the six-year time period 2010-2015. We have chosen to consider a six-year time period to make sure that we have a sufficiently large number of data points per journal and to guarantee the reliability of our analysis.

The dataset of pairs of co-cited articles was constructed as follows. First, we used every article published from 2010 to 2015 in the three journals under consideration classified as either “full research article” or “short communication”. Review articles were excluded since their specific co-citation patterns may be different from articles describing original research. Second, we restricted the cited articles (references) to those which are published in Elsevier journals. Although this did reduce the number of potential co-cited pairs to be studied, this restriction facilitated our study in that it allowed easy access to the abstracts and cited references of cited articles. It is important to note that, by considering only cited articles published by Elsevier, we still retained between one third and half of all cited articles for analysis (Table 1).

Given this selection, we defined six sets of co-cited article pairs for every journal, corresponding to the six co-citation levels defined above. At the article level and the lower levels, all co-cited article pairs were used. Co-cited article pairs at the journal level were sampled from the large number of possible pairs. For each pair of articles co-cited within the same article, the most detailed level at which it is co-cited was identified, and the pair was counted for that level and all higher levels up to the article level. The frequency of co-citations was not considered. Consider a pair of articles that have been co-cited multiple times at the article level (because at least one of the articles has more than one in-text mention). Suppose that one of the co-citations is at the bracket level. The pair of articles will then be considered as co-cited at the bracket level and consequently also at all higher levels.

The hierarchy of the number of pairs per level is shown in Table 1; for instance, Cell has 9,392 pairs at the sentence level of which 5,585 are also at the bracket level. For the journal level, we created a large set of unique pairs of co-cited articles for each journal by sampling with replacement from the available pool of articles that have been cited by articles from the given journal in the same year. The number of pairs maintained at the journal level is somewhat higher than the numbers at the article level. Characterization of the dataset at all levels for each journal is given in Table 1.

Table 1. Basic statistics of the dataset for each journal. All co-cited pairs counts consider only co-citations of articles that are present in the Elsevier full-text dataset.

Measures
The similarity between two publications can be conceptualized in many different ways. Here we focus on four main axes: textual similarity, intellectual overlap, author overlap and time distance.

To establish the textual similarity between two publications in a pair we considered their titles and abstracts and use the BM25 measure, widely adopted to rank documents for information retrieval given a textual query (Spark Jones et al. 2000) and more recently also used to cluster publications using their titles and abstracts (Boyack et al. 2011). Each publication (title and abstract) was reduced to lowercase and split into tokens for calculation of textual similarity (eliminating punctuation and then tokens of just one alphanumeric character). Given a publication \( q \) and another publication \( d \), BM25 similarity was calculated as

\[
s(q,d) = \sum_{i=1}^{n} IDF_i \frac{n_i(k_1+1)}{n_i+k_1(1-b+0.75|D|/|D|)},
\]

where \( n \) denotes the number of unique tokens in \( q \), \( n_i \) equals the frequency of token \( i \) in document \( d \), and \( n_i = 0 \) for tokens that are in \( q \) but not in \( d \). \( k_1 \) and \( b \) have been set to the commonly used values of 2 and 0.75 respectively. \(|D|\) denotes the length of document \( d \), in number of tokens. \(|D|\) denotes the average length of all documents in the collection. The IDF value for every unique token in the collection was calculated as

\[
IDF_i = \log \left( \frac{N-d_i+0.5}{d_i+0.5} \right),
\]

where \( N \) denotes the total number of documents in the collection and \( d_i \) denotes the number of documents containing token \( i \). IDF scores strictly below zero were discarded to filter out very commonly occurring tokens. BM25 is not a symmetric measure. We obtained a symmetric measure for the similarity of documents \( q \) and \( d \) as follows:

\[
\frac{s(q,d) + s(d,q)}{2}.
\]

A BM25 textual similarity was calculated for every article pair listed in Table 1. For each journal, we then divided by the maximum BM25 value among pairs from that journal in order for the measure to range between 0 and 1. We note that after applying this normalization BM25 values cannot be directly compared between journals.

We define the intellectual overlap to be the proportion of references that a pair of publications have in common (alternatively known as bibliographic coupling):

\[
\frac{N_{qd}}{\min(N_q,N_d)},
\]

where \( N_{qd} \) denotes the number of overlapping references of publications \( q \) and \( d \) and \( N_q \) and \( N_d \) denote the total number of references in publications \( q \) and \( d \) respectively. The intellectual
overlap equals one if all references of the publication with the shorter reference list are also cited by the other publication.

We define the author overlap as the proportion of authors that a pair of publications have in common. Analogous to the intellectual overlap measure we used the minimum number of authors of the two publications as the normalization basis (similar to Eq. (4)). If all authors of the publication with fewer authors are also authors of the other publication, the author overlap equals one. Matching of authors was done using the following process. Starting with a string of text for the surname of an author and one for the full name of the author, we converted both strings to lowercase. We then compared all possible combinations of author mentions. We considered two mentions to refer to the same author if the surname was identical and all components of the full name of the shorter name string had a match in the longer name string. For example, “John J. Abrams” will match with “J. Abrams” but not with J. M. Abrams”. Given that we operate within the context of a specific journal and that the procedure is fairly conservative, we deem the results as sufficiently accurate.

Lastly, we define the time distance as the number of months between the publication dates of a pair of co-cited publications. We used the publication month data present in the Elsevier full text data.

Results

Distributions

We start our analysis by considering the distributions of the similarity measures of pairs of articles co-cited at different levels for each journal under consideration. Figure 1 shows the results for textual similarity calculated using the BM25 measure. Clearly, textual similarity monotonically increases as the co-citation level goes down. The means are located above the medians, suggesting that the distributions of the similarities are right skewed. A closer inspection of the distributions of the similarities (not shown here) reveals that the distributions are fairly normal, but indeed with a slight skew on the right side. For all three journals the main increase in similarity is obtained by moving from the journal to the article co-citation level. The section level adds little afterwards. Behaviors then differ: whilst article pairs co-cited in EJOR and PLB gradually increase in similarity, this increase is more pronounced for Cell.
We consider next the intellectual overlap of pairs of articles with results shown in Figure 2. Intellectual overlap presents a generally more skewed distribution, and an even larger gain in similarity takes place from the journal level, where similarity is essentially zero, to the article level. Here too, the similarity rises monotonically as we move down in the co-citation levels. PLB has the highest intellectual overlap in co-cited articles. The rise in intellectual overlap is also more rapid for PLB, ending up at the bracket level with an average number of nearly one in every four references being shared. Pairs of articles co-cited in Cell, as well, present a rapidly growing overlap as the level lowers. This effect is less pronounced in EJOR.

With respect to author overlap, results are given in Figure 3. Its distributions are very skewed, as at any level most pairs of co-cited articles do not share authors at all. Nevertheless, we see that author overlap in the case of PLB is stronger than in the case of the other two journals. We note that articles published in and cited by PLB have a more skewed distribution of the number of authors than those of Cell and EJOR. Physics is, in general, known to have a larger number of kilo-authored papers than other fields. Cell, on the other hand, has a higher median number of authors per article, as shown in Error! Reference source not found., which might lower its relative author overlap.

<table>
<thead>
<tr>
<th>Table 2. Mean and median number of authors of the citing and cited articles.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cell</td>
</tr>
<tr>
<td>Mean (median) number of authors of citing articles</td>
</tr>
<tr>
<td>Mean (median) number of authors of cited articles (Elsevier only).</td>
</tr>
</tbody>
</table>
Lastly, in Figure 4 we consider the distance of the publication time for pairs of co-cited articles. *Cell* and *EJOR* in general refer to research more proximal in time as evidenced by their lower time distances at the journal and article levels. However, this difference nearly disappears with increasing proximity. As we move down in the co-citation levels, co-cited articles become increasingly similar in terms of their publication time, ending up at a median difference in publication time of about three years for each of the three journals at the bracket level.
Figure 4. Mean and median publication time distance (in months) of article pairs co-cited at different levels. Note that statistics are calculated at each discrete level, lines are only meant for readability.

Taken together these first impressions highlight how in general, and over four different dimensions (text, references, authors and time), co-cited articles that are located at lower levels tend to be more similar than those that are located at higher levels. Results confirm the intuitive hypothesis that, as the co-citation level lowers, research being co-cited is increasingly more related. The agreement of all similarities supports the idea that, especially at lower co-citation levels, authors tend to refer to coherent pieces of research that are similar in content, often similar in terms of authors involved, and that have been published around the same time.

Cumulative distributions
We now take another view by considering cumulative distributions. For each journal, each similarity measure and each proximity level, we inspect the proportion of pairs of co-cited articles with a similarity value equal to or below a certain threshold value. All results are shown in Figure 5. Starting with textual similarity, we can immediately appreciate how gains in similarity are not negligible at most levels. This is especially the case for pairs of articles co-cited in Cell, which seem to increase their similarity in three steps beyond the journal level: article/section, paragraph and sentence/bracket. For EJOR and PLB these steps are less well defined. The main increase takes place between the section and paragraph levels for these journals.

The cumulative distribution of the intellectual overlap follows slightly different patterns. The similarity of pairs of co-cited articles according to intellectual overlap is indeed more pronounced in PLB than in Cell and EJOR. Three major increases in similarity can be observed for Cell and PLB, namely at the article/section, paragraph and sentence/bracket levels, whilst for EJOR the only significant increase takes place between the section and paragraph levels.
Lastly, we consider the same distributions for the author overlap and the publication time distance. With respect to the author overlap, we notice how pairs of co-cited articles which share authors are relatively rare at all levels, as was indeed evident already from Figure 3, and the importance of this aspect for PLB is particularly remarkable. In a similar way to what we discussed for the intellectual overlap, the author overlap seems to follow a three step pattern in Cell and PLB. The distributions for the publication time distance are more compact, except for PLB, where gains in time distance moving to lower levels are more important.

All journals share an increase in similarity as we move to lower co-citation levels. The main transition happens between the journal and article co-citation levels. Cell and EJOR article pairs become relatively more similar with respect to textual similarity and time, PLB pairs with respect to their intellectual and author overlaps. A further distinction appears when we consider relative similarity gains at different levels. While Cell and PLB in general show noticeable similarity increases at three stages (article/section, paragraph and sentence/bracket), EJOR is more gradual and presents only two clear stages (article/section and below).
Conclusions
In this article we explored the similarity of article pairs which are co-cited at different levels. We considered three journals from different disciplines: Cell, the European Journal of Operational Research (EJOR) and Physical Letters B (PLB). Our results indicate that the similarity of pairs of articles increases monotonically with their co-citation level. In other words, the lower the level at which two articles are co-cited, the more similar the articles will be on average. We used different measures of similarity between pairs of co-cited articles: textual similarity, intellectual overlap, author overlap and distance in time. These measures all increase as the co-citation level lowers.

Our results provide a solid confirmation of the idea that there is value in using co-citation proximity information in order to capture stronger links between co-cited articles. This result has implications for, among others, science mapping and the retrieval of scientific literature. However, this study is not without limitations. In particular, it explores only three journals and thus cannot truly represent co-citation behaviors by discipline or field. Additional studies with larger data sets are needed to explore field-based differences. In addition, this study explores similarity measures independently without considering their interactions. Other similarity measures could be explored as well, for example by considering the frequency of in-text citations.

Is the Relationship between the Impact Factor and Papers’ Citations Really Weakening?

Yue Mingliang¹ Ma Tingcan²

¹ yueml@whlih.ac.cn ² matc@whlih.ac.cn
Wuhan Documentation and Information Center, Chinese Academy of Sciences, Wuhan (China)

Abstract
Recently, certain researches declared a weakening relationship between impact factor (IF) and papers’ citations due to the increasingly convenient access to individual papers in the digital age. In this paper, we study the publication distribution of the most cited papers on the most cited journals (i.e., journals with highest IFs) based on three pieces of data, i.e., Science Citation Index Expanded (SCI-EXPANDED), Essential Science Indicators (ESI) and Journal Citation Reports (JCR). The results show that either from the overall or research field perspective, there is no obvious clue to indicate the weakening relationship between IF and papers’ citations.

Conference Topic
The relationship and development of five metrics science concepts, that is, Bibliometrics, Informetrics, Scientometrics, Webometrics and Knowledgometrics.

Introduction
Ever since it was proposed, the discussion around Impact Factor (IF) has never stopped (Garfield, 2006; Russell, 2002). The debates always focus on whether IF is an effective way for research evaluation and arouse many variants of IF, e.g., the source normalized impact per paper (Moed, 2010), the Eigenfactor (West & Bergstrom, 2010), and the SCImago Journal Rank (González, 2009), etc. In all those works, IF is treated as an important factor that can influence the potential citations a paper can receive (Waltman, 2016). However, most recently, certain researches declared a weakening relationship between IF and papers’ citations due to the increasingly convenient access to individual papers in the digital age (Lozano, 2012). Whereas many others insisted that IF is still one of the most authoritative scientometric indicators for assessing the academic impact of journals and is influential to papers’ citations.

Focusing on this debate, in this paper, we study the publication distribution of the most cited papers on the most cited journals (i.e., journals with highest IFs) to analyze the relationship between IF and papers’ citations. Rather than ranking papers and journals with self-calculated citations and IFs (Lozano, 2012), we use citations and IFs published by Web of Science (WoS) and Incites. Further, we use IFs for journal ranking and Essential Science Indicators (ESI) baseline for top paper ranking. We believe this way is more objective and effective since WoS/Incites and ESI data is most widely accepted and used by scholars (Archambault, 2008; Meho, 2007). That means, if IF does have certain relationship with paper citation, it is WoS IF (rather than self-calculated IF) that affects scholars’ impression to a paper and the willing of citing it. The results show that either from the overall or research field perspective, there is no obvious clue to indicate the weakening relationship between IF and papers’ citations.

Method
We made use of three pieces of data in our analysis, i.e., Science Citation Index Expanded (SCI-EXPANDED), Essential Science Indicators (ESI) and Journal Citation Reports (JCR). We first downloaded the bibliography data of papers covering all areas of natural sciences from SCI-EXPANDED in between 2005-2014, and mapped every paper to the corresponding
research field according to the paper’s publishing journal based on the ESI category. Then we associated every paper with a top-level (e.g., Top 1%) based on the paper’s citation counts and the ESI citation baseline by considering the paper’s research field and publishing year, and used the Top 10% papers for statistics, involving 1.44 million papers and 20 research fields. Fig. 1 and Fig. 2 shows the number of papers published in each year and each research field respectively.

![Figure 1 Paper counts vs. Publishing years](image1)

Further, for every research field, we ranked its belonging journals according to their Impact Factors (IF) in the decrease order year by year, and calculated the top-level (e.g. Top 5% journals) for every journal in every year. Finally, we calculated the yearly publication distributions of the Top \(m\)% papers on the Top \(n\)% journals to assess the overall relationship between IF and papers’ citations and its variation trend, for \(m=0.1, 1, 10\) and for \(n=1, 5, 10\), where Top \(x\)% papers means papers with citation ranked in the Top \(x\)% and Top \(x\)% journals means journals with IF ranked in the Top \(x\)%. Moreover, we also carried out statistics in a more detailed perspective, i.e., research field, to test whether the overall trend holds in most research fields.
Results

Overall results

Fig. 3 to Fig. 5 show the percentages of the Top 0.1%, 1% and 10% papers published in the Top 1%, 5% and 10% journals, for all research fields and all countries (regions). From the figures, the following conclusion can easily be drawn: 1) in almost all the years, more than 80% of the Top 0.1%, 1% and 10% papers come from the Top 1% journals, and in average 88.9%, 87.2% and 86.3% of the Top 0.1%, 1% and 10% papers come from the Top 1% journals; 2) despite of small variations, the percentages of the Top 0.1%, 1% and 10% papers published in the Top 5% (10%) journals are all larger than 97% (99%); 3) none of the Figures reflects an obvious declining of the percentages (of top papers published in top journals). That is, in general best papers were still published in best journals, and there is no evidence to indicate the weakening relationship between IF and papers’ citations.

Figure 3 Percentages of the Top 0.1%, 1% and 10% papers published in the Top 1% Journals

Figure 4 Percentages of the Top 0.1%, 1% and 10% papers published in the Top 5% Journals
Field perspective

Here we aim to see whether the same relationship (among the top papers and the top journals) holds from the perspective of different research fields. To fully understand the relationship among the top papers and the top journals, here we focus on the Top 0.1% papers for illustration. In addition, the full statistic results including all the research fields and all the Top levels of papers and journals can be found in our supplementary materials†. From the results, we see that first, for the Top 1% journals, a) the percentages of the top papers published in the top journals are relatively low in certain research fields. As shown in Fig. 6, these fields include Material Science, Microbiology, Molecular Biology & Genetics, Physics and Psychiatry/Psychology. However, b) for all the remaining 15 research fields, the percentages of the top papers published in the top journals are approximately the same as the overall situation. As shown in Fig. 7, most of the percentages are larger than 80%, and in average 94.0% of the Top 0.1% papers come from the Top 1% journals.

† The supplementary materials are interactive dashboards formatted as PDF files, please refer to either of the following URLs: Google Drive: https://drive.google.com/file/d/0BwdzLr3JJ8qcZlJTMXJ3aWd3ZDQ/view?usp=sharing OR Baidu Cloud: http://pan.baidu.com/s/1mihsBO0 (Password for Access: zsni)
Second, for the Top 5% and 10% journals, in almost all the research fields and years, more than 90% (95%) of the Top 0.1% papers come from the Top 5% (10%) journals, as shown in Fig. 8 (for Top 5% journals) and 9 (for Top 10% journals).
From the above analysis, it can be seen that same as the overall situation, there is no obvious evidence to indicate the weakening relationship between IF and papers’ citations.

**Conclusion**

In this paper, we studied the relationship between IF and papers’ citations. The results show that either from the overall or research field perspective, there is no obvious clue to indicate the weakening relationship between IF and papers’ citations. That means IF still acts as a very important indicator for the quality of academic journals and can influence the potential citation a research paper can receive. We believe that at least three reasons contribute to this fact. First, higher IF can still attract papers with higher quality for publication. Then, higher IF journals may have scholars with higher academic attainments for peer review. Hence only papers with higher quality may appear on the journals. Those two facts guarantee the papers’ potential academic influence. Third, it is exactly because of the increasingly convenient access to individual papers in the digital age, that researchers can easily acquire large amounts of research results. Finding more appropriate references with higher quality becomes an urgent need. And it seems that currently there is no other way more effective and efficient than selecting based on IF and paper citation.

Abstract
We identified the names of all authors of Web of Science papers on cancer in 2009-11 and in 2014-16 with a UK address, and listed those in each postcode area (the first one or two letters of UK postcodes). Their ethnicity or national origins were determined from their names with the OriginsInfo database into seven main groups; African, Asian excluding South Asian, South Asian, Western European, Eastern European, Islamic World, and the UK/Ireland. We were thus able to determine the geographical distribution within the UK of members of the six immigrant groups in terms of their fractional contributions to cancer research. The percentage of research contributions from scientists with non-British (or Irish) names rose from 37% in 2009-11 to 39.4% in 2014-16. It was higher in London, and rose from 47% to 51%. The largest ethnic contributions were from Europe: in 2014-16 the percentages were 15.4% from Western Europe and 3.7% from eastern Europe. There were 8.1% of contributions from South Asia, and 5.6% from the rest of Asia; the largest were in four areas of London, and in Cambridge and Oxford. Female participation is still less than that of males, but it is increasing by about 2% per year.

Conference Topics
Country-level studies; mapping and visualization; participation in science; science policy

Introduction
This study began with an investigation of the role of immigrant scientists in UK science, and in particular with their presence at the higher levels - Nobel laureates, Fellows of the Royal Society and Fellows of the Academy of Medical Sciences. We showed that immigrants had played a substantial role at these higher levels, and that any restrictions that might be imposed on scientists from the European Union (EU) coming to the UK when it was no longer a Member State would have damaging consequences (Begum et al., 2016). The investigation also looked at the presence of scientists with foreign names among UK cancer researchers in 2009-11, and showed that about three quarters of such groups who authored papers recorded in the Web of Science (WoS, © Clarivate Analytics) contained at least one member with a foreign name, either continental European or from the Rest of the World (which would not be affected directly if the UK left the EU).

The present study builds on this, and examines the UK locations where the ethnic minority cancer researchers are working, the world regions from which they come, and (for most of them) their sex. It also examines two separate cohorts: those publishing papers in 2009-11, and a later one from 2014-16. It is intended to provide further evidence of the part played by immigrant researchers, and to show where they are most productive. It will also provide information on the sex balance of cancer researchers, both those with British names and those from the different ethnic groups or with different national origins.

There is a paucity of literature on the ethnicity or national origins of researchers. However, it has been shown that immigrants can make substantial contributions to the scientific output of their host countries in different disciplines. For example, Webster (2004) showed the
importance of different ethnic groups to UK science in several major fields. There are more Indian cancer researchers in Canada and the USA than in India itself (Basu, Roe & Lewison, 2012). In lung cancer research, there has also been much international migration (Lewison et al., 2016), and in Canada and the Nordic countries many of the researchers were from ethnic minorities.

In the UK, various organisations collect personal information on ethnicity as part of the concern to improve opportunities for minorities. The forms offer a number of options, but cannot be comprehensive or deal adequately with people of mixed race or ethnicity, and some respondents decline to answer. Although names do not necessarily provide an exact indicator of nationality, studies have consistently demonstrated (Webber, 2007; Mateos et al., 2007; Webber 2010) a very close correspondence between a person’s given and family names, taken in combination, and the cultural background of their forebears. They can also indicate a degree of cultural assimilation when people have a given name indicative of a different ethnicity than that of their surname, suggesting that they are second-generation rather than first-generation arrivals. This is explored in a little more detail in the Discussion section.

Methodology

The selection of cancer research papers.
Cancer papers were identified using a proprietary filter (Lewison, 2011) developed in consultation with Cancer Research UK and updated with Escuela Andaluza de Salud Pública; our Spanish partners on a previous EU mapping project. The filter comprehensively listed specialist cancer journals and title words that covered several cancer manifestations, genes implicated in one’s chance of developing or avoiding cancer, and drugs exclusively used for cancer treatment. It had a strong precision (0.95) and recall (0.98) and was applied to Clarivate Group’s Web of Science (WoS). The WoS literature search was limited to articles and reviews from both the Science Citation Index and Social Sciences Citation Index, which had at least one address in the UK, and were published in two specific time periods; 2009-11 and 2014-16. These papers were downloaded as text files, 500 at a time, and were then converted into a single Excel spreadsheet for each time period using a macro developed for WoS papers by Evaluametrics Ltd.

Since 2009, the WoS has tagged the authors of papers with their individual addresses in a column labelled “C1”, and these data were used to distinguish authors with a UK address from ones working abroad. Another macro listed the names of each UK author, with her or his postcode area (see below) and their total fractional contribution, based on the numbers of authors on each paper. Authors with an address in the UK and one elsewhere would have had their contribution divided between their different addresses, and similarly if they worked in two (or more) UK postcode areas.

Origins: Ethnicity

The list of cancer researchers with UK addresses with their given and family names was sent to OriginsInfo Ltd for classification by country of origin/ethnicity and sex using the OriginsInfo database. This is a large proprietary database of approximately four million surnames and one million given names. Ethnicity can be determined in 99.5% of cases when both names are present, and with 96% accuracy on the basis of surnames for higher-level ethnic categories (e.g. West African) and at 93% at lower-levels (e.g. Nigerian and Ghanaian). The ethnic categorisation of researchers was very detailed, sometimes distinguishing between distinct regions of the same country (e.g. Indian categories included Gujarati, Punjabi, Hindi, Bengali, Tamil, Sikh, etc.). Subsequently, this information was condensed to 11 main world regions identified by three-letter codes listed in Table 1. Some
“authors” were collaborative groups, and so were not assigned to a world region. Some authors were not assigned to a world region by the software, and the names were inspected so as to categorize some of them where it appeared clear which region they were from. Of the 78,101 names, 69 were groups and only 392 could not be assigned to a region (0.5%).

Destinations: Postcodes

Geographical distributions within the UK are conveniently described by postcodes, which form part of the address. The UK postcode operates at four levels (Shepherd et al., 1992):

- the postcode area, consisting of one or two letters (e.g., SE, G);
- the district, consisting of these plus one or two numbers, (e.g., SE1)
- the sector, consisting of these, plus a space and a single number (e.g., SE1 6);
- the full postcode, consisting of these plus two letters (e.g., SE1 6RT).

The full postcode normally defines a street, or part thereof, or a large building such as a hospital, but in our analysis we only used the first part, the postcode area, of which there are 124 for the UK, including the Isle of Man (IM) and the Channel Islands (Guernsey GY and Jersey JE). London has eight postcode areas: E, EC, N, NW, SE, SW, W and WC. The five major university hospital groups are mostly associated with one of these: Imperial with W, King's College with SE, Queen Mary (Bart's and the Royal London) with E and EC, St George's with SW, and University College with WC and NW (Royal Free).

An address macro was applied to the C1 column of the spreadsheet to identify all UK addresses with their postcode areas. This created two worksheets. One listed each author with an identifiable UK postcode in the C1 column together with their fractional
contributions to cancer research, and a second with any addresses without a postcode present or not in the address thesaurus. These needed to be manually searched and coded before the macro was subsequently re-run. This process characterised almost all UK addresses with their postcode areas, but some turned out not to be UK (e.g., they were in London, Ontario) and were coded “XX” or were too vague (e.g., University of London, London) and were left blank, or simply could not be found from a search on the Web. Altogether, we were able to find the postcode areas for all but 0.04% of the UK addresses.

Determination of the authors’ sex

This was the most difficult part of the exercise and we undertook the sexing of individual authors in five stages. The first was through the OriginsInfo database, which was able to assign sex to many of those with given names. In 2009-11, 33% of authors only had one or more initials, but by 2014-16, this proportion had reduced to 25%; this probably reflects the changing policy of journals and the desire of authors to distinguish themselves from others with the same surnames and initials.

The second stage involved the analysis of another large database, that of over 300,000 UK-registered doctors, which lists their given names and their sex. We tabulated all the different given names, with the numbers who were male and female. Of 51,865 different given names, 2,830 could be classed as male and 2,145 as female, on the basis of there being at least five people with the name of one sex only, or at least ten times as many of one sex as of the other. For example, there were 58 Ranjits who were male but only four female, so this name was treated as male, but there were 36 Padmas who were female but only two male, so this name was treated as female.

The third stage was to send lists of given names of people from particular regions or individual countries to people from these countries whom we knew (see Acknowledgement), who might be expected to know which given names were male and which female; if they were not sure or the names could be of either sex, they were not sexed.

The fourth stage involved the use of a special macro (written by PR) that examined names with only initials, and sought other authors with the same surnames and given names with the same initial letter. If a match was found, the possible matching given names were added. We then checked the sexes of these, and if and only if they were all either male or female (not blank), then we assigned a sex to the name with only initials. Thus Abel, P matched with both Abel, Paul and Abel, Peter, both of whom were male, so Abel, P was male. But Adams, C matched with both Adams, Christopher and Adams, Caroline, so could not be sexed. Some of these names could, however, be sexed in a fifth stage if the person with just an initial was working in the same postcode area as a person with a sexed given name and the others were working elsewhere.

Results

There were totals of 14,373 papers for 2009-11 and 17,107 for 2014-16, and there were 34,347 names and 43,754 names, respectively. Some of these were clearly the same people working in different postcode areas, and there were also name variants (either initials or given name, or sometimes both, e.g., Abdelrahman, Mostafa H.). The individual contributions from authors from each world region and each sex to each postcode area were listed by means of pivot tables for the two time periods, so that the regional contributions could be seen, and also the distribution by sex.
 Origins: ethnicity or national background

Table 2 shows the cancer research fractional contributions, and their percentages of the total, for the different ethnic groups in 2009-11 and in 2014-16.

Table 2. Ethnic composition of UK cancer researchers, 2009-11 and 2014-16. See Table 1 for regional codes.

</table>

The researchers with UK or Irish names form the largest contingent, of course, but "ethnic minorities" now make up about 40% of the total. The largest groups are the West Europeans and South Asians, but the East Europeans are growing much faster (nearly 29% increase between the two periods). The Africans and Latin Americans are also growing, but from much smaller bases. Figures 1 and 2, below, show the countries involved in the West and East European contingents, and from the Asian ones, for the whole six-year period. The digraph ISO2 codes used in the pie charts are identified in Table 3.

Figure 1. Contributions to UK cancer research in 2009-11 and 2014-16 combined by researchers from the "old" European Union (left) and from the "new" EU and other Eastern European countries (right); fractional counts of papers. Areas of pie slices are proportional to contributions.
Cancer research in the UK is concentrated in the "golden triangle" of Cambridge, London and Oxford, as Table 4 clearly shows. The 10 postcode areas for these cities accounted for 38% of the total UK contribution in the six years (data for London N not shown, but equal to 0.12%).
Table 4. Contributions to UK cancer research from the 25 leading postcode areas with > 200 papers in 2009-11 and 2014-16, with distribution of major regional ethnicities. Contributions of other ethnic groups are not shown.

</table>

The ethnic minority contribution among these major research centres varied between 12% in BT (Northern Ireland) and 56% in London W (mostly Imperial College hospitals: Charing Cross, Hammersmith and St Mary's). It was also quite low (< 30%) in Scotland and the north of England. Figure 3 shows a map of the UK, shaded according to the percentage of ethnic minority cancer research contributions.
The South Asians were mainly in London (WC, W and SE) followed by Birmingham and Manchester; the West and East Europeans again in London (WC and SW) followed by Cambridge.
The sex distribution of UK cancer researchers

Table 5 shows the distribution by sex for authors from different world regions for both time periods together.

Table 5. The numbers and percentages of both males and females, the percentages that could be sexed, and the ratio of females to the sexable total, for authors of UK cancer research from each world region (for codes and countries represented, see Table 1).

</table>

The largest group was people with British or Irish names, and nearly 87% of them could be sexed. Of those that were, women contributed 42% of the cancer research papers. This ratio was lowest (32%) for people from the Islamic World, and almost as low for people from South Asia. It was highest for people from Latin America and the few with North American names, and only slightly less for those with Eastern European names.

In view of the efforts currently being made (Equality Challenge Unit, 2017; Munir et al., 2014) to attract more women into science and to facilitate their careers, we investigated whether there had been any change in the percentage of females / (males plus females), which was 41.3% overall (v.s.). This ratio had increased from 39.2% to 42.9% in five years, or by 9.4%. A more accurate representation is the change in the percentage of female contributions; this increased from 35.3% to 39.1%, or by nearly 11%. This is about a 2% growth per annum. The average contribution from both males and females went down from 2009-11 to 2014-16, but this may be an artefact because the same individual may be represented in several different formats and also work in more than one postcode area. For example, Abraham, Jean E. also signed papers as Abraham, Jean and as Abraham, J. E., and worked both in Cambridge (CB) and in London EC (probably Bart's Hospital) and had five separate entries in the list, and a total fractional contribution of 1.31 papers over the six years.

Discussion

That London contains the postcode areas with the highest proportions of members of ethnic minorities is not surprising as it has for a long time been a cosmopolitan city (The Economist, 2003). The 2011 Census (ONS, 2017) showed that it had 40% of ethnic minority people, of
whom just under half (18.5%) were Asian. In a report by the London Sustainable Development Commission (2012), London was found to perform well on the innovation quality of life indicator which may help to attract researchers from abroad.

There are a number of limitations to this study. The first concerns the ethnicity ascribed to the researchers by means of the OriginsInfo and other databases. There is inevitably a problem in the identification of people who change their surnames upon marriage. However, given names will not normally change and this is taken into account by the OriginsInfo software. There is also a problem with Latin American names, which are often indistinguishable from those of Portugal and Spain; these researchers have mostly been classified as western European. On the other hand, the UK contributions may also have been over-estimated because Australian, Canadian and US researchers working here will often have “British” or “Irish” names.

Although the fractional contributions of the different groups can be calculated, it is much harder to determine the numbers of individual researchers because of different name formats, and the possibility of some researchers, particularly senior people, having appointments in more than one postcode area. We have therefore not attempted to count the numbers of people but only the contributions of the main ethnic groups.

The OriginsInfo classification system is also unable to distinguish between recent immigrants, who are often described as “first generation” ethnic minorities, and people whose family has been in the UK for some time and who were born and educated here, and usually regard themselves as British, even if hyphenated. There is a possible way round this problem, if we assume that the division into first- and second-generation minorities among cancer researchers is similar to that among medical doctors of the same ethnicity, based on their names.

For a given ethnicity, e.g., Indian, we first counted the number of doctors who had qualified in India, and we then determined the ethnicity of all UK doctors who qualified in the UK by matching their surnames, first, to the list of ones classed as Indian by the OriginsInfo database, and second, to the list of surnames of UK doctors who qualified in India. These two numbers were then summed to give an estimated total for the number of ethnic Indians who qualified as doctors in the UK. The results for six countries are shown in Table 6.

Table 6. Estimates of the numbers and percentages of doctors of given ethnicity who qualified in their 'ethnic' country and in the UK. GMC = General Medical Council list. Our hypothesis is that this division is similar to that for cancer researchers of this ethnicity. For country codes, see Table 3.

</table>
It may seem strange that so many "Germans" were actually educated in the UK, but a check on the Web of 16 leading UK cancer researchers who had been characterised as German by OriginsInfo revealed that only five of them (31%) were actually Germans who had been educated there. [There are many UK citizens with German names whose forebears came to this country in the 19th and 20th centuries, many to escape persecution under the Nazis, and who went on to have distinguished careers in many walks of life.] A similar check on 11 leading "Italians" indicated that six of them were really Italians who had studied there. [There have historically been fewer Italian immigrants in the UK.]

We did similar checks on 37 leading researchers with South Asian names (25 "Indians", seven "Pakistanis", four "Sri Lankans" and one "Bangladeshi"). Of the 33 whose education could be found from their websites, 21 had received their doctorates in the UK and 12 overseas, so only 36% were first generation South Asian immigrants, compared with 49% estimated in Table 6. So it appears that the above table may over-estimate the numbers of first-generation researchers from South Asia, because many ethnic Indians have been settled here for several generations. [There was free entry for Commonwealth citizens in the early post-war decades, and many also arrived when they were expelled from Uganda in 1972.]

However, the table may under-estimate the numbers of first-generation Europeans who have come to the UK fairly recently, often as a result of European fellowship schemes such as the Marie Curie programme (European Commission, 2017), or from taking up jobs in cancer research advertised internationally.

**Conclusion**

The use of names, both surnames and given names, has allowed us to determine the contribution of ethnic minorities to UK cancer research, which is now about 40% and is rising slowly. The earlier paper (Begum et al., 2017) indicated that the research teams containing immigrants were publishing cancer papers in higher impact journals, but that there was little difference in their actual citations. At the time of writing, the effects of the UK’s departure from the European Union are not known, but the scientific community is concerned to ensure that researchers from other countries will still be welcome.

The use of postcodes for the addresses on the papers has shown that these ethnic minorities are concentrated in London and other major cities, but not in the rest of Great Britain or in Northern Ireland. Most of the researchers could be sexed from their given names, and this showed that women were still contributing less than half the total fractional count of UK cancer research papers (43% in 2014-16) but that this proportion was increasing by about 2% each year.

Abstract
This study proposes that multiple-keyword co-occurrence can more accurately reveal the most frequently researched topics. The Apriori algorithm is used to mine the co-occurrence relation of keywords in order to predict the research hotspots by time series prediction. The keyword matrix of 15 core journals in library and information science in China is mined using related rules year by year via the Apriori algorithm. A total of 360 keyword sets are mined, including 1 five-keyword co-occurrence set, 6 four-keyword co-occurrence sets, and 39 three-keyword co-occurrence sets. Finally, 4 typical keyword sets are selected to predict their support, which will reflect the most widely researched topics for 2017.

Conference Topic
Co-occurrence analysis; Methods and techniques

Introduction
Callon, Courtial and Turner (1983) improved the theory and method of co-word analysis in the 1980s. Li and Ba (2017) considered that the statistical methods applied in co-term analysis dealing with word-related matrix mainly include co-term clustering analysis, co-term correlation analysis, co-term frequency analysis, and burst detection method. Li (2013) conducted a three-word co-occurrence analysis; regardless, studies have been rarely conducted on the coexistence between words from the perspective of multiple coexistence (Gao et al., 2014) and the multiple-keyword co-occurrence analysis derived from it. The current study presents the hypothesis that multiple-word co-occurrence analysis can reveal the research topic and content of a single thesis to more accurately reflect the research hotspot in this field.

The common methods revealing research hotspots by co-term analysis are multivariate statistical analysis and social network analysis (Tang and Zhang, 2014). In the multivariate statistical analysis, co-term clustering analysis and co-term correlation analysis are used to reveal the information of the correlation matrix. Apriori algorithm was first introduced into knowledge discovery based literatures by Hristovski et al (2000). Lei et al (2014) applied the association rules mining in
co-term analysis field and revealed the relationship between double phrases and ternary phrases in the target domains effectively. However, the research of multiple-word co-occurrence is still in its infant stage, which naturally confronts with lots of challenges, problems, and barriers during its maturation. The Apriori algorithm is used in the current study to mine the co-occurrence relation of the keywords. The most frequently researched topics in Library and Information Science are predicted in the time series.

Data and Methodology

Data Sources
To predict the research hotspots in library and information science, keywords from 15 Chinese journals were collected over a 10-year period from the China National Knowledge Infrastructure (CNKI) full-text database. These journals included the Journal of Library Science in China, Journal of Academic Libraries, etc. A total of 172,002 keywords were retrieved from 44,648 papers.

Data preprocessing
Co-term analysis uses accurate data as its basis. The collection of keywords obtained from the CNKI database includes many inconsistencies, which are not conducive to computer reading. Thus, data cleaning was necessary. In this study, data preprocessing employed manual processing, which mainly consists of the following steps: (1) deletion of unrelated data; (2) merging of synonymous Chinese and English keywords; (3) merging of singular and plural cases of English keywords; (4) merging of synonymous Chinese keywords; (5) separation of each keyword by a uniform delimiter.

Methodology
1. Multiple-keyword co-occurrence
Keywords are a collection of words that can be used to express the main knowledge structure and core knowledge content of a single study. The co-occurrence between two keywords can be referred to as a two-keyword co-occurrence, and that between three keywords is referred to as three-keyword co-occurrence, and so on. When a number of keywords appear simultaneously in a study, and the frequency of occurrence in the sample is very high, the field of study represented by these keywords is considered a widely researched area for a certain period. The higher the number of keyword co-occurrence, the more accurate the description of the research area represented.

2. Apriori algorithm
The Apriori algorithm is the most commonly used algorithm for mining frequent item sets with association rules. The core idea is to generate candidates and their support through a connection and then generate frequent item sets by pruning. The algorithm, which is currently applied in co-term correlation analysis, comprises four basic concepts: support, confidence, minimum support, and minimum confidence. Support is the probability that two keywords A and B appear simultaneously in a
where $Total\_count(A)$ refers to the number of all keywords sets, and $Support\_count(A \cup B)$ refers to the number of keyword sets that keyword $A$ and $B$ appeared simultaneously. Confidence is the probability that keyword $A$ appears at the same time keyword $B$ appears:

$$Confidence(A \Rightarrow B) = P(A | B) = \frac{Support\_count(A \cup B)}{Support\_count(A)}$$

where $Support\_count(A)$ refers to the number of keyword sets that have keyword $A$.

The minimum support is a threshold measuring the degree of support defined by the expert, indicating the minimum importance of the keyword set in the statistical sense. The minimum confidence is a threshold measuring confidence defined by experts, representing the lowest reliability of the association rule. Rules that satisfy the minimum support threshold and the minimum confidence threshold are called strong rules.

3. Time series prediction

Time series prediction compiles and analyzes time series according to the time series reflected in the development process, direction and trends. An analogy or extension is then made to predict the level that may be reached in the subsequent or later periods. This study employs polynomial fitting prediction, which aims to find a set of polynomial coefficients $a_i, i=1,2,\cdots,n+1$ that provides a better fit between the polynomial $\psi(x) = a_nx^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0$ and the original data and results in a smaller overall fitting error.

Results and Discussion

Multiple-keyword co-occurrence analysis

1. Setting the threshold of minimum support and minimum confidence

The setting of threshold about the minimum support and the minimum confidence can directly affect the number and reliability of the mined keyword set. Hu and Chen (2014) estimated the covariance ratio of the keywords in the field to be 0.73%. Given that semantic association and background knowledge between the words are neglected, the minimum support is set to 0.001, and the minimum confidence is set to 0.5.

2. Keyword set analysis

The Apriori algorithm is used to mine the association rules for keyword matrix each year, and a total of 360 keyword sets are mined. The sets include a five-keyword co-occurrence set, 6 four-keyword co-occurrence sets, and 39 three-keyword co-occurrence sets. The specific scenario is presented in Tables 1 and 2:

**Table 1. Keyword sets sorted by number of words (top 10).**
As shown in Table 1, outsourcing, MARC, information organization, metadata, and library catalogue are often bundled in keyword sets. Information organization, MARC, and metadata technology are applied in the library catalogue, and library catalogue develops outsourcing. Museum science, library science, and archive science are often bundled, which leads us to speculate that with the development of associated data, the concept and implementation of integration are moving forward. Big data, information engineering, and intelligent city are coming together, indicating that the construction of an intelligent city will be another important manifestation.

Table 2 shows that the college library was a research hotspot from 2007 to 2009. Building a knowledge map by CiteSpace was a research hotspot from 2012 to 2016. The support for keyword sets is generally low. While co-term association analysis

ignores the semantic relation between keywords, it also reflects that the research
direction of Chinese Library and Information Science field has been fragmented in the
recent 10 years and that research results develop in different areas.

**Time series prediction of research hotspots in library and information science in China**

At present, the co-term analysis applied to recognize research hotspots covers long
periods. Few people predict possible hotspots by using historical data. In this study,
research hotspots are analyzed year by year, and potential research hotspots are
explored by time series prediction.

Table 3 presents the highest support received by the keyword sets, arranged by year.

According to the specific scenario of research hotspots for each year, some
representative keyword sets are selected for analysis and prediction. These sets
include keyword set1 (CiteSpace–knowledge mapping), keyword set2
(library–college), keyword set3 (cloud services–cloud computing), and keyword set4
(museum–library–archives). The support corresponding to each set is plotted in
Figure 1.

![Figure 1. Age distribution of the support of some keyword sets.](image)

The keyword sets are grouped into 4 time series by age distribution. Polynomial
fitting is performed to make a prediction. The specific scenarios are depicted in Figure
The keywords sets and their corresponding support for 2017 are as follows: keyword set1 (CiteSpace–knowledge mapping), 0.2787%; keyword set2 (library–college), 0%; keyword set3 (cloud services–cloud computing), 0.2317%; and keyword set4 (museum–library–archives), 0.0265%. Cloud services–cloud computing has the potential to be a research hotspot, which mainly discusses how to build a cloud service model in the cloud computing environment. CiteSpace–knowledge mapping is supposed to continue to be a hot subject of research in the area of scientometrics. Visualizing and analyzing trends and patterns in scientific literatures by using CiteSpace software will still to be a research hotspot in the field of library and information science in China. The research results indicate that library–college will not to be a research hotspot. The research on information service and resources construction of college library has been perfected. A small number of researchers are expected to remain interested in researching the digital libraries and archives.

**Conclusions**

This study proposes multiple-keyword co-occurrence analysis, which can show the research topic of the study to provide a more accurate result for research hotspots. By using the Apriori algorithm, the keyword matrix of 15 core journals in library and information science in China is mined with related rules year by year; 360 keyword sets are mined. Polynomial fitting is then used to predict the support corresponding to each of the four typical keyword sets for a certain period; the most popular research topic for 2017 is predicted.

This study has successfully mined keyword sets for co-term analysis and provides a short-term forecast by time series forecasting. Regardless, data disambiguation and short-term forecasting can still be improved. In addition, the semantic correlation between keywords should be ignored. This study sets the future research direction toward the combination of the semantic correlation between the keywords themselves to construct richer association rules.

Abstract
This project was part of a large mapping exercise on the research on five non-communicable diseases in Europe in 2002-13. This involved the identification and analysis of over 700,000 papers and also examination of their impact through citations in other papers, on clinical guidelines and in European papers. Stories in newspapers inform many groups, from politicians to the general public, about progress in medical research, but they can also report selectively and so bias our understanding of the state of play. We employed a large multi-lingual team to search the archives of 32 newspapers in 21 countries, and compiled an archive of over 9000 stories and the papers that they cited. These were mostly about cancer, how to prevent it rather than treat it, and over-cited European research but neglected that from east Asia. Some papers were cited in many different newspapers and so achieved wide coverage. Commentators’ views on the importance of the research were sought on 13% of the continental newspaper stories, but 37% of those in the UK Daily Mail. The latter paper mostly quoted UK charities who thereby gained free publicity.

Conference Topics
Indicators; science policy and research assessment; science communication; the application of informetrics on evaluation

Introduction
There is extensive literature about the stories of medical research in newspapers, but almost all of them concern only a single country and one type of research (e.g., cancer or genetics). Studies have been carried out in the UK (Entwistle, 1995; Robinson et al., 2013); in the USA (Burns et al., 1995; Stryker, 2002); Russia (Lichterman, 2002); the Netherlands (Hijmans, Pleijter & Wester, 2003); on prostate cancer screening in Australia (MacKenzie et al., 2007); on healthy lifestyles and hypertension in Canada (Hayes et al., 2007; Collin & Hughes, 2011); on diabetes in Japan (Akamatsu, Naito & Nakayama, 2009); on male circumcision in Kenya (Muzyka et al., 2012); in Brazil (Teixeira et al., 2012); and on medical uses of cannabis in Israel (Lewis, Broitman & Sznitman, 2015). An exception is the study of the newspaper coverage of the Severe Acute Respiratory Syndrome (SARS) in 2003-04 (Lewison, 2008) where news of the research that was hurriedly started was analysed in 15 news media from seven countries. The present paper is the first to examine the variation in coverage between 21 different European countries, with a combined total of 15 languages, and five distinct non-communicable disease (NCD) areas. These are cardiovascular disease including stroke, diabetes, mental disorders, cancer and respiratory diseases. Each of these was further subdivided into different disease areas, and the types of research were also analysed. So the study affords a wide view of how the European public is informed about medical research.
Despite falling circulations in many countries, newspapers are still very influential as news sources. Large headlines about medical research on the front page can grab the attention of many types of reader – politicians, their senior advisors, healthcare administrators, medical personnel, other researchers and the general public. They have the advantage over the social media of relative permanence so that analyses are reproducible. Moreover, many newspapers maintain searchable archives, or they can be searched through full-text databases such as Factiva or ProQuest NewsStand.

Newspaper stories have some of the characteristics of journal articles, in that they have a source (country and newspaper, date), an author, a title (headline), one or more citations, and (sometimes) commentators who put the new research in context. Reports of research in the mass media can also lead to higher citation scores for the papers cited in the stories (Phillips et al., 1991; Lewison et al., 2008; Fanelli, 2013).

Our objectives were to examine the balance of news coverage between the five NCDs in the different countries, and where appropriate, the balance of individual disease areas and also the types of research being reported. We also sought to investigate the extent of countries’ over-citation of their own researchers. This also occurs in mainstream research outputs (Lewison & Roe, 2012), and in the references on clinical guidelines (Grant et al., 2000), but we wondered whether journalists would be even more chauvinistic than scientists, and over-cite their own countrymen to a greater extent. Finally, we wanted to see the extent to which external commentators were brought in by the journalists to put the recent research results in context.

**Methodology**

*Selection of newspapers.*

Our original intention was to cover about 60 newspapers in all the 31 European countries (the 28 European Union Member States (MS) plus Iceland, Norway and Switzerland). There would be three newspapers in the large MS such as Germany and Italy, two in each of the medium-sized countries such as Austria, Belgium and Portugal, and one in the small countries. The selection was intended to cover both right- and left-wing newspapers, and “broadsheets” and “tabloids”, though these terms are now no longer an accurate reflection of the market being served. However the work proved to be more time-consuming than we had expected, so we perforce needed to restrict our coverage to some 31 newspapers in 22 countries, see Table 1. The trigraph (three-letter) codes for the individual papers are composed of the countries’ ISO codes and a letter to indicate the paper title.

*Selection of stories.*

In order to collect the relevant stories in these different newspapers, we assembled a team of some 31 recorders, with the appropriate language skills (see the Acknowledgement). Some were from our five European partners in the EU project; some were recruited from among King’s College London graduate students; and there were three volunteers from Cyprus, Hungary and Sweden who participated in this project and in return were given detailed data on NCD research in their countries.

All the recorders were brought to KCL for briefing and training by EP. They were shown how to select the stories, either from the newspaper archives or from the Factiva database © Dow Jones, by means of five search statements such as the one for cancer:

\[
(cancer \text{ OR } \text{leukaemi}^* \text{ OR } \text{melanoma}^* \text{ OR } \text{lymphoma}^*) \text{ AND (research}^* \text{ OR study OR scientists OR expert}^*)
\]
This, of course, had to be translated into the languages of the individual newspapers. The recorders then had to read the stories to check that they were citing research papers in journals—many were not, or the details given were inadequate to identify the paper, and were discarded. All relevant details were copied and pasted to an Excel spreadsheet, and all recorders used exactly the same format, even if some of the data were not present. The data included the source (codes as in Table 1), the date, the name(s) of the journalists, and codes to characterise the NCD (CARDI, DIABE, MENTH, ONCOL or RESPI), the disease area (e.g., cancer site or mental disorder), and the type of research (e.g., drug treatment, epidemiology). The recorders also tabulated the names of the cited scientists, their institutions and the journal in which the research was published, and the details of any commentators who were cited.

**Identification and analysis of cited papers.**

The recorders were then instructed to try and identify the research papers that had been cited in the stories in the Web of Science Core Collection (WoS), and to download their full bibliographic details to a series of text files. All document types could be included though in practice most were "articles". The files were converted to Excel spreadsheets by means of a macro (written by Philip Roe of Evaluametrics Ltd) and then the details of individual papers were copied across to the spreadsheet of stories. Only stories with papers in the WoS were retained for analysis.

The individual spreadsheets were then all combined to create a master sheet with over 8800 stories and their cited papers. These papers were then analysed by their addresses, with fractional country counts, and for cancer and mental health papers, by their type of research, although this was also coded by the recorders from the stories. Our main interest was in the European research papers, and the contributions of European countries were compared with their presence in NCD research in the years 2002-13, obtained from the mapping exercise.

Results

Comparison of NCD news coverage with disease burden.

Figure 1 shows the distribution of news stories by NCD for the complete set of papers and for the nine countries with at least 300 stories: Belgium, Germany, Italy, Netherlands, Portugal, Romania, Spain, Sweden and the UK. [These are not necessarily the countries with the greatest overall coverage of medical research in the popular press.] The percentages mostly sum to more than 100% because some stories described research affecting more than one NCD, for example rising obesity will increase both diabetes and heart disease, and smoking affects both cancer and Chronic Obstructive Pulmonary Disease (COPD), a respiratory disease.

Is this a fair representation of the relative burden from the five diseases? This is conveniently measured in Disability-Adjusted Life Years, which takes account not only of early death (compared with life expectancy in Japan), but also of disability. Figure 2 shows the pattern for the five NCDs as a group, based on data published by the World Health Organization for 2012 (WHO, 2014).

One would hardly expect these two charts to be in synchrony, but there are some notable differences between them. First, cancer (ONCOL) is the most reported story in all countries except for Romania (RO) and Sweden (SE), where cardiovascular research (CARDI) gets more coverage. This is as expected in Romania where it accounts for more than half of the total disease burden from the five NCDs as a group, and it also causes a higher burden than cancer in Sweden – as it does in Europe as a whole – but overall there are over 70% more ONCOL stories than CARDI ones.

![Figure 1. Distribution of newspaper stories among the five NCDs (cardiovascular disease, diabetes, mental disorders, oncology and respiratory diseases) for nine individual countries (ranked by total number of stories) and all 22 countries in Europe (see Table 1).](image)

Diabetes research (DIABE) gets much more coverage in newspapers (11%) than its current burden (4.2% of all DALYs for the five NCDs, and 2.6% of DALYs for all diseases) would suggest, but the burden is increasing rapidly, largely because of increasing obesity, so this may be a sensible amount of coverage in view of the need for citizens to take more care of
their health. On the other hand, respiratory disease research (RESPI) is under-reported, with 6.5% of stories compared with 8.2% of DALYs, and particularly in the UK (6.8% of stories, 12.7% of DALYs) and Portugal (3.0% of stories, 9.2% of DALYs).

Figure 2. Distribution of disease burden from five NCDs in 2012 among nine European countries and in all 31, DALYs, all ages, both sexes.

Mental disorders research (MENTH) is mostly reported proportionately to its relative burden, except in Sweden and Spain, which feature few MENTH stories. But Romania has many such stories, despite having a low burden (13% of all DALYs compared with the European average of 23%).

Reportage of individual diseases within each NCD.
The five NCDs each cover a number of different diseases, and the next analysis shows how they compare with the European burden from each. In cardiovascular disease research (CARDI), the two main areas are ischaemic heart disease and cerebrovascular disease, or stroke. In 2012, these accounted for 14% and 8% of the DALYs for the five NCDs, but the numbers of stories were only 11% and 4%, so stroke research, in particular, was somewhat neglected by the journalists.

We selected five mental disorders for analysis: addiction (ADD), alcoholism (ALC), Alzheimer’s disease and other dementias (ALZ), anxiety (ANX) and unipolar depression (DEP). Figure 3 shows the percentages of DALYs, of European research, and of newspaper stories, all relative to the total for the five NCDs. Figure 4 gives data for eight leading cancer sites.
Figure 3. Five mental disorders in Europe: disease burden (DALYs), research and newspaper stories; all as % of total for five NCDs.

Figure 4. Eight cancer sites in Europe: disease burden (DALYs), research and newspaper stories; all as % of total for five NCDs.

Figure 3 shows that the amount of research in these five mental disorders is not large compared with the disease burden, particularly for alcoholism and depression. On the other hand, the amount of newspaper coverage is good for Alzheimer's disease and other dementias, where the burden is increasing because of greater longevity. Alcoholism is a serious problem in Europe (Rajendram et al., 2006), and is ranked as one of the three main risk factors in the Healthgrove website for almost half of the 188 countries listed, and for 30 of the 31 European countries (all except Malta).

For the different manifestations of cancer, Figure 4 shows that lung cancer is under-researched in relation to its burden, together with pancreatic cancer whose incidence is increasing. The news coverage is reasonable for most cancers, but seems excessive for breast cancer, melanomas and prostate cancer. These seem to be the ones of most concern to people, both women and men, so it is perhaps not surprising.
Coverage of research on the last NCD, respiratory diseases (RESPI), has already been presented (Pallari et al., 2016). They found that asthma, although much less burdensome than COPD, was nevertheless researched much more and reported even more, probably because the sufferings of asthmatic children are more newsworthy than those of old smokers.

The types of research that were reported.

We employed four-character codes to designate research types; they were not the same for the different NCDs but most were common to them all. Overall, the research types were as shown in Table 2. Most of the stories involving surgery were on cancer, as were all of those on radiotherapy. The sum of the percentages is greater than 100% because many of the stories covered two (or more) research types, but some could not be coded in this way.

Table 2. Types of research that were mainly cited in European newspaper stories about NCD research, 2002-13.

It is striking that so many of the stories reported research on how the NCDs could be avoided (EPID, LIFE and NUTR) and that treatments (most involving drugs) were very much a secondary concern. For cancer, the main treatments described were of new drugs used in chemotherapy, some used for immunotherapy or targeted therapy; surgery and radiotherapy (which actually can cure cancer) were rarely mentioned. This is a serious matter as the public are thereby persuaded that the provision of expensive drugs is the way to improve cancer survival, and the case for better radiotherapy equipment is not appreciated by either the public or politicians.

The countries whose research was cited by the newspaper stories.

The addresses of the papers cited in the newspaper stories were analysed on a fractional count basis for the countries. It was immediately apparent that European countries were over-represented in these papers compared with their presence in research in the five NCDs for the years 2002-13: the over-citation ratios varied between x 1.19 in RESPI and x 1.51 in ONCOL. But some countries' research was much better cited than others’, as Table 3 shows.

Research from the five Nordic countries is clearly very well-cited in all five NCDs with minor exceptions (notably Norwegian work in diabetes). It is particularly striking that Icelandic research attracts so much attention, especially in cancer and mental health. Even though the numbers of papers are small (6.4 and 5.1, respectively) they are statistically significant (on the Poisson distribution) with p << 0.001%. On the other hand, research from central European countries (Austria, Germany, Hungary, Italy, Poland and even Switzerland) is under-cited compared with the countries' presence in these NCDs. The same is true for research from east Asian countries (China, Japan, Korea and Taiwan) even though most of it is published in English.

A possible explanatory factor is that the coverage of NCD research in our archive of stories is very unequal between countries, and one would expect that newspapers would preferentially
cite research from their own researchers. This is the case, and small countries (in terms of scientific output) over-cite their own research by a bigger factor than do large countries, see Figure 5; the comparison is with the countries' presence in the five NCDs as a group.

Figure 5. Over-citation ratio of own country papers by European newspaper stories about NCD research (countries with 160 or more stories only), fractional country counts.

Figure 5 shows that the Nordic countries over-cite their own countrymen more than expected, and this may be one reason why their papers are so well cited (Table 3). Conversely, German journalists seem relatively reluctant to cite German research, and this may be a factor in the low newspaper citation scores of German papers in Table 3, particularly in comparison with the UK, whose presence in research in the five NCDs as a group is similar to that of Germany.
*Highly-cited papers*

In conventional citation analysis, papers are often ranked by the number of times that they have been cited by other research papers. This should be in a fixed time window, often three or five years. There are also papers that receive many cites in newspapers, and if we had been able to process all European daily newspapers, it is likely that the citation scores of NCD papers would have been much greater. It is still worthwhile to examine the distribution of citation numbers, but it is not really necessary to use a particular time window because most stories report on new research as soon as it is published, or even beforehand if the paper appears online prior to the print edition of the journal. One paper received 18 newspaper cites and two others, 10; two were in cancer and one in cardiovascular research. The distribution for the other papers cited twice or more in our selection of newspapers is shown in Figure 6. It is well fitted by means of an exponential relationship.

![Figure 6. Distribution of numbers of citations to NCD research papers in European newspaper stories, 2002-13.](image)

*Commentators*

Some of the newspaper stories attempted to put the research findings into context by seeking the views of a knowledgeable commentator. For the continental European newspaper stories, only 741 did so (12.6%), but for the UK *Daily Mail*, 739 of its stories had a commentator (37%) and for *The Guardian* 204 had one (25%). The commenting organisations were coded with their sector (government, private-non-profit, industry; the PNP sector was further divided into charities, foundations, hospitals, universities and other non-profits) and their country. Table 4 shows the main parameters of these organisations for the stories from 21 continental countries (many of which appeared to have no commentators) and for the two UK papers, *Daily Mail* and *The Guardian*.

The big difference between the two is that the *Daily Mail* and *The Guardian* sought the opinion of charities far more often than did the continental journalists. Most of these were UK-based, such as Cancer Research UK (186 mentions), the British Heart Foundation (99), and the Alzheimer's Society (70). (UK charities were also quoted 42 times in the continental newspaper stories.) The two UK papers also sought the opinion of over 75 other non-profit organisations, including several Royal Colleges of professional medical personnel and other professional associations. There were also some lobbying groups such as Friends of the Earth, JABS (Justice Awareness and Basic Support – for victims of vaccination), and the
Salmon Farm Protest Group. For the continental papers, the main source of comments was universities, especially in Sweden (61 mentions), Belgium (52) and the USA (44).

Discussion
This study inevitably suffered from the varied quality of the individual contributions by our many recorders – see the acknowledgement below. We could check that the cited papers matched those in the stories because often these listed some of their details, such as the name of the journal or one of the institutes where the work was done, but we could not verify the extent of coverage, the details of the commentators or the accuracy of the codes that the recorders entered in their spreadsheets because of the languages of the stories. For some countries and newspapers, the amount of coverage did seem rather low, but one reason for this was that many stories gave few details of the research so that it was not possible to identify the paper(s) being cited. On the other hand, some newspapers were punctilious in giving their sources, notably Le Soir in Belgium and the Daily Mail in the UK.

We consider that our main conclusions are robust, as they appeared in the newspaper coverage in many different countries. These are that prevention and causation, rather than treatment, and that within treatment drugs rather than other therapies, are the main topics. It was also striking how nationalistic many journalists were, especially in the small countries as Figure 5 demonstrates. There was very little coverage of research from east Asia, even though most of it is in English and in international journals. This suggests a subtle racial bias which will cause readers to be unaware of the enormous increases in medical research output in these countries in recent years, and to continue to believe in the unchallenged supremacy of Europe and the USA in biomedical progress.

Acknowledgments
This project was supported by funding from the European Community’s Seventh Framework Programme under grant agreement EC/FP7/602536. The newspaper stories collection and identification of the cited research studies in the various European newspapers and languages was done by the following individuals, for Austria, Germany and Switzerland: Natalia Kelsch, Anne Spranger, Victor Stephani and Tobias Schumacher from Technische Universität Berlin, Germany; for Belgium: Ann-Sophie de Mol and Gabrielle Emanuel from King’s College London (KCL), UK; for Bulgaria: Eva Nacheva and Christina Tencheva from
KCL; for Croatia: Ria Ivandic Emanuel from KCL, UK; for Cyprus: Chryso Th. Pallari from the University of Cyprus, Nicosia, Cyprus; for the Czech Republic and Poland: Kasia Zemanek from KCL; for Denmark: Maria Dahl and Maria Emilsson from KCL; for Estonia: Argo Soon from the Estonian Research Council, Tartu, Estonia; for Greece: Laura Mantovani from KCL; for Hungary: Csajbok Edit from Semmelweis University, Budapest, Hungary; for Italy: Ludovica Borsoi from Università Commerciale Luigi Bocconi, Milan, Italy; for Latvia: Ingrid Jaselskyte, Estonian Research Council, Tartu, Estonia; for Luxembourg and the Netherlands: Ann-Sophie de Mol from KCL; for Portugal: Diana Gosałvez-Prados, Elisabeth María Ilidio-Paulo, Camila Higueras-Callejón and José Carlos Ruiz-Jiménez from Escuela Andaluza de Salud Publica, Granada, Spain; for Romania: Maria-Cristina Juverdeanu from KCL; for Spain: Diana Gosałvez-Prados and Elena Salamanca-Fernández from Escuela Andaluza de Salud Publica, Granada, Spain and Tahereh Dehdarirad from Universitat de Barcelona, Barcelona, Spain; for Sweden: Gustaf Nelhans from Sahlgrenska Göteborg, Göteborg, Sweden; for the UK: Argo Soon, Marleen Saidla and Tiina Tasa (Estonia) and Eva Nacheva from KCL partly assisted EP on the data collection. The Excel VBA programs were written by Dr Philip Roe of Evaluametrics Ltd, St Albans, England.

Abstract
This paper proposes a new measure to trace the main paths of knowledge flows, which are characteristics of particular semantics and can cater to different research or application demands. The traditionally main path analysis usually neglects the inequivalence between citations (H&D, 1989), leading to inaccurate results. To address this problem, we take the documents’ associated attributes into account to measure the inequivalence, and further transform the inequivalence into a relevant relationship. Our method is a modification based on SPC from Batagelj (2003), using meta-path to describe and quantify the relevancy on the basis of associated attribute’s correlation, then incorporating the relevancy into the link’s traversal weight, and finally combining it with original SPC traversal weight to form a modified index. Synthetic biology is taken as a case study to test the performance of the new index and the results proved that our method can be an effective complement to main path analysis. Our method mainly boasts two beneficial effects: (1) it further developed the methodology of main path identification. A heterogeneous bibliometric network based on citations was constructed, and meta-paths were used to enrich main paths with more information and semantics; (2) the application scenario of main path analysis was expanded. Selected associated attributes can be integrated into main paths, catering to different research or application demands.

**Introduction**

Citation network is the collection of citing and cited articles (Price, 1965), reflecting the knowledge transfer from cited articles to citing articles. With the passage of time and rapid growth of literatures, citation network has become a huge and intricate system, making it hard to figure out paths in a specific research field. However, identifying the disciplines’ development trajectory from the large and complex citation network is a necessity for researchers to understand and grasp the developing trends in their field, which fosters the practical demand for main path analysis. Meanwhile, research results prove that a discipline is mostly defined by a few important literatures and scholars in its history of development (Small, 1970), providing theoretic support for main path analysis. Main path analysis has not only been used in the article citation networks to identify core papers and knowledge diffusion paths, but also applied in the patent citation networks to identify key technologies and describe technologies’ evolution paths.

Specifically, the main object of this study is to propose a new measure; it can track the main paths of knowledge flows, which are characteristics of particular semantics, and caters to different research or applied demands. Our method is modified on the basis of SPC (Batagelj, 2003) in main path analysis (H&D, 1989). The main difference is that documents’ associated attribute is analyzed and employed in our method to analyze the inequivalence between the citations. With this new method, inequivalence can be transformed into a relevant relationship and meta-path of heterogeneous bibliographic network will be used to describe and quantify the relevancy based on associated attribute’s correlation. The relevancy was then added to link’s traversal weight.

We conducted a case study on synthetic biology to test the feasibility and applicability of our new method. The comparison between our index and SPC proved that our method can be an effective complement to MPA. The main contributions of our study can be summed up in three aspects: (1) enriching the methodology of main path identification; (2) expanding the application scenario of MPA; (3) revealing the knowledge diffusion path of synthetic biology domain. The rest of the paper is organized as follows. Section 2 introduces MPA and related works, followed by Section 3 which presents research questions and methodology. Section 4 is a case study, which applies our new method and original method to a set of papers related to synthetic biology, and a comparison is made between the results respectively obtained by ours and by the original one. Finally, we give the discussion and conclusion.

**MPA and Related work**

Hummon and Doreian (1989) put forward a method called “main path analysis” which uses citations’ similarity to identify the most representative articles and theories. The method offers three indices to exam connectivity in an acyclic network, which are NPPC (node pair projection count), SPLC (search path link count) and SPNP (search path node pair). The basic procedures of MPA can be summarized as follows: first, one of three indices is chosen to assign weights to all links in the network; then, starting at the source nodes, a greedy method is used to search a link sequence and this process is repeated until all the source nodes are touched; at last, the sequence that is the highest in sum of link weights is selected. However, our paper aims to introduce another index SPC, proposed by Batagelj (2003). In a citation network, when all paths from every source to each of the sinks are searched, the SPC for each link is defined as the total number of times the link is traversed. We choose SPC index as the basis and comparison object of our method.

According to Wang’s work (2013), we divide MPA into five parts: ① network topology. As a
directed network, the network topology order of citation network is fixed; ② links’ initial weights, which are equal to 1 in the form of traversal count; ③ links’ traversal weight index (SPC); ④ main path selection principle, generally selecting the main path with largest sum of traversal weights; ⑤ starting node selection of searching, namely where to begin the search in the network. Here are the milestone works on ④ main path selection principle. Aiming to address the problem of local optimum caused by greedy strategy, Verspagen (2007) extracted all paths from sources to sinks and chose the path with the largest sum of weights as main path. Liu (2012) suggested a method of multiple main paths which relaxed the search constraint to obtain paths with the top overall traversal counts and thus revealed more details. Bekkers (2012) proposed to extract the main paths according to H&D, and then add the nodes with knowledge contribution to main paths. Then, we move to the works on ⑤ starting point selection of searching. The original main path analysis is featured by searching forward, to be specific, searching from sources to sinks. Liu (2012) uncovered a new method, which is searching backward from the latest papers to the earliest papers. Liu also suggested “key-Route Search” to solve the potential problem that the link with the highest traversal count may be excluded.

we are most concerned about ② links’ initial weights and ③ links’ traversal weight index. Yeo & Kang (2014) applied the aggregative approach to improve SPC and other link count indices and used the stochastic approach to carry out path dependent search to separate merging papers. Zhu (2015) substituted an integrated weight for the traversal weight to identify main paths. The integrated weight was composed of an external correlation of citations such as citation, co-citation and coupling relationship and an internal text correlation between the citing paper and cited context. Chen (2016) translated patent documents into sets of vectors and calculated the semantic similarity between patents to search multiple main paths which focus on certain technology topics.

The above researchers have made great contributions to overcoming the limitations of MPA and expanding the concepts and unlocking characteristics of MPA, yet few researchers attach importance to citations’ inequivalence, which is important but unexplored. To address the problem and fill the void in the literature, this research will further probe into ③ links’ traversal weight index.

Research questions and new index

Research questions

So far, MPA either has treated citations equally or calculated the correlation between the citing and cited documents based on the text content. However, both ways revealed the structure of knowledge merely from the literature itself, and failed to take documents’ attached information such as authors, institutions and journal into account. We define this kind of attached information as documents’ associated attributes. According to our literature investigation result, few researches are carried out with the consideration of documents’ associated attributes. In the paper, three research questions are raised: (1) How to describe and quantify the relevancy between the citing and cited documents based on their associated attributes? (2) How to modify the traversal weight by using the relevancy and SPC index? (3) What are the differences between main paths identified by SPC traversal weight and our modified traversal weight? In order to answer the above questions, we tried a variety of methods including heterogeneous bibliographic network and meta-path, linear combination and comparative analysis.
Meta path for new weight

In a heterogeneous information network (HIN), two objects can be connected via different paths called meta paths (Sun & Hun, 2011). Meta paths are abundant in semantics and different meta paths imply different correlations or relationships between objects. Heterogeneous bibliographic networks, which capture the semantics of a real-world network (Sun & Hun, 2013), are a typical example of HINs. On the basis of citation relationships, we construct a heterogeneous bibliographic network in which nodes can be connected via different associated attributes to form various kinds of direct or indirect relationships. Meta paths that show objects’ direct relationships are short; however, this type of meta paths can also become long by concatenating them through direct relationships. Direct relationships (meta paths) extracted from the bibliographic data and two long meta paths are presented in Table 1.

It is necessary to stress that the starting node and ending node on meta path are restricted to citing and cited documents. For example, two papers can be connected via “paper → author → paper → author → paper” path or “paper → institution → paper → institution → paper” path, which means two papers forms a citation relationship and meanwhile the relationship is elaborated with such connections as “author” and “institution”. The chains extend and progress with these connections which also write other similar paper(s). In other words, the citation relationship also involves co-author relationship or co-institution relationship.

Associated attribute weight (AAW)

We want to know whether and how documents’ co-author relationship or co-institution relationship relate to the citation nodes. We use the meta path to describe and qualify the relevant relationship, and define the relation as associated attribute weight (AAW), that is, documents’ similarity based on meta path. Considering that authors or institutions in citing and cited documents may have weak connections, a long symmetric meta path is constructed. Allowing for the meta path’s symmetry and nodes’ homogeneity, Pathsim (Han & Sun, 2011) is used to calculate nodes’ similarity.

When a symmetric meta path $\mathcal{P} = (A_1 A_2 \cdots A_n)$ is given, PathSim between two objects $x_i$ and $x_j$ of the same type can be calculated by $s(x_i, x_j) = \frac{2M_{ij}}{M_{ii} + M_{jj}}$. Formula (1), where $M$ is the commuting matrix for the meta path $\mathcal{P}$, $M_{ij}$ is the number of instances of the paths between $x_i$ and $x_j$.
$x_i$, $M_{ii}$ and $M_{jj}$ are the visibility for $x_i$ and $x_j$ respectively in the network. $M$ is defined as $M = W_{A_1A_2}W_{A_2A_3} \cdots W_{A_{i-1}A_i}$, where $W_{A_iA_j}$ is the adjacency matrix between type $A_i$ and $A_j$. For the long meta path, it's convenient to calculate the nodes' similarity by path concatenation. Suppose $\mathcal{P} = (\mathcal{P}_i\mathcal{P}_i^{-1})$, $M_p$ and $M_p^T$ are commuting matrices of $\mathcal{P}_i$ and $\mathcal{P}_i^{-1}$, and $\mathcal{P}$ 's commuting matrix is $M = M_pM_p^T$. The meta path can be obtained by repeatedly concatenating $\mathcal{P}$ for $k$ times is signified as $\mathcal{P}_k$ or $(\mathcal{P}_i\mathcal{P}_i^{-1})_k$, and its commuting matrix is $M_{pk} = M_k$ or $(M_p^k = M_pM_p^T)_k$ Formula (2).

Taking meta path $P \xrightarrow{WB} I \xrightarrow{W} P \xrightarrow{WB} I \xrightarrow{W} P$ for example, which is symmetric and can be written as $\mathcal{P} = (PIP I)$. It is obtain by concatenating short meta math $PIP$ for two times, whose commuting matrix is defined as $M = W_{p1}W_{ip}W_{p1}W_{ip} = (W_{p1}W_{ip})^2$. $W_{p1}$ and $W_{ip}$ are the co-occurrence matrix of papers and institutions, which are transposed each other. Thus, $M$ can be transformed into $M = (W_{p1}W_{ip}^T)^2$. Table 2 shows the sample commuting matrix of meta path $PIP$ between five papers. Table 3 is the corresponding path similarity calculated by formula (1), namely the AAW in the paper.

Modified transversal weight (MTW)

When MPA is applied to identify main paths, Pajek will automatically calculate all links’ SPCs according to the network’s topology. More clearly, this SPC refers to SPC traversal count. In order to smooth the range of traversal values, and eliminate the degree of variation, it is necessary to normalize the counts. After being normalized, SPC traversal count will be transformed into SPC traversal weight (SPC TW).

Next efforts are made to construct a new index based on SPC traversal weight. We make a combination between the associated attribute weight (AAW) and the original SPC traversal weight, and define it as modified transversal weight (MTW). According to the above analysis, two questions have to be answered. The first one is how to normalize the SPC traversal count. Three ways of normalization are included in Pajek, namely normalized by flow, max and logarithmic. Results acquired through these three normalization ways will be compared mutually, and compared to the associated attribute weights (AAWs). One normalization way will be chosen. The second research question is how to combine the two weights. Since there are so many zeroes in the AAWs, we have to make a linear combination, which is expressed in $MTW = \alpha SPCTW + \beta AAW$. Formula (3). In the formula, $\alpha$ and $\beta$ are weight coefficients, which will be fixed after the actual data was observed and tested.

Case study: Synthetic Biology

Data collection and processing

We retrieved data from the web of science database which has been widely used by worldwide researchers. It offers the citation information dating back to 1864. We retrieved 869 papers with the
query of “synthetic biology” to a topic field, and the time horizon was set from 1900 to 2010. It should be noted that if the range of retrieve time was set until 2016, over 7000 papers will be obtained, which will form an extraordinarily large pool of authors and institutions. As a result, the research topics will be quite disperse. To avoid this problem, the paper selects the synthetic biology literature from 1900 to 2010 to identify the main paths and analyze the relevancy between associated attributes and citation nodes. In this way, the research process becomes more feasible and the research purpose can be effectively fulfilled.

After duplicate titles were removed, papers without authors and institutions were deleted and the final number of papers amounted to 859. All the 859 records were then imported in CitNetExplorer to generate citation network within the scope of data set. The largest connected component with 636 nodes and 2607 edges was extracted as the research object.

Associated attribute “institution” was taken for example to compare main paths separately identified by SPC and our method. Firstly, SPC traversal weights (SPC TWs) were calculated and 2607 SPC traversal counts were obtained ranging from 1 to 72680. Results obtained from the three ways of normalization show that the two ways normalized by max and flow are not suitable and that the traversal weights are too small to combine with AAWs. Logarithmic weights are reasonable. 339 edges’ traversal weights are zero and we corrected them as 0.01 to ensure the network’s connectivity. Secondly, associated attribute weights (AAWs) were calculated. Meta path \( P = (PIP) \) was constructed and its commuting matrix was obtained by using Formula (2). AAWs of all citations were then calculated by using Formula (1). AAWs of 365 citations are nonzero, ranging from 0.027 to 1. At last, modified traversal weights were calculated (MTWs). Four groups of test value were set for \([\alpha, \beta]\), that is \([0.9, 0.1] , [0.8, 0.2] , [0.7, 0.3] \) and \([0.6, 0.4]\). It is found that the group \([0.7, 0.3]\) is reasonable by comparing SPC TWS, AAWs and MTWs. Finally, \( MTW = 0.7SPC\ TW + 0.3AAW \) Formula (4) was deduced. All links’ MTWs were calculated by Formula (4).

Experiments and results

We tested SPC AW and AAW on the citation network, identified two kinds of forward local main paths, multiple forward local main paths, backward local main paths, multiple backward main paths, standard global main paths and global key-route main paths, and made a comparison to verify our method’s effectiveness and necessity. Due to the space constraint, we will elaborate on the findings of the multiple local main paths, and make a brief introduction to the findings of the other main paths.

Results of SPC traversal weight-Multiple forward local main path

A total of 22 papers are found in the forward multiple main path shown in Fig. 1, including 17 papers of forward local main path (labeled in yellow) and the other 5 papers (labeled in blue, No 85,87,108,210,283). The thicker the line is, the higher SPC index is. The node is marked in the form of “serial number in the dataset-first author (publication year)”. The arrowhead indicates the cited article, and the tail indicated the citing article.

1-Hobom (1980) published the first paper titled as “synthetic biology” to describe a bacteria genetically engineered through recombinant DNA technology. Seven important papers sprung up in the year 2004 and 2005. 9-Hendrickson (2004) introduces in detail how various types of polymerase were widely differed in the interaction with c³dA. 10-Benner (2004) describes the roles of nucleobases and phosphates of DNA in the molecular recognition processes played by synthetic
chemistry. 23- Sismour (2004) is a follow-up study to the Benner’s. 8-Ball (2004) puts forward some questions about the risks of redesigning life and 18-Benner (2005) made a response. Two works of Sismour (2005) are further explorations on synthetic techniques.

Both 61-Chin (2006) and 107-Drubin (2007) are important review articles on advances in synthetic biology. 240-Filipovska (2008) focuses on “orthogonal” approach to build metabolism within the cell. 279-Purnick (2009) summarizes the research works before as the first wave which is featured by “cells-level” and the second wave on the way “systems-level”. 284-Carr (2009) affirms the trend by looking back on 50 years’ history. 295-Lu (2009), 454-Khalil (2010) and 455-Cullura (2010) are achievements of a joint library set up by several top biomedical research institutions. 295-Lu (2009) looked forward to the next generation synthetic gene networks, 454-Khalil (2010) reviewed the practical applications of synthetic biology, and 455-Cullura (2010) confirmed the advantages of the lab’s RNA-based system. 456-Nissim (2010) constructs a dual-promoter integrator to target diseased cells. It’s clear that the citation between 295-Lu (2009) and 454-Khalil (2010) had the largest weight, which plays an important role in the development in synthetic biology. The other 5 papers locate together, topics of which focus on the quantitative experiments and standardization measures of gene recombination.

Results of SPC traversal weight-Multiple backward local main path

34 papers were found in the multiple backward local main paths shown in Fig. 2, among which 23 papers were labelled yellow and formed the backward local main path.

In the year 2010, research on synthetic biology is in the stage of rapid development, with the number of academic works mushrooming. 454-Khalil (2010), cited by ten papers, is in the core of the whole path in terms of the practical applications of synthetic biology. The citing papers make a variety of further innovative explorations in different fields. For example, 488-Weber (2010) highlights the advances in mammalian synthetic biology while 628-Fritz (2010) pointes out two developing strategies and a conceptual model to improve the performance and the structure of biological systems.

In conclusion, forward local main path presents fundamental articles, important researchers and the knowledge diffusion traces between the articles and researchers; by contrast, backward local main path reveals the hot topics and research frontiers, and their backtracking of research basis or references. Multiple main paths can give more details.

Results of modified traversal weight-Multiple forward local path main

In spite of the relative complexity of the multiple forward local main paths (Fig. 3), it can still be clearly divided into two sub paths, including the forward local main path labeled in yellow. The forward local main path is relatively short with only 9 papers. It is quite different from the forward local main path obtained by SPC AWs, since they have nothing in common except the three head codes. Obviously, the AAWs play an important role in directing the main path.

Four citations have a large AAW. AAWs of citations between 9-Hendrickson (2004), 10-Benner (2004), and 18-Benner (2005) are equal to 1 because they come from the same institution, Department of Chemistry, University of Florida. 113-Marguet (2007), 301-Tanouchi (2009) and 346-Pai (2009) are connected by Department of Biochemistry and Institute for Genome Sciences and Policy, Duke University. 530-Armengaud (2010) and 531-Christie-oleza (2010) are colleagues of Lab Biochem System Perturb. On the whole, the forward local main path consists of three research groups, which successively reviewed the recent advances of synthetic biology along the time line.

The upper sub path and the forward local main path underneath are connected by 19-Medanial.
The upper sub path is comprised of four research groups. 19-Medanial (2005) and 13-Basu (2004) have the same corresponding author Ron Weiss, who comes from Department of Molecular Biology, Princeton University. Green branch, 16-Rackham (2005), 61-Chin (2006), 62-Chin (2006), shows the achievements of Medical Research Council Laboratory of Molecular Biology, in building new functions in living organisms. 47-Anderson (2006) and 85-Anderson (2007) are publications of Howard Hughes Medical Institute, Physical Biosciences Division, Lawrence Berkeley National Laboratory and other institutes, mainly focus on environmental information sensing and integration. 167-Lee (2008), 350-Carothers (2009) and 570-Carothers (2010) belong to the Joint Bioenergy Institute, which includes Sandia National Laboratory, Lawrence Berkeley National Laboratory, University of California and other branches.

Results of modified traversal weight-Multiple backward local main path

The multiple backward local main paths (Fig. 5) are much more complex and can still be divided into two sub paths, including the backward local main path labeled in yellow. The nodes labeled in blue without distinct index values won’t be stressed.

Fig. 5 Multiple backward local main path at 30% tolerance (38 papers)

On the backward local main path, the institutes’ correlation is much lower and only three citations have large AAWs. 3-Zhou (2004) and 4-Tian (2004) are important pioneers on microfluidic technology for multiplex gene synthesis. They are commonly connected to three institutes, namely Department of Chemistry, University of Houston, Atactic Technologies, Houston, and Chemical Engineering Department, University of Michigan. 21-Sprinzak (2005) and 109-Haseltine (2007) research synthetic gene circuits from different angles and they both belong to California institute of technology. 293-Gulati (2009) and 524-Szita (2010) publish two reviews about microfluidic approaches on a themed issue about Systems Biology and their co-institutes include University College London and Imperial College London. Papers of 19-McDaniel (2005) to 292-Boyle (2009) are related to synthetic gene circuits or micro-organisms combination techniques yet with much smaller AAWs. Institutes on the branch 110-Yeh (2007), 171-Lucks (2008), 421-Skerker (2009), and 484-Skar-gislinge (2010) seldom cooperate with each other.

On the below sub path, authors of blue branch 19-Medanial (2005), 106-Batt (2007), 279-Purnick (2009) come from Department of Electrical Engineering, Princeton University. Green branch 295-Lu (2009), 454-Khail (2010), 455-Callura (2010), 456-Nissim (2010) presents cooperation between Howard Hughes Medical Institute, Harvard University and Boston University. These three universities or institute have conducted many empirical experiments on synthetic bacteriophage or riboregulator. The upper sub path contains three research groups including 9-Hendrickson (2004) to 24-Sismour (2005), 167-Lee (2008) to 570-Carothers (2010), and 107-Drubin (2007) to
Comparison between results

This section makes a comparison between the main paths separately identified by SPC traversal weight (generally called as SPC main paths) and modified traversal weight (generally called as MTW main paths). The similarities and dissimilarities on the path structures, path changing trend, path functions and application scenarios are summed up as following:

Path structures and changing trend. Contrary to SPC local main paths which are longer with a number of starting nodes and a single ending node, the modified local main paths are shorter with one single starting node and ending node, and can directly and clearly represent the citations with the maximum relevance of institutes.

SPC multiple main paths are somewhat disordered and unseparated, and present the most representative articles and theories. While modified multiple main paths with clear skeleton are much more regular and can be separated, which describe multiple knowledge flows. Besides, two kinds of modified multiple main paths show great differences. The multiple forward main path begins from the earliest time with “a narrow entrance” due to fewer literatures. It reveals the most important sources of the research domain, and new research groups’ emergence, development and cooperation following the sources. On the opposite, the multiple backward main path starts from the most recent time with “a broad entrance” because of the large amount of literatures. It can pick up multiple topics and trace their historic origins, so it’s relatively theme-focused. Along the main path, the earlier research works and groups related to the particular theme can be found.

Two global main paths are almost identical. It is simply because the AAWs only accounts for 30% of the modified traversal weight and many of AAWs are zero. However, the modified global main path can still reveal the institutes’ connectivity between the citations. Local key-route main paths are sensitive to the parameter and specifically a small increase in parameter will cause a large increase in the number of nodes. In addition, two kinds of main paths cannot be easily compared owning to their great complexity and difference. A small-scale global key-route main paths will have identical nodes, but the paths become more diverse as the scale is enlarged. Besides, the trend of modified main paths shows more rapid and notable growth.

Functions and application scenario. SPC main paths present the the most representative articles and theories according to the citation network’s topology and connectivity. While MTW main paths reveal those important articles with specific characteristics due to network connectivity and associated attribute, present the process and history of knowledge diffusion in a view different from SPC main paths, supplying more detailed information in a particular scenario.

Discussion and Conclusion

The aim of this paper is to find a new method of main path identification by constructing an index on the basis of SPC traversal weight. We have quantified the relevance between the associated attribute and citation nodes, and integrated it into weight to identify special main paths.

Based on the results from the case study, the conclusion can be drawn that our method has the following beneficial effects: (1) methodology of main path identification is developed and improved. A heterogeneous bibliometric network is built based on citations, and meta-path is used
to enrich the information and semantics of main paths. We made an investigation on the citing and cited paper pairs connected via $P \rightarrow I \rightarrow P \rightarrow I \rightarrow P$ to find out whether and how institution may affect the main path. Research results showed that, 365 out of 2607 citations embedded an institution co-cooperation relationship, and such semantic relationship was well presented by the modified main paths; (2) application scenario of MPA is expanded. Selected associated attribute can be integrated into main paths, catering to different research demands. The example “institution” successfully demonstrates that main paths can unveil important research institutes, outstanding groups and their cooperation. For example, in the early stage, Steven A. Benner and A. Michael Sismour of Department of Chemistry, University of Florida, and Cynthia L. Hendrickson of Nuclear Medicine Department made much contributions to synthetic biology’s development. There are more internal cooperation. In the subsequent period, some research institutes gradually stood out, such as Department of Biochemistry and Institute for Genome Sciences and Policy, Duke University, Department of Molecular Biology, Princeton University, Howard Hughes Medical Institute, Lawrence Berkeley National Laboratory and etc. Scientific cooperation tends to be external and cross-organized. We consider the modified main path analysis method can be used to help to do agency evaluation; (3) the knowledge diffusion path of synthetic biology domain is identified to help researchers know about the domain quickly.

This study makes an initial contribution to main path identification concerning the documents’ associated attribute and shows an effective performance; however, the limitations should be considered when interpreting the results. First, our method is tested on synthetic biology, other academic fields are excluded due to limited time. Second, the study is restricted to testing a single attribute, failing to unlock the full potential of this method. Thus, further studies on different attributes and academic fields are needed to improve this method. The future researches can be done in the following directions: (1) choosing and analyzing other associated attributes and integrating them into the traversal weight for new indices; (2) trying asymmetric meta paths with different lengths to describe more kinds of relevancy; (3) comparing the results in this paper with those possible ones obtained through (1) and (2) for further findings.

Abstract
The Journal Impact Factor has a significant influence on author of submission proverbially. On the basis of a panel data analysis method, this present study aimed to clarify whether open access (OA) is beneficial to the Journal Impact Factors or the dissemination of academic achievements. The study was carried out in analyzing journals of medicine in databases such as Web of Science and Ulrich’s Periodicals Directory. The results indicate a causal relationship between the journal impact factors (JIFs) and OA, specifically that: (1) OA enhances JIFs; (2) countries that are less developed in science and technology are more likely to choose OA; (3) control variables such as language, amount of published papers, and release cycles all have a significant impact on JIFs.

Conference Topic
Journals, databases and electronic publications
Introduction

With the continuous development of information technology, social environment, and network technology, the traditional ways to disseminate academic achievements have been changed. Undoubtedly, the digitalization of research articles and the establishment of online academic communities will have a certain impact on the pre-publication stage. In addition, modern journal publications are facing problems such as high prices, publication delay, and difficulties in public acceptance. These issues have prompted publishers and researchers to seek corresponding solutions. The establishment of online network information exchange platforms for academic papers not only can effectively save resources, but also can help researchers understand the latest academic trends and reveal research frontiers in a timely manner. Therefore, open access (OA) came into being in the late 1990s. By the end of February 2016, the number of journals included in the world’s two largest OA journal retrieval platforms (i.e., Directory of Open Access Journals and Open J-Gate) increased by 1.5 times (from 7,522 to 11,441 journals) and 2.7 times (from 8,300 to 22,000), respectively, when compared with the same period in 2012. These two platforms also show that the number of OA papers has increased by 2.9 times (from 761,000 to 2,233,000) and 3.9 times (from 2,000,000 to 7,840,000) during those five years (2012-2016).

Literature review

The idea of impact factor was first proposed by Eugene Garfield (1955) in Science. Garfield and Sher (1963) introduced Journal Impact Factor (JIF) as a tool to select journals for the Science Citation Index (SCI). Since 1976, JIFs, clearly using the formula still used today, are published on a yearly basis in the Journal Citation Reports (Shi et al., 2017). Currently, JIFs have been widely used as an index to measure the quality of journals and, even worse, articles published in it (Alberts, 2013; Bollen, Rodriguez, & Van de Sompel, 2006; Kurmis, 2003; Seglen, 1997; Simons, 2008; Vanclay, 2009).

The previous research on the influence of OA papers mainly investigated the advantages of OA citations, namely whether OA journals were more easily cited than non-OA journals. The main conclusions from this literature review were: 1) OA papers have had certain advantages in citations, but there were obvious differences of citation advantage among different disciplines (Antelman, 2004; Craig et al., 2007; Davis, 2009; Eysenbach, 2005; Gaulé, 2009; Hajjem et al., 2006; Metcalf, 2006; Norris et al., 2008; Piwowar et al., 2007; Schwarz, 2004; Tonta et al., 2007). Researchers have found that OA can increase citation frequency, but there are varying degrees of impact on different disciplines. 2) No citation advantages for OA papers. In 2008, Davis et al. (2008) studied the relationship between OA and citation frequency based on random trials. The results showed that OA journals downloads were more than non-OA journals in the first year of publication, but none was highly cited. Moed (2007) argued that the citation advantage was related to quality bias and early view effect, and therefore had no relevance as to whether the paper was OA or not. Lansingsh (2009), using a multiple linear regression model and controlling the characteristics of papers, did not find a significant relationship between the paper acceptance and its citations at that period in time. Calver (2010) adopted a linear regression model to analyze eight journals of biology found that the OA citation advantage has disappeared after controlling for the characteristics of papers and increasing control for the characteristics of the authors. Based on a quantile quadrant analysis, Koler-Povh (2014) analyzed 2,007 papers in OA journals in the field of civil engineering, and the results also showed that there was no significant relationship between OA and citation frequency. Given the lack of consensus in the literature, does OA really promote the spread of academic achievements and increase JIFs? Is there a certain correlation between this effect and other factors?

In previous studies, the influence of OA in disseminating academic achievements was mainly explored through descriptive comparisons, random tests, and regression analyses. There are far fewer studies on causal relationships
and most used only one or a few influencing factors that are not systemic. In addition, most previous studies focused on the effect of OA on the number of long-term citations, rather than short-term citations, e.g., the citation window considered in JIFs. Therefore, based on general influencing factors for academic achievements, a quantitative method from the field of social science was adopted to systematically investigate causal inferences and to explore the relationship between OA and the impact factors of academic journals. The implications of this analysis include suggestions for improving academic exchange mechanisms, constructing academic exchange platforms, and transforming academic achievements.

**Data and methodology**

**Data source**

It is worth drawing attention to some of the advantages of selecting the field of medicine for our study. Firstly, medical journal publications are characterized by long spans of time and a relatively complete system. Since *New Advances in Medicine* began its publications in France in 1665, many varieties of medical journals ranging from comprehensive content to specialized subjects have been developed in the last 300 years, which means that there is now a robust system of academic publications in the field of medicine. Secondly, there is a wide distribution of medical journal publications in most countries around the world. Specifically, our statistical analysis showed that as of the end of February 2016, at least 84 countries have medical journal publications that correspond to 36 different subfields within medicine, based on the Web of Science (WoS) subject categories. Thirdly, it is feasible to obtain a relatively complete sample of publications from various databases. Many publishers have established comprehensive medical databases, such as the Medline, the PubMed, the WoS, etc. Therefore, sampling medical journal data implies having a reliable representation of the population, as well as a high level of data collection feasibility.

The data in this study consist of two parts. The first part came from the Journal Citation Report (JCR) published on the Web of Knowledge, of which there are 36 subjects related to medicine out of a total of 226 catalogued subjects. The data we collected from JCR fully included 36 subjects from the 2011-2015 period, based on total citation frequency between 2010 and 2014, JIFs, and impact factors with self-citations removed. In the 2015 JCR, a total of 2,404 journals were screened from the 36 subjects in the field of medicine. 2,045 journals were left after excluding duplicates and invalid JIFs. The remaining dataset included 172 OA journals and 1,873 non-OA journals. OA journals were identified as such in the JCR.

The second part of the data came from Ulrich's Periodicals Directory, the websites of journal publications, ResearchGate, Google Scholar, etc. From these platforms, the information was collected concerning: changes in the editor, changes in the name of the journal, the year of the first publication, OA year, academic subject information, number of papers, release cycle, language, country of publication, publishing medium, publisher, and other pertinent data.

**Methodology**

In the field of social science, in order to prove causality, we encounter the problem of “endogeneity””. Because it is hard to know whether there is a disturbance factor, it can influence the cause as well as the effect. In this case, the results obtained by regression analyses using the ordinary least squares model (OLS model) may produce errors, which will no longer give us causal inferences (Chen, 2012). Although panel data analysis can solve individual heterogeneity to a certain extent, the regression model itself may contain endogenous explanatory variables. In this study, there may also be an endogenous problem between the OA and the JIF: is the OA leading to a change in the journal’s impact factor, or is it because of the change in the OA journals’ impact indicators and the choice of being OA? Therefore the common instrumental variable method was adopted to solve the endogeneity problem. Because
the OA cannot appear in the year or even second year after the selection of the journal, eliminating the interference of time factors must be considered, thus presenting a need to introduce a fixed effect model. Therefore, to avoid the problem of possible endogeneity between independent variable and dependent variable, the interference factors of time was eliminated. A first order lag fixed panel analysis model was combined with the fixed panel instrumental variables model to explore the causal relationship between OA and JIF in this study.

Analysis Model

Factor analysis

Based on previous studies as shown in Table 1, the impact factors that influence journals can be divided into two aspects: 1) internal factors, such as author group, number of published articles, release cycle, editor, language, journal type, journal name change, etc.; 2) external factors, such as subject, publisher, search platform, etc.

</tr>
</tbody>
</table>

In addition, there were two main factors that affected the size of impact factor based on the definition of JIFs: one was the number of papers published in the journal, and the other was the citation frequency of the journal articles. Therefore, the factors influencing JIFs could also be considered from the perspective of number of papers and citation frequency.

Variables

Based on the previous section, the impact factors of domestic and international journals were summarized. The release cycle, the number of papers published in the journal, the year of first publication, the language, country of publication, and so on were considered to have an impact on JIFs. The selection of variables is shown in Table 2. The samples in our study were SCI journals from the field of medicine. We selected JIFs for a five-year period (2010-2014). Ensuring that each journal had an impact factor, 7,815 samples were selected in the end. Tables 2 and 3 show that the average
JIF of the sample was 3.058666; after removing self-citations, the average JIF was 2.806097. Only 4.4% of 7,815 journals chose OA. In other words, the vast majority (95.6%) of journals did not choose OA. In addition, the average age of journal history was 40.7 years. Journal history was at least 2 years, with the longest being 194 years. The average release cycle was 9.4 publications per year; the lowest issue was only one per year, and the highest was 60 (not considering publications that are issued irregularly). There was an average of 299.9 published articles in each statistical year corresponding to the JIF. The lowest number of articles in a journal was one per year, and the highest number was 3,458. Since dummy variables, such as country and language, were numerous, they were not included in Table 2.

Analysis model construction

We first changed the regression model to address the issue of missing variables, and then used the two-stage least squares method. The specific models are as follows:

\[
JCRIF = \alpha + \beta_1 \text{OA} + \beta_2 \text{Age} + \beta_3 \text{Issue} + \beta_4 \text{Articles} + \beta_5 \text{language} \\
\quad + \beta_6 \text{Country} + \mu_i + \varepsilon_i 
\]  

(1)

\[
\text{JIFnscite} = \alpha + \beta_1 \text{OA} + \beta_2 \text{Age} + \beta_3 \text{Issue} + \beta_4 \text{Articles} + \beta_5 \text{language} \\
\quad + \beta_6 \text{Country} + \mu_i + \varepsilon_i 
\]  

(2)

In these models, \( \alpha \) represents constant term, “OA” represents whether the journal is OA, “Issue” represents the release cycle, “Articles” represents circulation, “language” represents language that the journal is published in, “Country” represents the country of publication, \( \mu_i \) represents the year fixed effect, and \( \varepsilon_i \) represents random interference.

Then, to ensure the reliability of the model, it was necessary to deal with the potential endogeneity problem. If the endogenous problem did not exist, the two-stage method of least squares would not be as effective as the OLS method. For this purpose, the Durbin-Wu-Hausman test (DWH test) was used to test endogeneity. The model is as follows:

\[
JCRIF = \alpha + \beta_1 \text{OA} + \beta_2 \text{Age} + \beta_3 \text{Issue} + \beta_4 \text{Articles} \quad + \beta_5 \text{language} \\
\quad + \beta_6 \text{Country} + \rho + \delta_i + \mu_i + \varepsilon_i 
\]  

(3)

In this model, “\( \nu \)” represents the residual of one-stage regression, and the t-test was performed on the original hypothesis (\( H_0: \rho=0 \)) by using cluster robust standard deviation. If the original hypothesis is rejected, then an endogenous problem would be considered to exist. Otherwise, the population structure variables were exogenous. The p-value of the t-test of the original hypothesis was 0.0001, and was therefore rejected at the 0.001 significance level. Therefore, it is necessary to introduce instrumental variables to estimate whether the variable “OA” is in the JIF.

In order to deal with the potential endogeneity problem, and then accurately identify the causal relationship between OA and journal impact factors, this study took the publisher’s OA bias as the instrumental variable, and then used the panel data to produce a regression analysis of the instrumental variable. The equation for this is as follows:

\[
\text{OA} = \alpha + \beta_{\text{publisher}} + \gamma X_i + \delta_i + \mu_i + \varepsilon_i 
\]  

(4)

In this equation, “publisher” represents the OA bias of the publishing company. Publisher’s OA bias was highly correlated with the journal’s choice in having or not having an OA strategy. The OA status of the journal was entirely determined by the publisher. For instance, Biomed Central Company was a publishing firm dedicated to the promotion of OA that had a strong OA intention; all of its journals were therefore OA. In contrast, a total of 22 journals were

</table>

Note: Regression analysis included numerous dummy variables, such as country and language, which are not included here.
published by Elsevier Japan KK, none of which were OA. Elsevier Japan KK would therefore be labeled as “no OA intention”. And the publisher’s OA bias was used as a tool variable because there was no positive connection between the publisher’s OA bias and JIF. The weak instrumental variable test showed that the F-value was greater than 10, and there were no weak instrumental variables in the regression. The publisher’s OA bias could have been used as instrumental variables in this study.

Robustness test

Robustness testing is a necessary step to verify the suitability of the research model and the reliability of the results. To guarantee the reliability of the conclusions, we take into consideration that the influence of OA on the JIFs may be delayed. The panel data instrument variables model was thus used to verify the robustness of the model. Both the panel data and fixed effects models were able to elimination time deviations, but each had its advantages. The original model could be considered reliable if the results of the two methods were consistent.

Based on the regression results (Table 4), there were significant positive relationship between OA and JIFs, between JIFs and the release cycle, and between JIFs and the number of paper. However, the relationship between JIFs and journal’s year of first publication was still positive but not yet significant. That is to say, the robustness test results were consistent with the original model. Therefore, OA was considered to be one of the reasons that lead to the increase of JIFs in the field of medicine.

Results

Based on the regression analysis results shown in Table 5, all regressions were controlled for the fixed effects of time
Model 1 and Model 2 respectively represent the relationship between OA and JIF of non-self-cited journals when there were no control variables and instrumental variables. Model 3 and Model 4 respectively represent the relationship between OA and JIF of non-self-cited journals when instrumental variables were not introduced. Model 3 and Model 4 respectively represent the relationship between OA and JIFs of self-cited journal by adding instrumental variables. Regression analysis showed that the F-test was significant at the 0.01 level, and proved that the whole model was more significant and the regression results were more accurate.

From the regression results of Model 1 and Model 2, the journal hindered the promotion of JIFs and self-citations removed JIFs after the selection of OA but was not a significant effect. After adding the control variables, the regression results (Model 3 and Model 4) still showed that OA would hinder the promotion of JIFs and the self-citations removed JIFs. The parameter estimation of OA was smaller than no control variables. There were many reasons for the JIFs; both known and unknown impact factors would certainly have had an effect on the regression results. It was a negative impact but was not significant based on regression results. In other words, it did not have the explanation from the perspective of measurement. Therefore, the estimated size needed to be compared after adding instrumental variables.

Publisher’s OA bias can directly affect whether the journal chooses OA or not, but publishers cannot directly influence the JIFs, so instrumental variables were introduced to solve the endogeneity problem. The original regression results (Model 3 and Model 4) and regression results of Model 5 and Model 6 were observed after adding instrumental variables, which showed a reversal of the parameter estimates from negative to positive, and the results were significant. It was revealed that OA could increase the JIFs after removing endogeneity. The null hypothesis could therefore be rejected: OA had a significant influence on the impact factor of medical journals. OA was the cause of the JIF increase, and the OA could improve the influence of the journal.

4. *** p<0.01, ** p<0.05, * p<0.1

The control variables include journal history, release cycle, number of papers, the country, the language and so on. “Journal history” refers to the total of years since the founding of the journal. For example, A Cancer Journal for Clinicians was first published in 1950, so its journal history is 66 years. There was a positive correlation between the JIFs and journal history but it was not significant, which showed that more established journals did not necessarily have higher JIFs.

The number of papers is a control variable directly related to the formula of the JIFs and has a close relationship to JIFs. The results showed that larger number of papers resulted in higher impact factors, while shorter release cycle also resulted in higher impact factors. However, there was a bigger effect of release cycle on the JIFs. The reason probably lies in the idea that researchers are more likely to submit papers to a journal with a larger number of published papers and shorter release cycle, therefore reinforcing this trend. This is obviously more beneficial to the rapid publication of scientific achievements.

The regression results were not displayed in Table 5 due to the excessive number of two dummy variables “country” and “language”. On the whole, the coefficients of country and language were both positive and significant. There could be a phenomenon related to the relationship between the country in which journals are published, their OA status and the JIFs: countries such as France, Australia, Germany and Sweden have had a higher average impact factors and a stronger overall influence on scientific development. The number of OA journals as a proportion of the total number of journals were lower in these countries, which also correspond to countries with relatively lower OA biases. Countries with lower impact factors and higher numbers of OA journals were more likely to have an OA bias, such as Columbia, Serbia, Uganda and other countries/regions. The analysis of countries with relatively weak scientific development influence revealed that most of journals were included in the WOS platform after selecting the OA, for example, Colombia Medica in Columbia. In addition, there was a positive relationship between the JIFs and language. English is the international language of scientific publications and therefore has the greatest impact on the JIFs among all languages. Most countries with smaller research capabilities have chosen English as the standard language of their academic journals. It could therefore be seen that OA was also an opportunity for these countries, not only to circulate scientific research achievements via OA platforms, but also gain free access to the most up-to-date international research data and results, thus promoting the development of science in a virtuous cycle.

Discussion and conclusions

In order to further understand whether the open access online environment could improve the impact of academic achievements, general instrumental variables and fixed effects models that were used to solve endogeneity problems in econometrics were adopted to study the causal relationship between OA and academic influence. The factors that may influence academic achievements were identified on the basis of previous studies and were treated as the control variables in our study. Our main research findings are the following:

First, OA can enhance the impact of academic achievement in the field of medicine. There are two main reasons behind this: One is free access and consequently, greatly increasing diffusion of the scope of knowledge; another is timely quality control based on peer review.

Second, countries with relatively low science and technology development are more likely to have an OA bias. France, Australia, Germany, Sweden and other countries have had a higher average impact factors, thereby also having a strong influence on scientific publications, and lower willingness to choose OA in the field of medicine, especially
because the top journals have relatively stable readership and reference groups. On the other hand, other countries such as Columbia, Serbia, and Uganda were more likely to choose OA with lower JIFs, which then enhanced the influence of JIFs to the point where they could be included in the WOS platform.

Last but not least, number of papers, release cycle, and the language of the publication also had a significant impact on the JIFs. English was found to expand the scope of knowledge diffusion because it is the international lingua franca. The larger number of papers and the shorter release cycle, the higher the JIFs.

Based on the results of the above analysis, it is suggested promoting the OA strategy for enhancing the influence of scientific research in countries with catch-up potential in science. However, since only high quality academic journal papers can be used to serve the majority of researchers, strict quality control procedures must be the prerequisite.

Some of the shortcomings in this study include: 1) Some journals may lack several JIFs due to being included in the SCI and then deleted, so the integrity of the entire medical field academic publication data cannot be guaranteed for a small number of journals. 2) The results of this study were limited to the medical field, so the conclusions may not be applicable to other disciplines. Future studies should add other academic fields for comparisons. 3) Insufficient sources of data. Citation data from SCOPUS and Google Scholar could be used in future studies to evaluate the influence of academic achievement in the OA environment.

Abstract

Rheumatology is a wide research area with an extensive background in scientific publications. Thus, the aim of the present study is to identify the highly cited papers in Rheumatology research field, analyzing some aspects such as, the documents distribution by years, journals, authors, institutions, countries and topics. In order to perform the analysis, the H-Classics methodology, based on widely used H-index, has been used. As result it is obtained that Arthritis and Rheumatims is the journal with highest number of documents, with more than half of detected documents. Professor Wolfe, from the University of Kansas, and professor Dougados, from the Paris Descartes University, are the authors with more highly cited papers. The University of California (USA), the University of Boston (USA) and the University of Toronto (Canada) are the main institutional contributors. USA is the main producer, with more than half of the highly cited papers. The present study shows a useful insight into the development and evolution of the Rheumatology research field, revealing actors that have made the biggest research contribution to its development.

Conference Topic
Citation and co-citation analysis

Introduction

Rheumatology is considered as a subspecialty of internal medicine and paediatrics. It includes clinical problems in joints, soft tissues, autoimmune diseases, vasculitis and heritable connective tissue disorders (Cheng and Zhang 2013). In fact, this kind of musculoskeletal diseases are extremely common and have important consequences to the individual and society, being one of the major causes of disease burden around the world (Brooks 2006).

The present study aims at identifying the Highly Cited Papers (HCP) into the Rheumatology scientific production. HCP could be considered important in a research field development because they have attracted the interest of the research community. The concept of citation classic consists in characterize the HCP of a scientific discipline (Garfield 1977). Citations classics help to discover potentially important information towards the development of a discipline, and understand its past, present and future scientific structure.

According to the research literature, a series of papers have been published focusing the bibliometric impact of the Rheumatology research field Cheng and Zhang.
2013) analyzed the articles published in 39 rheumatology journals from 1996 to 2010 using the Scopus database; the number of articles, citations, h-index, and international collaborations were determined by countries or regions. In Chen et al (Chen et al. 2011), the Impact Factors of rheumatology journals from 1999 to 2008 were analyzed and compared with other fields. Cheng and Zhang (Cheng & Zhang 2010) evaluated the scientific production on rheumatology field in the 3 major regions of China (Mainland, Hong Kong, and Taiwan) during the period 2000-2009. Battle-Gualda et al.(Battle-Gualda et al. 1998) analyzed the magnitude, evolution and characteristics of the Spanish scientific production from 1990 to 1996 in Rheumatology. Redondo et al.(Redondo et al. 2016) performed a bibliometric study of the scientific publications on patient-reported outcomes in Rheumatology. However, the HCP of the Rheumatology research field have not been analyzed.

The main aim of the present study is to identify the HCP in the Rheumatology research field using the H-Classic concept. Some aspects can be analysed by identifying the set of highly cited documents: I) the HCP distribution during the period studied; II) the most productive journals, authors, institutions and countries; and, III) the main topics covered by the papers detected.

**Methods**

The set of documents to perform the bibliometric analysis is based on the journals indexed in the Rheumatology category of the Journal Citation Report (JCR-2014), which is used to construct an adequate list of the Rheumatology journals. It has been suggested that JCR contains the most important research documents of the different scientific disciplines, since they are considered as a very important criterion in tenure, promotion and other professional decisions(Hodge and Lacasse 2011; Seipel 2003).

Therefore, in order to develop the HCP analysis, the documents published by the 32 journals indexed in the JCR Rheumatology category were obtained. The search was performed on February 2016. Finally, a total of 96,642 documents (articles and reviews) were retrieved, containing the following information: authors, affiliations, title, year of publication, citations, sources, abstract and keywords.

In order to analyze the HCP, is common to establish a threshold value to discriminate whether a paper is considered as highly cited or not (Garfield 1987; Garfield 1977). In the present study, the concept of H-Classics (Martínez et al. 2014), based on the popular H-index,(Hirsch 2005) is applied to identify the highly cited documents in Rheumatology research field. The concept of H-Classics can be defined as follows (Martínez et al. 2014): “H-Classics of a research area are composed of the H highly cited papers with more than H citations received”.

This approach provides an unbiased and fair criterion to construct a systematic search procedure for highly cited documents. Furthermore, the H-Classics provides a rigorous and scientific method to discover the most relevant papers in a field. Finally, 308 H-Classics (Table 1, full access at [https://doi.org/10.6084/m9.figshare.4648450.v1](https://doi.org/10.6084/m9.figshare.4648450.v1)) were obtained using the approach mentioned above.
Results
In the following sections, the 308 HCP identified (Table 1) in Rheumatology research field are analyzed: I) the distribution of HCP per year of publication is studied, II) journals, authors, institutions and countries producing the highest number of HCP are identified, and III) a content analysis is provided.

Table 1. Highly cited papers (only 10/308 papers are shown, full table can be accessed at https://doi.org/10.6084/m9.figshare.4648450.v1)

Distribution of HCP
As afore mentioned, the study was performed with a collection of 96,642 documents, 308 of which were classified as HCP. The distribution of the HCP documents per year is shown in Figure 1. These documents are published between 1957 and 2013, covering a long period of time and concentrating the production in 1990, 1995, and the period 1998-2006. The year with more HCP documents published is 2002. The first document was published by Kellgren et al. (Kellgren and Lawrence 1957) in 1957, and the last document was published by Jennette et al. (Jennette et al. 2013) in 2013. It is worth noting the ranking position of the last document, published in 2013 and ranked 141 (about half of the table). Furthermore, although HCP are usually identified at the beginning of the period, Rheumatology research area is attracting the research community attention in relatively recent years.

![Figure 1. Distribution of Rheumatology H-Classics documents per year of publication.](image)

**Most productive journals, authors, institutions and countries**
Analyzing the social units (journals, authors, institutions and countries) the most productive journals could be detected. In this sense, Table 2 shows the journals with 4 or more H-Classics in the Rheumatology research field. *Arthritis and Rheumatism* with 200 documents is the most productive journal, followed by *Annals of the Rheumatic Diseases* and *Journal of Rheumatology*, with 40 and 26 respectively.

Otherwise, Table 3 shows the authors with 10 or more HCP documents in the Rheumatology research field. Wolfe, F., affiliated with the University of Kansas (USA), and Dougados, M., affiliated with Paris Descartes University (France), are the authors with the highest number of HCP. It is worth noting that 10 authors are from USA, 2 authors from UK, and the rest from France, Canada, Austria, Netherlands and Germany.

On the other hand, according to the information on author addresses contained in the research papers, the corresponding institutions and countries can be identified. Table 4 shows the ranking of institutions with 10 or more HCP. The top 3 most productive institutions are the University of California (USA), the University of Boston (USA) and the University of Toronto (Canada), with 29, 23, and 20 documents, respectively.

Finally, Table 5 shows the ranking of countries that produce the HCP in Rheumatology research field. The country with the highest number of HCP is the USA with 156, the half of total number of documents. It is followed by UK and Netherlands with 78 and 56 documents respectively. The predominance of USA in the Rheumatology HCP production is really evident.

It is important to highlight that each document was considered from all authors’ institutions and countries, not only the first or corresponding author.

HCP content analysis

In view of the above information, a conceptual evolution of Rheumatology HCP can be carried out. The first HCP are from the late 50's. Kellgren et al. (Kellgren and Lawrence 1958; Kellgren and Lawrence 1957) wrote the first one on the radiological diagnosis of osteoarthritis, and the second on the frequency of degenerative joint diseases in urban population. Ropes et al. (Ropes et al. 1959) conducted a review of diagnostic criteria in rheumatoid arthritis. From the 60's, only two documents are considered as HCP. One of them (Balazs et al. 1967), based on the parameters of hyaluronic acid in synovial fluid in patients with arthritis, and the second (Mason and Barnes 1969) on the diagnostic criteria of the Behçet's syndrome. From the 70's, several HCP appears with a wide range of topics, such as Lyme's arthritis (Steere et al. 1977), Behçet's syndrome (Shimizu et al. 1979), the American Rheumatism Association classification criteria for gout (Wallace et al. 1977), or a correlational study on four scales for pain measurement (Downie et al. 1978). From the 80's, a total of 44 HCP appear. The HCP first ranked, Arnett et al. (Arnett et al. 1988), appears in this decade and it is about the classification criteria of rheumatoid arthritis. Furthermore, two studies on the rheumatic diseases classification were conducted, one of them by Altman et al. (Altman et al. 1986) centered on knee osteoarthritis, and another by Cassidy et al. (Cassidy et al. 1986) focused on juvenile rheumatoid arthritis. According to our classification, there is great interest in studies centered on different measurement scales and questionnaires about health status, symptoms and disabilities in rheumatic patients. From the 90's, documents are centered in two thematic areas. On the one hand, there are documents focused on the different rheumatic diseases. On the other hand, there are HCP about the questionnaires, indexes and scales validation for measuring the impact and the physical activity on these diseases. In 2002 appears the highest number of HCP. Vitali et al. (Vitali et al. 2002) publishes the document with highest impact, it is about a revised European classification criteria for Sjogren's
syndrome. Furthermore, there are documents focused on the articular cartilage repair (Hunziker 2002; Wakitani et al. 2002), mesenchymal stem cells and their role in rheumatic diseases (Jones et al. 2002), circulatory manifestations and their expression patterns of autoimmune diseases (Cervera et al. 2002; Van Doornum et al. 2002).

From 2002, the number of HCP decreases. The last document appears in 2013, Jennette et al. (Jennette et al. 2013) conducts a review of the International Conference of Chapel Hill (CHCC1994) in the nomenclature of systemic vasculitis, whose goal was to reach a consensus on the names of the most common forms of vasculitis and build a specific definition for each one. It is noteworthy that since 1988 in which appeared a classification of rheumatoid arthritis (rank 1) (Arnett et al. 1988), an update appeared in 2010 (Aletaha et al. 2010), conducted by the American College of Rheumatology in collaboration with the European League Against Rheumatism (EULAR). Also, we should remark that although this document is relatively recent, it appears in a good position (rank 34).

Conclusions

In the present study, Rheumatology HCP have been identified and consequently analyzed using the concept of H-Classics. The analysis of the HCP allows us to highlight the following remarkable findings:

• 308 Rheumatology HCP were identified in the time period 1945-2015, with citation counts ranging from 309 to 9773. The HCP with the highest citations count, about the criteria for the classification of rheumatoid arthritis, is authored by Arnett et al. (Arnett et al. 1988) in 1988.
• Aletaha et al. (Aletaha et al. 2010) in 2010 and Jenette et al. (Jennette et al. 2013) in 2013 (with 907 and 228 cites, respectively), are also remarkable because articles normally need a long period to accumulate citations. The first one is ranked 34 and the second one 141 (about half of the table).
• Arthritis and Rheumatism is the most productive journal with 205 highly cited documents.
• Professor Wolfe, from the University of Kansas, and professor Dougados, from the Paris Descartes University, are the authors with more HCP in the field studied.
• The University of California (USA), the University of Boston (USA) and the University of Toronto (Canada) are the main institutional contributors of HCP.
• The predominance of USA in producing HCP is remarkable. Its production represents more than half of the total of HCP identified.
• The three most cited HCP focus on rheumatoid arthritis, fibromyalgia and osteoarthritis. The research topic that is addressed more within Rheumatology HCP is the diagnostic criteria of different rheumatic diseases, the most frequent are rheumatoid arthritis and osteo-arthritis.

It is worth mentioning the practical application of the present study as it provides a potentially important information to help understand the past, present and future scientific structure of the Rheumatology field that could help its future research development.

Abstract
There is an increasing amount of research investigating retractions. Yet little attention has been paid to the relationship between retractions and collaboration. In this paper, we test the hypotheses regarding the relationship between retractions and collaboration on a unique publication dataset of retractions and its control group constructed by the nearest-neighbor-matching approach. Our analysis finds no significant evidence indicating that collaboration suffers from producing flawed research, at least in the form of retraction. We also find that ceteris paribus publications with authors from elite universities are less likely but more quickly to be retracted. There also is no significant impact of collaboration size on the speed of retraction of Chinese articles, although China stands out with the fastest retracting speed. Our findings have policy implications for the governance of global science, especially that involves collaboration.

Conference Topic
research collaboration; retraction; diffusion of responsibility; scientific misconduct
Introduction

Team-dominated knowledge production has become ubiquitous globally. The trend of co-publishing escalating is evidenced by steadily growing team size and proportions of multi-authored publications, many of which are across nation’s borders (LaFollette, 1992; Cronin, 2001; Newman, 2001; Wuchty et al., 2007; Royal Society, 2011; National Academies, 2014). Reasons for producing joint research vary, from greater epistemic authority (Beaver & Rosen, 1979), more easily secured funding (Melin & Persson, 1996), higher-quality work due to cross-pollination of different minds (Cronin, Shaw, & Barre, 2004; Youtie et al., 2013), to possibility of the work receiving more citations (Royal Society, 2011). Meanwhile, the number and the annual rate of retraction of scientific research, or the official declaration of withdrawal of an article from the literature for scientific misconduct or significant errors, also have surged exponentially over the last decade (Steen, 2011a; Van Noorden, 2011; Zhang & Grieneisen, 2012; Riederer, 2014; Sheth & Thaker, 2014). The seeming coincidence, or at least co-concurrence, of the rising collaboration and retraction raises following questions: Is teamwork more likely to be associated with retraction? What factors contribute to the elapsed time between publication and retraction of collaborative work?

Unfortunately, in spite of extant research that examines factors impacting retraction, within our best knowledge, no research has systematically investigated the relationship between retraction and collaboration. This study aims to fill this gap in the literature by examining the effect of collaboration – type and size – on retraction. To do so, we draw on two opposite notions from the social psychological literature on group interaction – diffusion of responsibility and internal auditing – and test our hypotheses regarding the relationship between retraction and collaboration on a unique publication dataset of retractions and its control publication dataset constructed by the nearest-neighbor-matching approach. There is evidence in support of teamwork premium inhibiting retraction; ceteris paribus publications with authors from elite universities are less likely but more quickly to be retracted; and among existing and emerging scientific powers measured by the number of publications, China stands out with the fastest retracting speed. These findings will have policy implications for the enhancement of the governance of knowledge production in collaborative research.

The rest of the paper is structured as follows: Section 2 highlights topic importance and some noteworthy studies on retraction, while Section 3 delineates key notions and hypotheses for testing. Section 4 outlines the data and methodology, followed by analysis in Section 5. Major findings and policy implications are discussed in Section 6.

Revisiting the literature of research retraction

In the knowledge economy, both public policies and individual decisions, ranging from health to education, from parenting to business choices, are now increasingly dependent on the findings from scientific research, thus rendering scientific rigor and research integrity more important than ever (Macfarlane, Zhang, & Pun, 2014). Policy makers and research administrators come to realize that fraudulent findings endanger not only the operation of scientific enterprise but also the wellbeing of the society at large, not to mention wasting rising but still scarce public investment\(^1\) and tarnishing the trust of the public toward science and scientists (Zuckerman, 1988; Lacetera & Zirulia, 2011; Azoulay et al., 2012; Steen 2014). Unsurprisingly, over the last decade, a growing number of studies have investigated the rising phenomenon of retraction, from which four major research streams have emerged.

The first line of research describes the phenomenon. Studies consistently show that both the number and the growth rate of retracted articles have risen sharply over the last decade (Nath et al., 2006), and that such phenomenon has a strong national orientation (Liu & Hu, 2012). While research seems to suggest a high incidence of retractions in articles indexed in PubMed, a biomedical database, anecdotal evidence indicates that publishing misconduct is
significantly greater in non-PubMed articles than in PubMed ones (Zhang & Grieneisen, 2013). Grieneise and Zhang (2012) also argued convincingly that repeat retractors are globally distributed and have skewed distribution at country and institutional levels. Retraction is particularly prevalent for research produced in countries such as the USA, Germany, Japan, China, the UK, and India. For example, China leads in duplicate publications, followed by the USA and India (Grieneise & Zhang, 2012).

The second line of research categorizes reasons for retraction for the sake of policy prevention and intervention. Wager and Williams (2011; 2013) pointed out that reasons for retraction vary, including but not limited to honest but significant research errors, redundant publications, and plagiarism. Steen (2011b) further concluded that about three quarters of the retracted PubMed papers between 2000 and 2010 are due to errors or undisclosed reasons. Fang et al. (2012) refined previous research on causes of retraction. By combining information from Retraction Watch, a blog reporting on retractions of scientific papers, the US Office of Research Integrity (ORI), and other public sources, they reported that only one fifth of the retractions resulted from errors, whereas over two thirds of the papers were removed because of scientific misconduct manifested in falsification, fabrication, and plagiarism. Nath et al. (2006) performed a study to determine how commonly articles had been retracted on the basis of unintentional mistakes and whether such articles had differed from those retracted for scientific misconduct in authorship, funding, type of study, publication, and time to retraction. Their finding is consistent with previous ones, that is, number of retractions was correlated significantly with impact factors of the journal in which the retracted paper was published. Steen (2011b) also argued that journal’s impact factors were often significantly higher for fraudulently produced papers. And Noyori and Richmond (2013) confirmed empirically that the higher the impact factor of a journal, the more cases of retractions there had been.

The third strand of investigation explores the retraction phenomenon from the perspective of scientists. For example, Lacetera and Zirulia (2011) proposed a game-theoretic model to help understand motivations of scientists committing fraud as well as approaches of detecting and preventing fraud. By setting retraction in a dynamic game with asymmetrical information, they found that elite scientists were more likely to commit scientific misconducts but were less likely to be spotted than average misbehaved scientists. They also suggested that more intensive competition might in fact reduce scientific malfeasance because competitors closely monitor new findings.

Recently, studies have appeared treating the event of retraction as an independent variable and examining its impact on the individual and research domain levels. For example, Azoulay et al. (2012) investigated the extent to which “false science” impacts the rate and the direction of scientific change. Lu et al. (2013) also looked at how the retraction event impacted citations through comparing an expanded treatment group, which includes not only retracted articles but also prior articles of the retracted authors, and a control group, which consists of papers with similar citation patterns to treated papers prior to the date of retraction. They found that citation penalty for non-self-reporting retraction goes beyond the retracted paper itself. Along this line to investigate the impact of retraction on the citations to retracted authors’ prior work, Jin et al. (2013) documented a heterogeneous impact of retraction penalties on eminent and less-famous collaborators. The reverse Matthew Effect, in their words, hints at protection of established reputations.

The current study continues these inquiries following especially research streams one and three. One research gap that we spotted is a possible connection between co-publishing and retraction. In a departure from past scholarship, we try to understand the mechanism that governs the behavior of individuals in research collaboration. In particular, we are interested in knowing whether working together helps encourage responsible publishing effort.
Theories and hypotheses

As an old proverb goes, too many cooks spoil the broth. In the social psychology literature, diffusion of responsibility, also referred to as bystander effect, suggests that an individual is less likely to take responsibility for action or more likely to be idle with the presence of others, as the individual assumes that others either are responsible for taking action or have already done so (Darley & Latane, 1968; Forsyth et al., 2002). This bystander inaction could also occur in real-life academia. In the case of joint publication, for example, it is reasonable to assume that each coauthor feels that the responsibility for credibility and quality of the coauthored work is diffused, thus not necessarily taking care of the validity of the collective knowledge product.

A closely related but different notion is social loafing (Williams & Karau, 1991). That is, team members can become disgruntled and de-incentivized by unfair workload distribution due to social loafing (Tsai & Chi 2008). In the case of scientific collaboration, social loafers contribute less than their fair share to collective efforts but reap the benefits of the efforts of group members as the entire group is rewarded or punished by new knowledge demonstrated in the joint publication (Aggarwal & O’Brien, 2008; Smalheiser et al., 2005).

This underperformance due to diffusion of responsibility and social loafing, combined with the cost of collaboration (such as knowledge fragmentation and coordination failure), thus increases the likelihood of producing flawed scientific findings, which, in return, leads to a higher probability of retraction. Accordingly, our first hypothesis is as follows:

- **Hypothesis 1a**: As the size of the coauthorship increases, there will be greater incidence of retraction.

In contrast to diffusion of responsibility embedded in the social loafing theory, internal auditing, which is linked to the social interdependence theory (Johnson, 2003), provides an alternative scenario. Conceivably, due to internal auditing, more coauthors mean a higher likelihood of carrying out more scrupulous checking and knowledge validation and ensuring higher standard of quality control, thus leading to robust research that is less likely to be retracted. In other words, without collaborators’ internal auditing, a single author might be more likely to produce sloppy or even false work. So, our alternative hypothesis is:

- **Hypothesis 1b**: The size of coauthorship is negatively associated with the possibility of retraction holding other factors constant.

Factors impacting retractions

While Pozzi and David (2007) reported a lag of three years for investigated retractions by the US ORI, Redman et al. (2008) documented a much shorter retraction time – 20.75 months on average – in their study of the 315 retracted papers in the 1995–2004 PubMed data. However, existing research has paid very little attention to the factors impacting the time between publication and retraction, with few notable exceptions. A recent study conducted by Furman and colleagues (2012), for example, argued that no observable factors impacted time to retraction except for publication year, whose statistically significant and negative regression coefficient provided strong evidence in support of the trend of shortened times of detecting flawed findings.

Intuitively, multi-authored research on average receives more scholarly attention and scrutiny and thus is possibly quicker to be detected for its shaky or fraudulently produced findings. So our second null and alternate hypotheses are:

- **Hypothesis 2a**: The size of coauthorship is negatively associated with the elapsed time between publication and retraction.
- **Hypothesis 2b**: The size of coauthorship is positively associated with the time between publication and retraction.
Methodology
In order to test our hypotheses, we first constructed datasets in a series of sequential steps. Our primary source is a retracted paper dataset retrieved from Thomson Reuters’ Web of Science (WoS), an index of 11,600 peer-reviewed journals world-wide with coverage spanning a wide range of scientific disciplines. To develop this dataset, we started with using a composite Boolean query to search retraction notices, from which we eventually identified 2,087 unique retracted papers then downloaded the full bibliographical records of the retracted articles indexed in WoS from 1978 to 2013. Only original research articles were included in our dataset. We consider this a more up-to-date dataset than not only that built on PubMed, the database adopted by most previous studies, but also that utilizing information from WoS. Therefore, our dataset reveals a more comprehensive picture of the retraction phenomenon and especially the factors that have impacted retractions.

Based on the nearest-neighbor-marching principle proposed by Furman et al. (2012), we additionally identified two control articles for each retracted one by choosing its nearest neighbors. We started with the two articles immediately before and after the retracted article in the same issue of the same journal in which the retracted article was published. If neither one is qualified (for example, its document type is conference abstract, letter, correction, and editorial, among others), we next tried its nearest neighbor. The farthest neighborhood distance is 3, i.e. three papers ahead of or behind the retracted one, and we stopped search if we still were unable to locate a matching article. If a retracted article was the first or last one in that issue, we only included one comparison. In this way and with several rounds of data cleaning and standardization, we finally identified 3,970 control records with 96.6% matching rate. This approach of matching baseline of journal and publication time has an explicit and effective merit as it holds constant other factors that might have affected the incidence of retraction.

The two datasets were then imported into the text mining software VantagePoint. Our final core dataset for analysis consists of 6,057 records with 2,087 retracted articles and 3,970 associated control matched articles. We further retrieved journal impact factors from the 2013 ISI Journal Citation Reports (JCR) and global rankings of the institutional affiliations of the authors of the retracted and control articles from the 2014 Academic Ranking of World Universities (ARWU) released by Shanghai Jiaotong University and merged them into our dataset.

Analysis

Descriptive analysis
Our data indicate that between 1978 and 2013, both retraction quantity and rate increased with time. Measured by the year when the retracted articles were published, only three retractions appeared in 1978 publications, but retractions rose to 198 in 2000 and 213 in 2010. According to the year of retraction notices, the frequency of retraction appears to be precipitous, yet the publications between 2010 and 2013 were retracted more than ten times those between 2000 and 2003.

We calculated the subject-specific quartile impact factors of each journal based on the 2013 ISI JCR. If a journal is assigned to different subject categories or disciplines, we took its impact factors at both the highest and lowest quartiles (Liu and Hu, 2016). Consistent with previous findings, noted above, our analysis indicates that retractions appeared substantially more frequent in journals with higher impact factors. As illustrated in Figure 1, even in the pessimistic mode of taking the lowest quartile, 46% of the retracted articles were published in Quartile-1 (high-impact-factor) journals while only 11% in Quartile-4 (low-impact-factor).
journals. In the optimistic mode of allocating journal’s impact-factor quartiles, the retractions were 55% in Q1 but 7% in Q4.

Figure 1 Distribution of Journal Impact Factors of Retracted Articles by Quartile

With regard to research domains, retraction was more common in hard sciences, especially in the biomedical and life sciences, similar to Lu’s findings (2013), although Lu’s research only focused on post-2000 WoS retracted articles. As illustrated in the inner circle of Figure 2, over 60% of the retracted articles were in the life sciences & biomedicine; by sharp contrast, only 0.1% of the arts & humanities papers and 5.1% of the social sciences papers were retracted. The highly uneven distribution of retractions across disciplines may reflect possible lower incidences of false science or lower rates of detection of problematic research in the arts & humanities and social sciences where knowledge validation norms may differ. We then benchmarked the distribution of retracted articles against all publications in five research areas between 1990 and 2013 (shown in the outer circle of Figure 2). Apparently, the proportion of retracted life sciences & biomedicine articles is one third more than their share in the WoS articles, which only contributed 42.5% of the indexed publications. The leading scientific nations of the USA, China, Japan, Germany, and India all witnessed a higher proportion of retractions in the life sciences & biomedicine relative to their shares of papers in this research domain. The enormous consequences and economic potential of the research in these fields as well as fierce competition for positions, promotions, funding, and especially priority of discovery and peer recognition might lead life scientists to rush to publish, thus also subjecting their research to stricter scrutiny.

The distribution of flawed research also is highly skewed nationally. The top five countries in terms of the number of retracted articles were the USA (622), China (341), Japan (263), Germany (184), and India (141). As shown in Figure 3, the USA published and
retracted almost similar percentages of papers; China, Japan, and Germany each produced some 7% of the global WoS papers, but China and Japan retracted much higher percentages of papers than Germany; and the India’s share of its retracted papers was 2.5 times its share of the global WoS papers.

Table 1 compares the collaboration size (number of authors, number of affiliations, and number of countries) and time to retraction for retracted vs. control paper groups. Apparently, at all three dimensions of author, affiliation, and country, retracted articles have smaller scopes of collaboration. We particularly took a close look at China by extracting out a sub-sample of 341 retracted articles matched with 629 comparisons. As shown in Figure 4, there is no significant difference in collaboration size between the Chinese and global retractions, but the time to spot and retract flawed research involving Chinese researchers was
Figure 3. Article distribution by countries: Retractions vs All WoS articles

Note: Records retrieved and calculated by authors. The number and proportion of WoS articles in countries were retrieved and analyzed online on June 18, 2016.

much shorter: the median time for the Chinese retractions was 12 months, which is about half of that for the global retractions. Next we examined whether such difference is statistically significant controlling for other factors.

Regression analysis

Dependent variables

Our unit of analysis is article. The two key focal variables of the study are 1) retraction of flawed research, and 2) retraction time lag. The first dependent variable, retraction, is a dichotomous variable: an article is coded 1 if it is in the retraction group and 0 if in the control group. The second dependent variable is time to retraction, a continuous variable measured by the natural log of the elapsed months between an article’s publication and retraction\textsuperscript{11}.

Explanatory variable

The major independent variable of the study is collaboration size. Following common practices, we measured collaboration size by the following three indicators:

• Number of authors: numerical variable, number of authors
• Number of affiliations: numerical variable, number of unique affiliations
• Number of countries: numerical variable, number of unique countries

Control variables

In addition to year of publication, research domain, and journal’s impact factor, which were explicitly controlled by our nearest-neighbor-matching approach, as explained, we also controlled for research environment by adding a dummy variable indicating affiliation of any primary author (i.e. first author and reprint author) or any author with a global elite or Top-100 university on the 2014 Academic Ranking of World Universities. The logic is very simple: scholars from elite universities are more likely to care about their academic
reputations and those of their institutions as well as the devastating ramifications of retraction for their career. Additionally, we added a set of primary country dummy variables to the regression models to control for the research culture factor.

For testing Hypothesis 1 we used logistic regressions while OLS regressions using the natural logarithm of the time-to-retraction in months were adopted for testing Hypothesis 2. Our primary results are presented in Tables 2 and 3 (in both tables, Panels 1 and 3 are for the global dataset while Panels 2 and 4 zoom in the China sub-dataset). Whole counting was adopted here, as there is no one-to-one link between authors and their reported institutions for multi-authored publications indexed in WoS (Agrawal, McHale, & Oettl, 2013).

Notes: * Significance at 10% level; ** Significance at 5% level; *** Significance at 1% level.
For robustness testing, we also test if the first author or the corresponding author is affiliated with any of the Top-100 or Top-50 research universities. The results are similar.

Three findings on global retractions are worthy of noting (see Panel 1of Table 2 and Panel 3 of Table 3). To begin with, Hypothesis 1a is not supported. Instead, we found suggestive evidence in support of internal auditing occurring. The odds ratios of collaboration size are less than 1 and statistically significant at authors and affiliations, indicating that collaboration size is negatively associated with the retraction event holding other factors constant. All else being equal, one additional coauthor increases the odds of being retracted (versus not being retracted) by a factor of 0.95; one additional collaborated institute increases the odds of being retracted by a factor of 0.92. In other words, given that the diffusion of responsibility is more likely to occur under conditions of anonymity, we are happy to report that collaborative research does not necessarily mean to be dysfunctional. The logic is simple that a larger collaboration size means wider channels of knowledge diffusion and validation and therefore a higher probability of being identified for fraudulent findings or significant errors. Or, there is internal auditing at work. Hypothesis 2a is not supported either. As shown in Panel 3 of Table 3, collaboration size measured by number of authors and number of affiliations has statistically positive impact on retraction time, but such impact is insignificant for number of nations (see Global-Models 4–6).

Second, our data suggest that publications with authors from elite universities were less likely to be retracted. In the global dataset, only slightly over one in five (22.6% to be exact) retracted articles involved at least one author from a Top-100 university, and 14.9% of the
retracted articles had a first or reprint author from a global elite university. As shown in Global-Model 1 of Table 2, the odds-ratio for authors affiliated with a Top-100 university to withdraw a paper is 0.77. That is, holding other factors constant the odds of an article with at least one author from a Top-100 university being retracted were 23% lower compared with one without such an author, which suggests a more pronounced premium of global elite universities in inhibiting flawed science through collaboration. The same pattern also holds for collaboration size measured by number of institutional affiliations and number of countries. Meanwhile, if a paper enlisting an elite scientist had to be retracted, it was retracted quicker (see Global-Models 4–6 of Table 3).

One speculation for this phenomenon is that collaboration involving leading scientists is likely to produce findings at the frontier so as to be scrutinized by a larger community for their validity. Therefore, flaw, if any, is also quicker to be detected. This result is different from those of Furman et al.’s (2012), which, controlling for first-year citations and affiliation of authors with a Top-25 US university, concluded that neither retraction nor its quickness is correlated with the characteristics of the article, article’s author, or author’s institution. Furthermore, researchers, especially those at renowned universities, care more about their reputations, thus often assuming rather than diffusing the responsibility of validating the collective product.

The third and final interesting finding concerns collaboration involving scientists from the countries of interests. As demonstrated in Panels 2 and 4, among the top five countries with the largest number of retractions, ceteris paribus, China and India stand out with the largest likelihoods of retraction of the research involving their scientists as primary contributors, and China also is the very country with the fastest retracting speed. Adjusting for contributions made by the other variables in the model, the likelihoods of articles with a primary author from China and India being retracted were 1.96 and 2.65 times those of articles with a primary author from the US respectively. This finding supports Segal’s statement (2011) that the emerging scientific powers whose goals of intimately linking scientific research to the national pride of catching up with and surpassing the incumbents sometimes have ended up with unintended and mostly undesirable consequences.

Panel 3 suggests that among the top five countries with the largest number of retracted articles, only articles with primary authors from China demonstrates negative association with time-to-retraction. We further zoomed in the Chinese case, which consists of 341 retractions and 629 corresponding matches. Opposite to the findings from the global dataset, China’s internationally collaborated articles are more likely to be retracted compared to the work produced solely by its domestic researchers (China-Model 3 of Table 2). This does not suggest that collaborative research between domestic Chinese scientists is less problematic but only means that the rate of spotted retractions is less for such research than the international collaboration involving scientists from China. And the inhibiting role of elite authors on flawed research is even more substantially evident for Chinese retractions: the odds of an article with at least one author from a Top-100 university being retracted were 52% (i.e. 1–0.48) lower than the work involving no such an author. We also did not observe significant impact of collaboration size on the speed of retraction of Chinese articles. But as shown in China-Models 4–6 of Table 3, again, once China’s flawed research was spotted, the involvement of authors from a global elite university speeded up retraction significantly.

Conclusion and Discussions
Drawing upon two different social psychological notions – diffusion of responsibility and internal auditing – on team effectiveness and applying them to retractions of collaborative research, we provide empirical evidence on the relationship between collaboration and
retraction and examine the driving factors and the speed of retraction. Our findings especially contribute to the ongoing debate on factors impacting retraction at two fronts. First, given its importance as a driver for publication quantity and visibility, collaboration is worth studying in relation to retraction. In fact, to our knowledge, this is the first study coming up with evidence in support of the premium of team effect on deterring flawed research. Second, collaboration, especially involving elite scientists, seems to be more effective in helping spot then discourage, if not prevent, flawed research. Nevertheless, rising retractions, including those from collaboration involving scientists from elite institutions, also point to the existence of social loafing. There would have been less retractions had the flaw been detected in the stages of research, preparation of manuscripts for submission or internal checking.

As well as inspired by the prior scholarship (Azoulay et al., 2012; Furman et al., 2012; Lu et al., 2012; Jin et al., 2013), our research brings a new perspective – collaboration – into the literature on research retraction. We adopted the same nearest-neighbor-matching approach (Furman et al., 2012) and tried to analyze the same two factors that correlate with the retraction event and the retraction time lag. While Furman et al. (2012) focused on medical sciences using data from PubMed between 1977 and 2006, our analysis covered broader fields with data retrieved from WoS for a longer period of time between 1978 and 2013, thus extending the study of the retraction phenomenon to a much larger retracted group (2087 vs. 677). While Furman et al. (2012) controlled for Top-25 US universities, among others, we examined the global retraction phenomenon by controlling for the involvement of authors from global Top-100 universities, and explicitly measured collaboration through three indicators: number of authors, number of affiliations, and number of countries. As such, in contrary to one of their major findings that retraction rate is “uncorrelated with article, author, or institution characteristics,” we found that publications with authors from elite universities are less likely but quickly to be retracted.

Indeed, in addition to collaboration, other factors also may be associated with the likelihood and speed of retraction. But our methodological innovation – both the nearest-neighbor-matching approach and the use of logistic regression and OLS – allows us to control for such factors as research domain, publication year, journal visibility, research environment and culture. Although we are not seeing “direct” linkage between collaboration and retraction, our findings provide suggestive evidence to lend support that working together helps encourage responsible research behavior among researchers. As such, we are able to confidently conclude that even controlling for other compounding factors, on average, collaborated research is less likely to be “false science”; and that such “false science,” once so labeled, is quicker to be retracted. Of course, the number/type of collaboration itself could be endogenous and driven by the factors mentioned above as well as other factors such as easy access to facilities/resources, validation of knowledge, inherently interdisciplinary and exceptionally explorative nature of the research at the frontier, or increased efficiency of knowledge production due to division of labor (Beaver and Rosen, 1979; Uzzi & Spiro, 2005). Given that this empirical study is based upon secondary data, we can only speculate explanations within our knowledge of research governance practice and extant literature.

As our interest in the relationship between collaboration and retraction is partly driven by the co-concurrence of increasing dominance of team science and increasing invalided knowledge, our findings have policy implications for the governance of global science, especially that involves collaboration. To begin with, scientific misconduct is becoming a major horny problem that has bedeviled the research community for the last couple of decades. Therefore, globally, there is a compelling government interest in promoting responsible research behavior; and researchers taking responsibility in collaboration is one of the ways to inhibit false science. Our study suggests that jointly published research, especially with contributions of primary authors from top universities, is less likely to be retracted. This finding offers

644
empirical support for policy proposals that endorse research collaboration, especially that with elite scientists at top universities.

Second and related, our findings are particularly relevant to current performance evaluation policy in some countries that highly de-incentivizes collaboration (Zhou, Thijs, & Glanzel, 2009; Yan, Rousseau, & Huang, 2015). Our analysis suggests that collaboration is positively correlated with the probability of reducing flawed research. China is now the second largest knowledge producer. Yet, in many Chinese universities only the status of first author or reprint author is counted toward faculty tenure and promotion (Tang, Shapira, & Youtie, 2015). For example, the written criteria for tenure and promotion at some institutions, such as Shanghai Jiaotong University, clearly state that to be eligible for promotion to a higher academic rank a faculty member must publish two first- or reprint-authored papers in WoS-indexed journals. This means that any paper in which an academic is listed as a second or other author will be highly discounted if not completely excluded. Therefore, academics are understandably reluctant to collaborate if they are not listed as the primary authors, especially with competitors within the same college. This has suffocated internal collaboration (Wang et al., 2015). If, however, Chinese universities change policies to give credits to all authorship toward tenure or to count all authorship reasonably, this would incentivize academics to collaborate. This may also invite free ridership. Therefore, some universities, such as the Shanghai University of Finance and Economics, have adopted sophisticated fractional counting formulas for credit sharing to reduce the existence of possible ghost authors. Of course, collaborators need to understand that the privilege of authorship comes with not only credits but also responsibility.

Third, our empirical analysis demonstrates that collaborative publications with Chinese or Indian scientists as primary authors are far more likely to be retracted than those led by scientists from other major countries. This is consistent with the general concern about developing and emerging scientific countries such as China and India that still lack intellectual capital but strive to seek their seats at the league table of global academia (Zhou & Leydesdorff, 2007; The Economist, 2012; Liu, et al., 2013; Liu, et al., 2015; Tang & Hu, 2013). Therefore, the Chinese and Indian governments should have incentives to tackle the frequent and rising incidence of problematic research involving their scientists as such research has severely damaged the reputation of not only their scientists but also their countries. Scientists from these countries need to make extra efforts to maintain the integrity of their work as problematic research, if not stopped, will only discourage collaboration and delay the process through which these countries pursue scientific excellence.

Fourth, notwithstanding unsupported evidence of diffusion of responsibility in publishing retractions, we appeal for authors and journal articles to explicitly state who has contributed what in collaborative research.

Before concluding, a few reminders on the caveats seem necessary. Retracted articles do not necessarily entail scientific misconduct; unintentional but significant errors can also lead to retraction. In this paper, we have not examined the reasons for paper retraction. It is conceivably fine for this particular work as, regardless of its heterogeneous causes, retracted articles are flawed research, or “false science,” a shaky/unsteady stepping stone for later follow-on investigations (Mokyr 2002; Azouley et al., 2012).

References

---

1 For example, Steen (2014) established that on average each retracted article funded by the National Institutes of Health between 1992 and 2012 incurred an average direct cost of $392,582.
2 The ranking order of these countries changes a bit depending on the coverage of retraction articles analyzed.
3 Different samples and coding schemes are the two main reasons accounting for the different results between Steen (2011b) and Fang et al. (2012). First, while both used PubMed as data sources, Steen (2011b) covered about 800 retracted articles between 2000 and 2010 and Fang et al. (2012) looked at some 2000 retracted articles between 1973 to May 2012. Second, Steen (2011b) collapsed “undisclosed reasons” of retraction to the category of errors based on retraction notices, while Fang et al. (2012) improved the research by combining information from ORI. Please note Steen also is a co-author of Fang et al. (2012).
4 We searched “retract*” in the fields of title, key words and abstract and confined to the document type of corrections for the period from 1978 to 2013. For each retrieved hit, we linked to its retracted article. After several rounds of independent verification and cross-checking of two team members, 2,087 unique retraction notices and their corresponding retracted articles were identified and downloaded in January 2014.
5 Among them 60 retracted articles have one single match for each.
6 Considering the journal coverage dynamics of WoS, if the impact factor is not available in JCR 2013, we used its latest available impact factor.
7 For consistency, non-university institutions such as the Chinese Academy of Sciences and US national labs were treated as non-elite.
8 For example, Acta Neurochirurgica (ISSN: 0001-6268) had an impact factor of 1.766 in 2013, which ranked it the 124th among 192 journals in the field of clinical neurology, i.e. the third quartile in the pessimistic mode, and 84/198 in surgery, i.e. the second quartile in the optimistic mode.
9 Only four document types – article, review, note, and letter – are considered in our record retrieving and calculation.
10 Among 341 retractions involving scholars from China, 310 have Chinese primary authors, including 303 reprint authors and 7 first authors.
11 There are 108 retracted articles with missing values of the publication month for either retracted article or retracted notice. We estimated their elapsed months by assuming the same month of publication and retraction.
12 Furman et al. (2012) confined elite universities to Top-25 or Top-50 US ones.
13 i.e. 2.19/1.12=1.96; and 2.97/1.12=2.65.
For robustness tests, we set a stringent criterion of any primary author from a Top-100 university involved in retraction (Please see Appendices 2 and 3), and similar patterns hold. Additionally, we also conducted the following robustness tests: Recode three collaboration size variables into dummy variables, i.e., single-authored paper vs. multi-authored paper, intra-organization collaboration vs. inter-organization collaboration; domestic paper vs. internationally collaborated paper; and added the squared terms of three collaboration size variables into the model. Such tests did not change the major findings. Results are available upon request.

The concern is comparatively less as Chinese researchers do not compete against international partners for promotion and research funding. But still secondary authorship is highly undervalued for Chinese researchers in the situation of international collaboration.
Abstract
There are three main reasons for retraction: (1 ethical misconduct (e.g. duplicate publication, plagiarism, missing credit, no IRB, ownership issues, authorship issues, interference in the review process, citation manipulation); (2 scientific distortion (e.g. data manipulation, fraudulent data, unsupported conclusions, questionable data validity, non-replicability, data errors – even if unintended); 3) administrative error (e.g. article published in wrong issue, not the final version published, publisher errors). The first category, although highly deplorable has no effect on the advancement of science, the third category is relatively minor. The papers belonging to the second category are most troublesome from the scientific point of view, as they are misleading and have serious negative implications not only on science but also on society. In this paper, we explore some temporal characteristics of retracted articles, including time of publication, years to retract, growth of post retraction citations over time and social media attention by the three major categories. The data set comprises 995 retracted articles retrieved in October 2014 from Elsevier’s ScienceDirect.

Conference Topic
Scientific fraud and dishonesty; citation analysis; Altmetrics

Introduction
Retracted articles, although only a tiny fraction of the total number of articles published raise considerable interest and can have both scientific and societal implications (e.g. the article hinting that MMR vaccinations can cause autism – Wakefield et al., 1998 – not included in the reference list on purpose, which was retracted after 12 years and caused parents to refuse to vaccinate their children). Retractions can also affect the lives of the authors of retracted articles – dismissal from workplace, and in the most extreme case even committing suicide (see Cyranoski, 2014).

There are a large number of studies on retracted articles examining different aspects of the phenomenon (e.g Cokol, Ozbay, & Rodriguez-Esteban, 2008; Steen, 2011; Fang, Steen & Casadevall, 2012; Fanelli, 2013; Budd, Coble & Abritis, 2016; Bar-Ilan & Halevi, 2017). Several studies suggested to categorize reasons for retraction (e.g. issues with data quality and/or interpretation of data; ethical misconduct; data fabrication or falsification; plagiarism; duplicate publication; publisher error; authorship disputes and copyright infringement (Grieneisen & Zhang, 2012; Nath, Marcus & Druss, 2006; Singh et al., 2014; Wager & Williams, 2011).

Previous studies alerted on continued citations of articles after retraction. We call these “post-retraction citations”. The dataset used for this study is comprised of 995 articles that were retracted on or before October 2014. The number of citations these articles received was recorded in October 2014, January 2016 and April 2017, allowing us to examine the temporal trends in post retraction citation. In addition, Mendeley reader counts were also collected at these dates, which serves as an altmetric indicator of interest in scientific publications by a
wider community of people interested in science, but are not necessarily authors of scientific publications (Bar-Ilan, Shema & Thelwall, 2014; Haustein et al., 2014). The reasons for retraction were classified into a number of specific categories along the lines of previous studies mentioned above. The specific categories were collated into three major categories: (1) Ethical misconduct (2) Scientific distortion and (3) Administrative error. The temporal trends were analysed per major categories, highlighting the differences between the categories.

Data Collection
ScienceDirect, Elsevier’s full text database was accessed in October 2014. The database was queried for the term “RETRACTED” in the article title. In ScienceDirect, each retracted article is preceded with the word “RETRACTED”. A total of 1,203 results retrieved from which 995 were retracted articles. The results that were retraction notices, duplicates and papers whose original titles included the word "retracted" were excluded. Each retracted article is accompanied with a retraction notice which explains who retracted article and the reason for retraction. Usually, but not always, the reason for retraction – called Retraction Notice – is published in the same journal at or near the time of retraction. From the year of publication of the retraction notice the year of retraction was deduced. If no separate retraction notice was published, the year of retraction could not be established (this happened for 218 papers (21.90%) in our dataset.

A classification of reasons for retraction, based on earlier studies was developed. The content of retraction notices was analysed by both authors and classified into 18 specific categories independently (there was 92.5% agreement between the two coders). The specific categories were collapsed into three major categories with a 96.28% agreement between the coders:

Ethical misconduct which includes:
- Authorship disputes, citation manipulation, copyright/legal issues, duplicate publication, plagiarism, missing credit, review fabrication, unauthorized data reuse and other ethical issues (e.g. no IRB approval)

Scientific distortion which includes
- Data errors (intentional or unintentional), data fabrication, data integrity, data manipulation, data cannot be validated, findings not replicable, wrong interpretation of results

Administrative error which includes
- Final version of the article was published, wrong issue, etc.

The reason for differentiating between ethical and scientific issues is that although ethical misconduct is deplorable and is contradictory to the norms of science (Merton, 1942), it has no or only minor effect on the advancement of science. The usual name for the second category is scientific misconduct, however we preferred the term “scientific distortion”, as this category includes also data errors which might be unintentional. In either case, whether intentional or unintentional, articles belonging to this category are hurdles for the advancement of science, as they mislead scientists who rely on the results of such articles. The third category is a minor category covering other reasons for retraction that have no influence on the advancement of science.
Results and Discussion

Years to retract

It is well known that retractions take time as can already be seen in Figure 1, where the earliest retracted article in our dataset is from 1985, while the earliest retraction notice is from 1998 (note that the retraction date of 218 retraction notices could not be established). Sometimes problems with the article are not recognized immediately and are disputed, other times committees are set up to decide on the fate of the article (or articles if the investigation is against a person and not a specific paper), if a paper has multiple authors it takes time to agree to request a retraction and there can also be legal complications. COPE – the Committee on Publishing Ethics (Elsevier is a member of COPE) has clear guidelines on retractions (Wager, Barbour, Yentis & Kleinert, 2009). RetractionWatch (http://retractionwatch.com/) and PubPeer (https://pubpeer.com/, see also https://en.wikipedia.org/wiki/PubPeer) are “watchdogs” of scientific distortion and ethical misconduct.

Figure 1. Publications vs. retraction over time

Table 1 provides information on the number of years to retract an article by category for the articles for which retraction date could be established. More than 50% of the articles are retracted within one year, but there are differences by categories, scientific misconduct takes longer and administrative errors are corrected within 5 years or less. Note that there is a single article that was retracted after 28 (!) years form 1985 till 2013, the retraction was requested by the authors on ground of “duplication of data publication and text re-cycling “. There were twelve articles with retraction date after 2014, when they were already retrieved as “retracted”, indicating that it takes time to publish a separate retraction notice.

In total, there are 995 articles in the data set, 218 articles without retraction date, and when these are also included then the distribution between the categories becomes:

- 642 articles retracted because of ethical misconduct (65%)
- 302 articles retracted because of scientific distortion (30%)
- 51 articles retracted because of administrative reasons (5%)

Post retraction citations and reads

One of the most disturbing issues caused by retracted articles is citations after the article has been retracted (post retraction citations). Bar-Ilan and Halevi (2017) clearly demonstrated for a set of ten articles, that most post retraction citations ignore that the publication has been retracted, and cite the publication as legitimate while supporting the findings of the citing publication.

Here we provide evidence that citations and reads are continued to be accumulated. The number of citations at the date of data collection (October 2014) serves as baseline, as all the articles in the dataset were retracted by then. Citation and reads were collected two more times, in December 2015 and in April 2017. Citation counts were collected from Scopus and reader counts from Mendeley. Table 2 displays the number of citations and reads at each of these data collection points and the increase in percentage between the different data collection points.

Table 2: Growth in the number of citations and reads

<table>
<thead>

<td></td>
<td></td>
</tr>
</tbody>
</table>

Within a period of two and a half years, there was an increase of nearly 25% in the number of citations, even though some of the articles have been retracted for many years at the time of
data collection (3 years on average), thus the last data collection point is on average about 5 years after retraction. The number of reads on Mendeley more than doubled within the same time period. It is difficult to imagine that this enormous increase in Mendeley readership is only due to readers being curious as to why the article was retracted. Next, we look at citations and reads per categories (Tables 3 and 4).

Table 3: Post retraction citation growth per category

<table>
<thead>
<tr>
<th>Categories</th>
<th># articles</th>
<th>Sum of cits Oct14</th>
<th>Sum of cits Jan16</th>
<th>Sum of cits Apr17</th>
<th>Ave. cits Oct14</th>
<th>Ave. cits Jan16</th>
<th>Ave. cits Apr17</th>
<th>Growth Oct14 - Apr17</th>
</tr>
</thead>
<tbody>
<tr>
<td>Admin. Error</td>
<td>51</td>

<td>17385</td>
<td>14.04</td>
<td>16.04</td>
<td>17.47</td>
<td>3.43</td>
</tr>
</tbody>
</table>

Note that even though there are more than twice as many articles in the ethical misconduct category compared to scientific distortion, the articles in the scientific distortion category received more citations than articles in the ethical misconduct category. This is even more emphasized when looking at the average number of citations per paper in each category, and in the average number of new citations received during the two and the half year period. The same is true when considering reads (Table 4). This result is extremely disturbing, because as we noted before, scientific distortion is a hurdle in the advancement of science, and as previous studies showed most of the post retraction citations ignore the fact that these articles were retracted.

</tbody>
</table>

Conclusion and recommendations

The aim of this study was to show that retracted articles, and especially those that are retracted because of scientific distortion continue to be cited. The next step will be verifying the assumption that in the majority of the cases, papers are cited positively and their status as retracted is ignored.

One of the possible reasons for the continued citations is that Elsevier’s policy is to have free access to the retracted articles, even though the COPE guidelines require only the retraction notice to be freely available. The cope recommendation is not to delete the article altogether, but to clearly designate the article as retracted with a link or explanation of the reason for retraction. This free access vs. the other articles in the same journal that are behind paywall
may be an incentive for citing. We recommend that Elsevier will change its policy regarding free access to non-open access retracted articles, especially since it seems after conducting a small random check, that SpringerNature and Wiley charge for non-open access retracted articles. In addition, when searching Scopus, often the term “RETRACTED ARTICLE” does not appear in the title of the publication and only when retrieving the full text from the publisher, the searcher becomes aware of the retraction. Of course, there can be other versions of the retracted article freely available on the Web and not designated as retracted, but this is unavoidable.

We are not completely against citing retracted articles, if there is a specific reason for this, and it is clear to the readers that a retracted article is referenced. Publishers routinely run plagiarism checks. It is much easier to discover citations of retracted articles, since probably there are only a few thousand such articles.

Abstract
It is necessary to measure collaboration ability and identify the most appropriate potential partners in the current research environment. This study proposes a measuring model of collaboration ability, including the collaborative rate, the collaborative breadth and the collaborative depth, to measure author’s collaboration ability, then to identify the most appropriate potential partners. We use the articles published during the period 1978-2016 in Scientometrics for empirical research. Our research shows that collaboration is an important way in the scientific research activities in Scientometrics. Unfortunately, most author’s collaborative breadth and the collaborative depth are lower than mean. Therefore, the author’s scope and stability of collaboration is further strengthened in future. Authors can identify the most appropriate potential partners according to author’s research purpose and the region of the collaborative breadth - the collaborative depth. Therefore, the model can be used to evaluate author’s collaboration ability and identify the most appropriate potential partners.

Keywords measuring mode · collaboration ability · collaborative rate · collaborative breadth · collaborative depth · Scientometrics

Conference Topic
Indicators; Methods and techniques

Introduction
Collaboration is an essential part of academic life. Collaboration has the potential to solve complex scientific problems and promote various political, economic and social agendas (Sonnenwald, 2007). Nowadays, more and more scholars not only pay attention to scientific collaboration, but also carry out a series of studies, such as concept of collaboration (Katz and Martin, 1997), collaboration networks (Zhai, et al., 2014), collaboration pattern (Nankani, et al., 2008), potential of collaboration (Zinsstag, et al., 2005), etc.
How to measure collaboration ability and identify the most appropriate potential partners is the key to carry out collaborative research. In order to further enrich the evaluation system of collaboration, this paper proposes a measuring model of collaboration ability, which contains

Corresponding authors:
Xuqiu Wei(weixuqiu@163.com); Rongying Zhao(zhaorongying@126.com).
the collaborative rate, the collaborative breadth and the collaborative depth, and takes the articles published during the period 1978-2016 in *Scientometrics* as an empirical object to verify the feasibility and operability of the model.

2 Background

With the deepening of scientific research collaboration, it gradually forms a series of evaluation indicators. According to the difference of indicators, the studies are divided into two types of research:

*Single-indicator study:* Single-indicator study refers to the statistical study of single indicator data. For example, Newman (2001) studied a variety of statistical properties of our networks, including numbers of papers written by authors, numbers of authors per paper, numbers of collaborators that scientists have, existence and size of a giant component of connected scientists, and degree of clustering in the networks. Zhai, et al. (2014) studied the evolution and trend of collaboration networks in the field of information systems, and found that average collaboration degree and co-authorship ratio of articles over time were on the rise overall.

*Multi-indicator study:* Multi-indicator study is a comprehensive study of multiple indicator data. Schubert (2012) proposed partnership ability index. It combined the number of co-authors and the times each of them acted as co-authors with a given author exactly the same way as Hirsch’s h-index combines the number of publications and their citation rate. Wang, et al. (2014) introduced Schubert’s partnership ability index into China and analyzed its own unique theoretical and practical application value. And Sabaghinejad, et al. (2016) estimated the partnership ability of *Scientometrics* journal authors based on Web of Science from 2001 to 2013 via this index.

Single-indicator study seems relatively simple. Although multi-indicator study (partnership ability index) combined with a variety of indicator data seems relatively complex, it ignores the maximum scope of collaboration and the maximum collaboration intensity. The maximum scope of collaboration and the maximum collaboration intensity are important manifestation of authors’ collaboration ability. Therefore, this study combines the advantages of single-indicator study and multi-indicator study, proposes a measuring model of collaboration ability, which contains the collaborative rate, the collaborative breadth and the collaborative depth at author’s level, and uses the collaborative breadth and the collaborative depth to identify the most appropriate potential partners.

3 Measuring model / indicators/ data collection

*Measuring model*

The measuring model of collaboration ability is proposed in this section. The data processing of measuring model (Shown in Figure 1) is as followed: firstly, author fields in articles are extracted by using Bibexcel software to obtain OUT1 file and CIT1 file (OUT1 file is the distribution of author field per article, while CIT1 file is the cumulative frequency of author field). And author fields in collaborative articles are extracted to obtain OUT2 file and CIT2 file. Secondly, from CIT1 file, it will get the number of articles per authors; from CIT2 file, it will get the number of collaborative articles of this author, then it will calculate the collaborative rate (author level). And finally, the processed of OUT2 file through VBA and Excel obtains the collaborative breadth and the collaborative depth.
In this section, the collaborative rate, the collaborative breadth and the collaborative depth will be defined:

**Collaborative rate:** In 2012, Wei and Ji (2012) proposed the collaborative rate at country’s or institute’s level. It was determined by the percentage of collaborative publications relative to total publications for each country or institute. According this, the author’s collaborative rate is determined in this paper. It is that the percentage of collaborative literatures relative to total literatures for each author. It is used to reflect the author’s collaborative willingness in the discipline or research field. The larger value it is, the higher collaborative willingness the author has. In other word, it is easy for one author to build partnerships with the author who has high collaborative rate.

**Collaborative breadth:** It is used to reflect the author’s collaboration and communication ability, the scope of collaboration, namely, the total number of authors is that the author can be established collaboration relationship in a discipline or research field. For example, author a1, author a2 and author a3 published paper p1 together, author a1 and author a2 published paper p2 together, and author a1 and author a4 published paper p3, then the collaborative breadth of author a1 is 3 (author a2, author a3 and author a4), the collaborative breadth of author a2 is 2 (author a1 and author a3), the collaborative breadth of author a3 is 2 (author a1 and author a2), while the collaborative breadth of author a4 is 1 (author a1). Therefore, the collaboration and communication ability of author a1 is stronger than that of author a2, author a3 and author a4.

**Collaborative depth:** It is used to reflect the depth of author’s collaboration and communication, the stability degree of collaboration. It can use the maximum collaborative number between the author and other authors to represent. In the above example, author a1 and author a2 published 2 papers, author a1 and author a3 published 1 paper, and author a1 and author a4 co-published 1 paper, then the collaborative depth of both author a1 and author a2 is 2, the collaborative depth of author a3 and author a4 is 1. That is to say, one author can collaborate with author a1 or author a2 two times, however, he/she can only collaborate with author a3 or author a4 one time.

**Collaborative breadth and Collaborative depth:** In order to comprehensively reflect authors’ collaboration ability, then to identify the most appropriate potential partners, in this study, X-axis presents the collaborative breadth and Y-axis presents the collaborative depth to draw the
collaborative breadth - the collaborative depth scatter plot (Shown in Figure 2). To conveniently analyze the collaborative breadth and the collaborative depth of author’s, it should standard the above two indexes, namely, it scales the data, so that it will fall within a particular range, such as [0,1]:

\[
\text{Collaborative breadth (relative value)} = \frac{\text{Collaborative breadth (absolute value)}}{\text{Max collaborative breadth (absolute value)}} \tag{1}
\]

\[
\text{Collaborative depth (relative value)} = \frac{\text{Collaborative depth (absolute value)}}{\text{Max collaborative depth (absolute value)}} \tag{2}
\]

![Collaborative breadth - the collaborative depth scatter plot (Simple)](image)

**Figure 2**  The collaborative breadth - the collaborative depth scatter plot (Simple)

To visually show the author’s position in the scatter plot and achieve the purpose of identifying potential partners, two reference lines (the mean of the collaborative breadth and the mean of collaborative depth) are delineated in Figure 2. In Figure 2, the assumed value of the collaborative breadth or the collaborative depth is 1. Hence, the scatter plot is divided into four regions, named region I, region II, region III and region IV.

**Region I**: Both the collaborative breadth and the collaborative depth are higher. This indicates the author’s scope of collaboration is wider, and the stability degree of collaboration is higher. Therefore, the authors in this region are the best potential partners. Namely, the authors have more opportunity to establish collaboration relationship with other large authors, besides the stability degree of collaboration is also high.

**Region II**: The collaborative breadth is lower, while the collaborative depth is higher. It shows that the author’s scope of collaboration is limited, but the stability degree of collaboration is also relatively higher. Therefore, the authors in this region focus on the stability degree of collaboration.

**Region III**: Both the collaborative breadth and the collaborative depth are lower. This describes that the author’s scope of collaboration is limited and the stability degree of collaboration is also relatively low.

**Region IV**: The collaborative breadth is higher, while the collaborative depth is lower. It says that the author’s scope of collaboration is higher, but the stability degree of collaboration is also relatively low. Therefore, the authors in this region focus on the collaboration scope.

From author’s regional location shown in Figure 2, it can be learned that: the authors who have wider collaboration scope or have higher stability degree of collaboration provides a certain reference for identifying potential partners.
Data collection

Scientometrics is concerned with the quantitative features and characteristics of science and scientific research to provide guidance for the effective conduct of scientific research activities. During the developmental period of Scientometrics, the foundation of the journal *Scientometrics* (in September, 1978) was a landmark event. Following the works of previous researchers (Chen, et al., 2013; Hou, et al., 2008; Zhao, et al., 2015), this study used the journal as a representative model of Scientometrics research. Data was acquired from the Web of Science in Feb 2017. All 4,242 articles-covering articles and proceedings papers-published in the journal of *Scientometrics* in 1978–2016 (publication year) were downloaded. Among the above 4,242 articles, 2,890 articles were published by 2 authors or more authors.

4 Results and discussions

The importance of collaboration at article level

Table 1 lists the number of articles, number of collaborative articles and collaborative rate at articles level per year.

In 1978, there are 5 articles published in Scientometrics. However, in 2016, there are 341 articles published in Scientometrics. Compared the number of articles in 1978, the number of articles has increased in 2016. To further illustrate this growth trend, the trend line is developed using publication year and number of articles as variables. The trend line of publication year and number of articles is that \( y=17.565e^{0.0738x} \), \( R^2=0.8742 \). The increase in the number of articles suggests the importance of Scientometrics in scientific research management and policy making.

Description: NA presents the number of articles, NCA presents the number of collaborative articles and CR presents the collaborative rate at article level.

Although the number of collaborative articles also shows growth trend (Trend line: \( y=6.9051e^{0.0922x} \), \( R^2=0.9296 \)), the importance of collaboration in Scientometrics at article level cannot be judged. Therefore, the collaborative rate at articles level is calculated to illustrate this point. In 1987, it is 60.00%, less than than mean (68.13%); while in 2016, it ups to 85.34%
more than the mean (68.13%). Generally speaking, the collaborative rate at articles level also has increased. To some extent, it says collaboration is important in the research of Scientometrics. To better illustrating the importance of collaboration in Scientometrics at article level, the curve estimation was developed using publication year and collaborative rate at article level as variables. The result (shown in Table 2) indicates that it relatively accords with the linear model. It can be seen that with the development of science and technology, scientific research cooperation becomes more and more important.

This phenomenon occurs not only in Scientometrics, but also occurs in other research areas. For example, Gazni, et al. (2012) found that Collaborative rates continued to grow across disciplines and countries. Gazni, et al., (2012) found that the collaborative rate of the world had risen from 15.02% in 2000 to 16.85% in 2005 to 20.09% in 2010; while American collaborative rate had risen from 20.57% in 2000 to 23.63% in 2005 to 30.28% in 2010. Wei and Li (2014) found that the collaborative rate (article level) had been increased from 34.81% in 2004 to 54.36% in 2013 in library and information science. Therefore, all above indicate the importance of scientific research collaboration.

**Author’s collaborative willingness: collaborative rate**

The above section reflects the importance of collaboration at articles level. Author’s collaborative willingness (collaborative rate) determines the author's attitude towards scientific research collaboration. By the statistic, 5,296 authors are discovered from 4,242 articles in 1978-2016 in Scientometrics. The number of articles, number of collaborative articles and collaborative rate at author level are shown in Table 3.

Description: NA presents the number of articles, NCA presents the number of collaborative articles and CR presents the collaborative rate at author level.
As shown in Table 3, among those 5,296 authors, Glanzel, Schubert, Leydesdorff, Debackere, Zitt, Persson, Bordons and other 21 authors published more than 20 articles in 2006-2016. Among the 28 authors, except for author Eghe, 27 authors have high collaborative rate. Here, it will have a question that if author whose number of collaborative articles is high, his/her number of articles is high. Based on this problems, the correlation between number of collaborative articles and number of articles is analyzed by SPSS20, shown in Table 4.

### Table 4  Correlations between number of collaborative articles and number of articles at author level

<table>

</tr>
</tbody>
</table>

**. Correlation is significant at the 0.01 level (2-tailed).

From Table 4, the Pearson Correlation of between number of collaborative articles and number of articles is 0.954. This illustrates that there is a strong positive correlation between the two, and the probability P-value of the correlation coefficient test is approximately 0. Therefore, when the Correlation is significant at the 0.01 level, it should reject the original hypothesis of correlation coefficient test, that two of the total is not zero correlation. This further illustrates the importance of collaboration in Scientometrics.

In order to illustrate author’s collaborative willingness, the collaboration rate of 5,296 authors is measured. The Statistics of author’s collaborative rate is shown in Table 5.

### Table 5  Statistics of author’s collaborative rate

</tbody>
</table>

From Table 5, the Mean of 5,296 authors’ collaborative rate is 0.8887, the Median is 1, the Mode is 1 and the Std. Deviation is 0.29454. To some extent, those indicators show that authors in Scientometrics have high collaborative willingness. At the same time, Table 5 shows the Minimum is 0, i.e. some literatures were published only by one author. However, from the Percentiles in Table 5, only 15% authors, whose collaborative rate are less than 1, 85% authors, whose collaborative willingness are 1. It illustrates that authors in Scientometrics are willing to collaborate with other authors. This is to lay the foundation for potential collaboration in Scientometrics. At the same time, this also further suggests the importance of collaboration in research activities.

**Author’s collaboration and communication ability: collaborative breadth**

To reflect the author’s collaboration and communication ability, the scopes of collaboration, in Scientometrics, the collaborative breadth is introduced. By the statistic, 4,830 authors, who publish articles with other author(s), are discovered from 2,890 articles during the period 1978-2016 in Scientometrics. The collaborative breadth and its relative value of 4,830 authors are calculated, shown in Table 6. From Table 6, we can learn that the highest collaborative breadth is Rousseau, whose value is 60, i.e. author Rousseau has 60 authors to establish collaboration relationship during the period 1978-2016 in Scientometrics. The frequency distribution of
collaborative breadth is illustrated in Figure 3.

Figure 3 The frequency distribution of collaborative breadth

From Figure 3, the Mean of 4,830 authors’ collaborative breadth is 3.6609, the Median is 3, the Mode is 2, the Std. Deviation is 3.65641, the Minimum is 1, and the Maximum is 60. Besides, the collaborative breadth of 4,830 authors are mainly in the interval [1, 5]. This illustrates that authors in Scientometrics have 1-5 collaborators.

The main factors affecting the collaborative breadth are as followed:

(1) Researchers’ qualification. At universities or research institutions, the researchers (such as doctoral supervisor, master supervisor) always have higher qualifications, and they also have wider collaboration scope. 

① Researchers as doctoral supervisors or master supervisors are responsible for guiding students to familiar with the theoretical knowledge and cultivate the ability of students to identify problems, analyze problems and solve problems. During this process, the researchers have potential partners.

② Since those researchers with higher qualification, some researchers whose qualification is relatively low are willing to carry out collaborative research with them, then to enhance their own influence and research level.

(2) Researchers’ ability. To some extent, the collaborative breadth is determined by researchers’
ability. In process of research activities, researchers are willing to cooperate with the researchers who have higher capacity. Through the collaborative research, researchers who have lower ability can keep abreast of their lack in scientific research, and get some lessons and skills to quickly enhance their research abilities.

(3) Distance between researchers. The collaborative breadth is also affected by the distance between researchers. There are two kinds of distance: ① Spatial distance. In general, it is easy to see the collaboration between the same institutions. With the development of technology and internet, this phenomenon is eased. It is common to see multi-agency collaboration, inter-regional collaboration and global collaboration nowadays. And the multi-agency collaboration, inter-regional collaboration and global collaboration are gradually becoming new researches. ② Discipline difference. To a certain extent, the difference of discipline knowledge also limits the collaboration between authors: communication and collaboration is very common in the same discipline, the interdisciplinary communication and collaboration between the authors is less. However, knowledge of multiple disciplines is needed to solve many practical problems (Xu, et al., 2016). This promotes the cross combination of theories, methods, and technologies among different disciplines.

Author’s the depth of collaboration and communication: collaborative depth
To reflect the author’s depth of collaboration and communication, the stability degree of collaboration, in Scientometrics, the collaborative breadth is introduced. The collaborative depth and its relative value of 4,830 authors are calculated, shown in Table 7. From Table 7, the highest collaborative depth is author Braun and Schubert, whose value is 40. In 1981, author Braun and Schubert firstly published Some Scientometric Measures of Publishing Performance for 85 Hungarian Research Institutes together in Scientometrics. Over the next 22 years, they published 39 articles together. Obviously, their depth of collaboration and communication is deepest, and their relationship is most closely related. The frequency distribution of collaborative depth is illustrated in Figure 4.

![Collaborative depth](image1)
![Collaborative breadth](image2)

**Figure 4** The frequency distribution of collaborative depth

**Figure 5** The collaborative breadth - the collaborative depth scatter plot (982 authors)

From Figure 4, the Mean of 4,830 authors’ collaborative depth is 1.4290, the Median is 1, the Mode is 1, the Std. Deviation is 1.64461, the Minimum is 1, and the Maximum is 40. Besides, the collaborative depth of 4,830 authors are mainly 1. This illustrates that the stability degree...
of collaboration of authors in Scientometrics are 1. The main factors affecting the collaborative depth are as followed:

(1) **Collaborative time.** If two researchers have longer collaborative time, they will have more opportunity to carry out scientific research activities. Thus, the collaborative depth of them is higher. We believe that there are two time factors impact author’s collaborative depth. One is educational system, especially for supervisor or students. In China, the educational system of academic master’s education in library science is 2~3 years (Jiang and Yang, 2016); in the USA, it is 3~4 years; in England, it is 1~2 or 1~3 years (Wang, et al., 2009). This greatly limits teacher or students carry out researches together, then limits teachers’ or student’s collaborative depth. The other is time lag of paper publishing (Du, 2004). It takes a certain of amount of time for academic from received to be published. Unfortunately, in this study, the unpublished papers are not included in the measurement of collaborative depth. To a certain extent, time lag of paper publishing also affects author’s collaborative depth. However, this factor is difficult to avoid in the actual calculation process.

(2) **Research capacity level of bilateral collaboration.** From the definition of collaborative depth, the value of the collaborative depth is depended on both researchers. When both researchers have a strong research capacity, the collaborative depth is relatively high; when one side’s is high and the other’s is relatively weak, the collaborative depth is determined by the side whose research capacity is weak; and when both two researchers’ research capabilities are relatively weak, the collaborative depth is relatively weak. Therefore, we can say that the collaborative depth is determined by the research whose research capacity is relatively weak.

**Collaborative breadth & collaborative depth**

Either the collaborative breadth or the collaborative depth only reflects collaboration ability from a single aspect. To comprehensively reflect author’s collaboration ability in Scientometrics during the period 1978-2016, the collaborative breadth (relative) is calculated according to the formula (1), while the collaborative depth (relative) is calculated according to the formula (2). And the collaborative breadth - the collaborative depth scatter plot is drawn by SPSS20. Since labels exceed 1,000 limit in SPSS20, random sample (approximately 20% of all cases) is selected via SPSS20. In the end, we only show the collaborative breadth and collaborative depth of 982 authors in the scatter plot, shown in Figure 5.

Among 4,830 authors, in region Ⅰ, there are 646 authors (accounting 13.37%); in region Ⅱ, there are 370 authors (accounting 7.66%), in region Ⅲ, there are 2,756 authors (accounting 57.06%); and in region Ⅳ, it has 1,058 authors (accounting 21.90%). From the above result, it illustrates that the most of researchers (accounting 35.28%) during the period 1978-2016 in Scientometrics have higher collaborative breadth. And 21.03% of authors have higher collaborative depth. Therefore, the author’s scope and stability degree of collaboration is further strengthened.

The author’s position in Figure 5 shows the collaboration ability during the period 1978-2016 in Scientometrics. From the characteristics of author’s distribution in scatter plot, it is helpful for researchers, especially new researchers, to identify the most appropriate potential partners: (1) “Best” regional collaboration. In this region (region Ⅰ), both the collaborative breadth and the collaborative depth are higher, i.e. the author’s scope of collaboration is wider and the stability degree of collaboration is higher. The collaboration with authors in region Ⅰ is not only beneficial to expanding the scope of collaboration, but also help to carry out in-depth collaboration to improve their academic influence together in Scientometrics.
(2) Deepen stability regional collaboration. In this region (region Ⅱ), the collaborative breadth is lower than the mean, while the collaborative depth is higher than the mean. Compared with region Ⅰ, the scope of collaboration is limited, but the stability degree of collaboration is higher. Therefore, the collaboration with authors in region Ⅱ is help to carry out depth collaboration to mine some research contents or subjects deeply.

(3) General regional collaboration. In this region (region Ⅲ), both the collaborative breadth and the collaborative depth are lower. Researchers in this region should increase their scope of collaboration and stability degree of collaboration. So, they can collaborate with authors in region Ⅰ, region Ⅱ and region Ⅳ.

(4) Expand scope regional collaboration. In this region (region Ⅳ), the collaborative breadth is higher than the mean, while the collaborative depth is lower than the mean. Compared with region Ⅰ, the scope of collaboration is higher, while the stability degree of collaborative is limited. Therefore, the collaboration with authors in region Ⅳ is help to increase the scope of collaboration.

In short, according to author’s research purpose and the region of the collaborative breadth - the collaborative depth, he/she can identify the most appropriate potential partners to carry out collaborative research, especially for the authors who are new researchers in this field or whose collaborative breadth or collaborative depth should be further strengthened.

5 Conclusions

In scientific research, collaboration is becoming more and more important. It is important to measure author’s collaboration ability and identify the most appropriate potential partners. After research, we find that: (1) with the development of Scientometrics, both the number of articles and the number of collaborative articles have increased. What’s more, the collaborative rate at article level has increased. (2) The analysis of author’s collaborative rate, it find that author’s collaborative willingness are higher in Scientometrics. This not only further shows the importance of collaboration, but also reflects the author’s views on collaborative behavior. (3) The collaborative breadth of 4,830 authors are mainly in the interval [1,5], while the maximum is 60; the stability degree of collaboration of authors in Scientometrics are 1, while the maximum is 40. The author’s scope and stability degree of collaboration is further strengthened. And (4) the scatter plot is divided into 4 regions. According to the actual situation of the author, he/she can identify the most appropriate potential partners.

This research contributes several perspectives. First, this study proposes measuring model of collaboration ability. The collaborative rate reflects author’s collaborative willingness, however, the collaborative breadth and collaborative depth reflects the degree of collaboration and communication. Second, to reflect authors’ collaboration ability from multi-indictor data, this study comprehensively analyzes author’s collaborative breadth and collaborative depth in a scatter plot. Besides, based on the scatter plot, researcher can identify the most appropriate potential partners for himself/herself. And finally, in this article, we use empirical method to measure author’s collaboration ability and identify the most appropriate potential partners. It will provide an example for other disciplines or research field.

In this study, the present study has a little less, to be further improved: the empirical analysis only takes Scientometrics as a case, interdisciplinary collaboration ability will be discussed in the future. Overall, this study proposes measuring model of collaboration ability to measure author’s collaboration ability and identify the most appropriate potential partners.

Abstract
This paper is to reflect the China’s international collaboration in science during the period 1995-2015 and to discover the dynamics and the channel of international collaboration between China and the main scientific and technological powers. USA, Japan, Germany, UK, and France are chosen the international target countries to compare, the collaborative data of Big 6 are retrieved in Web of Science, and some descriptive statistical analyses are given. The data show that China’s share of internationally co-authored papers is still considerably lower than that of the other main countries. The numbers of collaborative papers in five nations have grown much faster than the numbers of non-collaborative ones. In China collaborative papers grow only slightly faster than non-collaborative ones, especially over the latest years. China’s international collaboration in science has obvious disciplinary preferences, focusing mainly on traditional fundamental disciplines. Overseas Chinese play an extremely important role in mainland China’s international collaboration, providing an optimal channel to overcome linguistic and cultural barriers.

International scientific and technological collaboration; China’s international collaboration; overseas Chinese phenomenon

Conference Topic
Country-level studies

Introduction
By the end of the fifties in the 20th century, Smith (1958) noted a trend towards more and more multiple authorship. This led Price (1963) to predict the demise of the single-author article. Although this prediction has not come true, the number of single-author articles has indeed steadily declined. Wuchty et al. (2007) confirmed the general increase of the influence of teams in science, including that by this phenomenon the process of knowledge creation has fundamentally changed over the years. Scientific collaboration can be described as a process by which scientists with common interests work together to create new knowledge (Katz, 1994, 1997; Coccia & Wang, 2016). It is generally accepted that team work increases quality and productivity and hence the received number of citations, although collaboration does not necessarily lead to success, such as a lot of citations.(Figg et al, 2006; Glänzel, 2008; Elango et al,2015). Generally speaking, nowadays a scientist is not anymore an isolated actor but one member, among many, of an international research team, working together to discover the rules of nature and society (Cronin, 1982; Finardi & Buratti,2016). Due to differences in research accumulation during investigations there
are always leading teams and followers (Zhou & Bormman, 2015; Ma et al., 2016). If researchers collaborate with the leaders, knowledge and technical barriers are reduced and this helps them to reach the research front. Yet, leaders too may benefit from collaborating, as increased manpower can greatly accelerate the development and diffusion of new knowledge, new technologies and new methods.

Developing countries can greatly extend their scientific productivity and strength, in the same time increasing the visibility of their researchers, by collaborating with leading countries (Rigby & Edler, 2005; Jonkers & Tijssen, 2008; Zhou et al., 2009; Ynalvez & Shrum, 2011; Wagner et al., 2015). Collaboration gives, moreover, direct access to complementary knowledge or skills, unique sites and facilities, and shares costs and risks (Kim, 2005; Birnholtz, 2007; Haustein et al., 2011). Starting as a developing (or at least a not-yet-fully-developed) nation China’s science and technology has increased considerably during the latest twenty years. The exponential increase in the absolute and relative number of WoS papers bears testimony of this fact (Jin & Rousseau, 2005). Yet, outstanding scientific and technological discoveries are not distributed evenly over countries, regions or provinces (or states) within a country (Wang et al., 2005; Zhou et al., 2009). By studying international collaboration we intend to obtain a better insight in the position of China with respect to other big countries.

We would like to add one more point, namely that collaborative research may not only lead to publications but also to patents (Chen et al., 2013). This aspect is not the topic of this paper. Hence, the main purpose of this article is to describe China’s position in the international fray, restricted to its output in scientific papers.

Data and Methods

The articles jointly written by several authors reflect scientific and technological collaboration. Consequently international collaboration is reflected by articles jointly published by authors in different countries. Articles co-authored by Chinese scientists in the context of international collaboration are mainly published in international journals. Zheng et al. (2012) mentioned that in domestic journals only 1.5% of the publications are the result of international collaboration. Hence, if one wants to study China’s international collaboration as shown by published articles one must make use of an international database. Consequently we use Thomson Reuter’s Web of Science (WoS). Publications are restricted to the article and review type.

The United States, the UK (taking care of the fact that the UK consists of England, Scotland, Wales and Northern Ireland), Germany, Japan and France are, together with China the countries producing the most articles. They will be referred to as the Big 6. In 2015, the total articles’ number recorded in WoS is 2,632,093, and the number produced by the Big 6 is 1,529,243. Nowadays we focus on these six countries. Taking the names of the chosen countries as retrieval terms, the retrieved data are divided into two groups: international collaborative papers on the one hand and non-international collaboration on the other (authors are all from China, including single author papers).
By choosing the above mentioned countries we expect to grasp the main trends and characteristics of international collaboration with special emphasis on the role played by China. Furthermore, we explore the dynamics of international collaboration and try to find the optimal path for China’s scientists when it comes to participation in international scientific and technological endeavors. Occasionally we will refer to papers written as the result of an international collaboration as “co-papers” (as a short-hand).

Because of this aim, the WoS data set of articles and reviews in 1995-2015 are retrieved. Besides all papers (of article and review type), we also consider separately the collaborative papers, written in collaboration with the main countries with which these countries collaborate the most. Articles by overseas Chinese are especially collected as well as the fields in which collaboration occurs. Data were collected in September 2016.

Results

International collaboration trends of the BIG 6 countries

Taking the name of Big 6 as retrieval terms, the retrieved data are divided into two groups: international collaborative papers, of which the affiliation consists of two or more than two countries, and non-international collaborative one, of which the affiliation only one country. The full counting is recorded every one year since 1995, and the growth rate is calculated respectively. The calculation results are shown in Table 1.

</table>
The data in Table 1 show that, except for China, the growth rate of international collaborative papers is much faster than the growth rate of non-collaborative ones. What could be the reason for this phenomenon?

When a society matures, the division of labor and in particular the numbers of practitioners engaged in scientific and technological research may stay constant, leading to a stabilization of its scientific and technological output. In order to maintain their international position developed countries must adapt their scientific policies and try to increase their attractiveness for foreign scientists, heavyweights as well as average ones. These and other factors must be optimized to maximize scientific and technological output. Supported by a national R&D policies, international collaboration promotes scientific development and progress, leading to prosperity in the collaborating nations. For these reasons developed states have vigorously strengthened international collaboration over the past twenty years. Promoting scientific and technological collaboration has become an important point in the research policies of most countries all over the world.

In contrast, China is not yet a fully developed country, and its society is changing at full speed. On the one hand, the number of practitioners engaged in scientific and technological activities in China continues to increase, and the number of scientific papers maintains a sustained high growth. On the other hand, there is no doubt that it is a good choice to promote scientific and technological development through international collaboration. Therefore, all Chinese papers (internationally collaborated or not) maintained a double-digit growth during the recent 20 years. Furthermore, while China's growth rate of non-collaborative papers tends to decrease after the peak in 2003; its international collaborative papers kept a sustained strong increase, and its growth rate is also higher than that of the other five nations. But until 2015, China’s scientific output(330,927) is still only about half of that of USA(646,528). As a not-yet-fully-developed country, it is of great importance for China to develop a sound scientific policies and to promote scientific research, including international collaboration, to follow or even lead world trends.

The role played by China in international collaboration

In international collaboration, the ranks of authors in the byline of papers usually reflect the contribution of participants, reflecting role differences in collaboration. In particular, the corresponding author is often the person responsible for the research project. Therefore, by analyzing whether an author in collaborative papers is the corresponding author or not, the scientific contribution of authors in such papers can be analyzed. In this section, we investigate if China undertook either a leading role or
a subordinate one in international collaboration by using the available information on corresponding authors. The proportion of corresponding authors, written as CAs, is calculated, and the publishing years are selected randomly.

Table 2. Proportion of corresponding authors (CAs) in international collaborative papers in 2007 and 2011

</tbody>
</table>

Table 2 shows that the proportion of corresponding authors in China’s international collaboration is over 50%, and staying relatively stable in 2007 and 2011. Of course, the simply descriptive statistical data only give us some superficial impression, and the in-depth analysis need to use panel analysis tools to reveal the rules.

Which role did China take in the collaboration with the five other important nations? Table 3 shows that in collaboration with major scientific and technological powers, the proportion of corresponding authors is slightly lower than the average of China in 2007 and 2011, especially in collaboration with Germany and France. Therefore, in order to enhance China’s capacities in international scientific and technological collaboration, the proportion of corresponding authors needs to increase.

How does the role differ according to discipline? Based on the SCI 22 subjects/disciplines we determine the proportion of corresponding authors in international collaborative papers for the years 2007 and 2011. The data shown in Table 4 reveal that in 2007, the following disciplines have a proportion of corresponding authors higher than the average (54.0%): agricultural sciences, chemistry, computer science, engineering, environment / ecology, geosciences, materials science, interdisciplinary, physics, plant and animal science. In the following disciplines the opposite is the case: clinical medicine, economics and business, immunology, molecular biology and genetics, neuroscience and behavior, social sciences (general). But in 2011, there are some changes. The following disciplines have a proportion of corresponding authors that is higher than average (56.2%): agricultural science, computer science, engineering, environment/ecology,
Some disciplines in which this proportion was higher than average in 2007 are now below average and vice versa. The collaborative counts of disciplines have doubled from 2007 to 2011; however, in terms of collaborative roles, in particular in terms of playing the leading role some disciplines, such as clinical medicine, immunology, molecular biology and genetics, and neuroscience & behavior, still show room for improvement.

Overseas Chinese play the role of bridges in international collaboration

The connecting role of countrymen or former countrymen working in other countries has been studied in several publications (Webster, 2004; Jin et al, 2007; Jonkers & Tijssen, 2008). When it comes to Chinese scientists we will use the term overseas Chinese referring to those scientists who are of Chinese descent, but have joined other nationalities, as well as those Chinese which temporarily work and study in other nations. Among the 38,327 Chinese international collaborative papers in 2011, there
are 25,995 papers including overseas Chinese, about 67.8%.

The proportion of overseas Chinese collaborative papers in 22 disciplines (Table 5) shows that in some disciplines, such as physics (75.1%), interdisciplinary studies (74.2%), immunology (73.5%), materials science (73.5%), molecular biology and genetics (73.2%), and computer science (72.2%), the overseas Chinese are very active, often leading the collaboration. Even in some disciplines with a lower proportion of overseas Chinese collaborative papers, such as plant & animal science (50.4%). In sum, the overseas Chinese have a very strong role as a bridge in international collaboration with mainland China.

**Conclusion and discussion**

This article analyzed the trends of international collaboration in science and technology using six leading nations (the United States, China, Japan, Germany, UK and France) as case studies. These data retrieved from the WoS show that the numbers of collaborative papers in five nations have grown much faster than the numbers of
non-collaborative ones. This means that the major scientific and technological nations focus on their own research capability while further promoting science and technology through international collaboration. The numbers of collaborative nations are continuously growing all over the world, but especially in China.

As a not-yet-fully-developed nation, China is playing an increasingly important role in international collaboration. Numbers of collaborative or non-collaborative papers have experienced a breakthrough growth. China’s international collaboration in science and technology has obvious disciplinary preferences, focusing mainly on traditional fundamental disciplines. Overseas Chinese play an extremely important role in mainland China’s international collaboration in science and technology, providing an optimal channel to overcome linguistic and cultural barriers. It is no surprise that China's S&T policies support and facilitate such collaborations.

Collaboration is an optimal strategy to promote science and technology

Why does the data show sharply increasing patterns of international collaboration in recent years?

In researchers’ level, collaboration is intrinsic needs in their careers. Everyone want to publish instead of perish, especially to publish in high level journal, such as SCIENCE or NATURE. Many data have verified the fact that partnering with collaborators anywhere can help them do the research, and even more importantly, get their papers accepted, especially partnering the prestigious professors. In earlier stage, the collaboration has taken place in colleagues, supervisor and students, even different institutes. With the support of IT, the collaboration gradually spread more remote distance, such as different states or nations. It can be called bottom-up pattern, which is driven by the researcher himself and is a self-organized process. The limitations of this pattern are stochastic and non-planned, but it is a critical factor to promote the sharp increment of collaboration, whether the local collaboration or international one.

International collaboration in science and technology besides being an effective way to boost productivity also promotes prosperity in the world. No nation, developing or developed, has enough resources to match its needs in science and technology. Therefore international collaboration has become an important aspect in scientific policies. We even claim that it is the optimal path to acquire needed resources. This is obvious in the case of Big Science projects such as CERN’s Large Hadron Collider (LHC).

Developed nations often have first-mover advantages in research and have enough resources to attract talented, excellent intellectuals from all over the world to participate in international collaboration. Due to their strength, they can be more selective with respect to the nature of their collaboration. In order to reach the research front of a discipline, developed nations have paid a lot of attention to increase their own scientific and technological capabilities, while promoting international collaboration and formulating appropriate international collaboration strategies.
Due to limitations in scientific and technological conditions it is impossible for developing or non-developed nations alike to carry out comprehensive research in all disciplines. Hence they have to formulate suitable strategies focusing on their best disciplines on the one hand, and promoting their other disciplines through international collaboration. Generally, developing nations often have an advantage in the number of human personnel, so that they have manpower to offer when collaborating with developed nations. Such collaborations may accelerate the development of science and technology in the world.

Therefore, international collaboration in science and technology is an optimal way to reallocate scientific and technological resources on a global scale. Every country sees international collaboration as a tool to develop its own R&D strength. This collaboration can be called top-down pattern, which is an optimal strategy driven by government policies. Not only the developing countries, such as China, but some developed ones, such as UK, have formulated some planning to promote international collaboration in science and technology. The impressive characteristics of this pattern are the target-oriented and the planned, and it can be used to interpret the preferred collaborative disciplines, institutions, and countries.

20 years ago or earlier, it is difficult to seek a collaborator in remote distance, especially different countries. It is the main thing that the advent of the internet has given more convenient condition to promote collaboration during the past two decades, especially the international cooperation. With the development of the Internet, scientific and technological collaboration in an international context has become easier. Gone are the days of hand written letters, difficult intercontinental telephone talks and an occasional long travel. Nowadays colleagues living on the other side of the globe are as close for discussions as a colleague working two stages higher in the building.

All of these, not only the needs of single researchers but the governmental policies and context changes of information techniques, together promote the international collaboration in science and technology. The bottom-up practices of collaborative needs in scientists have accelerated the increment of collaborative papers and settled the micro-foundation of collaboration, the top-down collaborative policies formulated by the government have facilitated the policies context, and the information techniques, particularly the internet, have eliminated the spatial barriers of communication and collaboration in long distances. The prosperities of international collaboration are due to the harmonious function of above factors.

Ethnic ties are a bridge to optimize collaborative channels for China

For developing nations, it is an important issue to seek an international collaborative partner in science and technology. Yet there exist many barriers to collaboration, such as culture, language, funds and policies. It is known that building on ethnic ties is an optimal channel to eliminate such barriers (Jin et al., 2007).

The ‘Overseas Chinese phenomenon’ (Jin et al., 2007) in China’s international
collaboration has developed from a deep social basis over many years. Chinese scientists leaving China, permanently or temporarily, are embedded in traditional Chinese culture, writing the same language, and having close social relations with China. These factors form a strong social basis binding overseas Chinese to a country with which they share many characteristics. This social basis is also where the opportunity lays for overseas Chinese to carry on international collaboration with China. From the foreign country’s perspective, the presence of a significant community of ethnic Chinese makes it easier to collaborate with scientists in mainland China. Indeed, Jonkers and Tijssen (2008) conclude that while countries may lose human capital when Chinese or other ethnic groups return to their homeland (a phenomenon referred to as “return brain drain”) they may also gain in terms of scientific linkages.

Furthermore, the government of mainland China has formulated several specific policies regarding overseas Chinese, such as *The Recruitment Program of Global Experts*, *Introducing Talent intellectuals Planning*, *Yangtze River Scholars Program*, *Thousand Talents program*, and so on. These programs attract outstanding overseas Chinese persuading them to return to their homeland.

Such ethnic ties are of a homophilic nature (McPherson et al., 2001), referring to the phenomenon that similar groups have more frequent contact than un-similar ones. On the one hand, we notice that overseas Chinese scientists establish emotional contact through family, relatives, teacher-student relationship and former collaboration, making future collaboration easier; and on the other hand, based on ethnic ties, this collaboration can enhance the prestige of participants in mainland China. In fact, this phenomenon may not only exist for Chinese, but also for other ethnic groups such as Indians and Koreans.

Multi-Scale H-Index: A New Measure to Assess the Scientific Impact of Scholars

Feng Ma¹ and Yuan Huang²

²HeFei University of Technology, Hefei (China)

Abstract
Quantitative evaluation on the individual’s scientific impact is an important research topic in the scientometrics and bibliometrics fields. As a pioneering milestone, the h-index measures the scientific impact of an individual’s research work by simultaneously considering the publication productivity and the article impact (citation count). However, the h-index ignores the additional citation count of those papers in the h-core publication list. To address this issue, lots of research efforts have been devoted and many alternatives are proposed but still suffer some limitations. In this paper, we extend the classic h-index and propose a novel multi-scale h-index to measure the scientific impact of scholars. In our approach, we first generate a multi-scale representation of a scholar’s paper citation record and calculate the h-index score for each scale. In this way, a multi-dimensional h-index score vector is obtained. To obtain a single number for quantitative evaluation and comparison, a final index score is calculated by summarizing those multi-scale h-index scores in an adaptive weighing manner. Our approach can be extended to consider all publication citations and subtly emphasizes those important papers with high citation count. To validate the proposed indicators, an experimental study is conducted on 82 scholars in the scientometrics field and comparison is made with several existing indices. Our proposed MH-index demonstrates to be more balanced and fine-grained for evaluating and comparing the scientific impact of individual scientists.

Conference Topic
Indicators

Introduction
In the scientific field, there is an important research problem, i.e., how to quantify the cumulative scientific significance and broad impact of an individual scholar. A proper overall quantitative index will provide a useful indicator to evaluate and compare different individuals competing for the same resource, such as universities faculty application or advancement and grant award, when scientific achievement is a critical assessment criterion (Hirsch 2005). To this end, generally, the publication and citation record of an individual is used to extract an overall indicator number. Early criteria commonly used include total number of papers, total number of citations, average citations per paper, number of significant papers, etc. Although intuitive, those criteria suffer from the imbalance between productivity and paper importance or the involvement of arbitrary parameters.

To avoid the disadvantage of the above criteria, Hirsch (2005) proposed the classic h-index as an easily computable indicator to characterize the scientific output of a researcher. As a pioneering work, the h-index measures the scientific impact of an individual by counting the maximal number of core papers with citation times over a threshold equal to the core paper number. Although simple and useful, the h-index suffers a nontrivial limitation that no additional credit is given to those highly cited articles, whereas every citation counts on scientific evaluation (Vanclay 2007, Rousseau et al. 2008, Schreiber 2008, Bornmann et al. 2008 and 2011). To address this weakness, many indicators are proposed, such as g-index (Egghe 2006), AR-index (Jin 2007), R-index (Jin et al. 2007), Tapered h-index (Anderson et al. 2008), Hg-index (Alonso et al. 2010), q-2 index (Cabrerizo et al. 2010), PR-index (Gao et al. 2016), ch-index (Kosmulski 2006), t-index (Tol 2009), pi-index (Vinkler 2009), w-index (Wu 2011).
To give credit to excess citation count, some other index schemes are proposed, such as e-index by Zhang (2009) and j-index by Todeschini (2011). Another limitation of h-index is that it relies on only those articles which have significant impact and high citation record, whereas every article contributes to research output and scientific impact of an individual. To consider the importance of all cited articles of an individual, several other indices are proposed, such as the multidimensional h-index by García Pérez (2009), mock h-index by Prathap (2010) central interval index by Dorta-González et al. (2011), two sided h-index by García Pérez (2012). To compare different index methods, comprehensive studies have been made by Bornmann et al. (2008 and 2011). Considering the difficulty to evaluate the scientific impact of an individual with a single indicator, some other researchers resort to the combination of two or multiple indicators (Martin 1996). Although such an idea seems interesting and promising, special concern shall be taken on the combination or aggregation scheme.

In this paper, we discuss the properties of h-index, e-index, multidimensional h-index, iteratively weighted h-index (iw(h)-index), EM-index, and propose a new measure named multi-scale h-index to evaluate the scientific impact of a scholar. The multi-scale h-index only considers those highly cited articles, but also counts those outside the h-core article set.

The rest of this paper is organized as follows. In “Related Work” section, we make a survey on some preliminary work including h-index, e-index, multidimensional h-index, iteratively weighted h-index, and EM-index, and discuss their advantage together with limitations. In “Multi-Scale H-Index” section, we elaborate our novel multi-scale h-index and its properties. After that, we conduct experimental study in “Experiments” section. Last but not least, we conclude this work in “Conclusion” section.

**Related Work**

This work is focused on the quantitative indicator of scientific impact based on an individual’s record of article publication and citation. In the following, several related indices are surveyed and analysed.

As the milestone index to measure an individual’s scientific impact, h-index (Hirsch, 2005) is defined based on the citation of an individual’s publication. The h-index of a scholar is $h$ if $h$ of his or her articles have at least $h$ citations each while the citation of each of the rest papers is no larger than $h$. Geometrically, given the citation curve of all papers in descending order, its intersection with the of the 45 degree line (the line $y = x$) gives $h$, as illustrated in Fig. 1(a).

![Figure 1](image-url)

**Figure 1.** Schematic illustration of (a) h-index, (b) multi-dimensional h-index, and (c) EM-index. The e-index is defined based on h-index with excess citation count considered, while the iteratively weighted h-index is a global representation of the multi-dimensional h-index.
The h-index only considers those high-cited articles but ignores those with less-cited ones. To address this problem, the multi-dimensional h-index is proposed. Given the citation record of a scientist, his or her multi-dimensional h-index \((h_1, h_2, h_3, \cdots, h_K)\) is generated as follows. All the involved \(N\) articles are sorted by the citation count in descending order. Then, \(h_1\) is obtained as the traditional h-index. After that, those top \(h_1\) most-cited articles are removed and we compute \(h_2\) as the h-index of the remaining \((N-h_1)\) articles. Similarity, \(h_{k+1}\) is obtained by computing the h-index on the bottom \((N-h_1-h_2-\cdots-h_k)\) least cited articles, which are obtained by checking the intersection of the line \(y = x - \sum_{i=1}^{k} h_i\) with the article citation curve, as illustrated in Fig. 1 (b). Such process is iterated until all articles with citation count no less than 1 are visited. Since multi-dimensional h-index is a vector and inconvenient for comparison, a global number is defined by the iteratively weighted h-index (Todeschini and Baccini 2016) as follows,

\[
iw(h) = \sum_{k=1}^{K} \frac{h_k}{k}.
\] (1)

To discriminate those highly-cited articles, some variants of h-index are proposed. Zhang et al. (2009) proposed e-index to consider the importance of the excess citation count over h-index. Specifically, given the sorted article citations \((c_1, c_2, \cdots)\) in descending order of a scientist, the e-index is defined as square root of sum of the excess citation count of \(h\)-core articles, as follows,

\[
e = \sqrt{\sum_{k=1}^{h} (c_k - h)}.
\] (2)

Another variant is EM-index (Bihari and Tripathi 2017), which adopts the concept of multi-dimensional h-index. Concretely speaking, for an individual with article citations \((c_1, c_2, \cdots)\) ranked in descending order, EM-index first generates a multi-dimensional index vector \((h_1, h_2, h_3, \cdots, h_K)\). The first component \(h_1\) is exactly the h-index value. The \((k+1)\)th component \(h_{k+1}\) is obtained by computing the h-index for the excess citation counts of the \(h\)-core papers in the \(k\)-th round, which are obtained by checking the intersection of the line \(y = x - \sum_{i=1}^{k} h_i\) with the article citation curve, as illustrated in Fig. 1 (c). Finally, the EM-index is defined as the square root of the sum over the all components in the index vector.

The above index schemes only consider the highly cited articles, but fail to explore all articles with at least one citation. To make a comprehensive evaluation, both the top and the tail citation counts should be taken into consideration. Towards this goal, García Pérez (2012) proposed a two-sided h-index. Bihari et al. (2017) extended their EM-index to EM'-index by considering the citation counts of all articles after subtracting the h-index from the h-core articles.

**Multi-Scale II-Index**

To evaluate an individual’s scientific impact based on the publication and citation records, the general principle beneath the existing schemes, such as h-index, e-index, iterative weighted h-index and EM-index, is to correlate the publication count with the citation count under some constraints. Following such a paradigm, an intuitive idea is to define a measure as: the index value of an individual is \(m\), if at most the \(m\) articles have citation counts over \(n\) while the citation counts of the remaining articles are all no larger than \(n\). A function \(f(\cdot)\) is defined to correlate \(m\) and \(n\) as follows,

\[
m = f(n).
\] (3)

In h-index, the correlation function is an identity function \(f(x) = x\), which is inherited by many other variants. Although some a function is simple and demonstrates effective in many cases, it is not flexible to well capture the fine-grained characteristics of the citation curve. Based on such a motivation, we propose to define the correlation function as follows,

\[
y = f_k(x) = 2^k x,
\] (4)
where $k$ is an integer. It is notable that, when $k$ equals 0, the above correlation function degenerates to that of the classic h-index. By checking the intersection of the line function $y = f_k(x)$ with the citation count curve, we can obtain the corresponding index component $h_k$. By varying the value of $k$, a multi-dimensional index vector $(\cdots, h_{-2}, h_{-1}, h_0, h_1, h_2, \cdots)$ is generated, as illustrated in Fig. 2. Each component $h_k > 0$ and $h_0$ is equal to the classic h-index value. With a larger $k$, the corresponding component $h_k$ considers articles with much higher citations.

Another perspective to interpret our scheme is the multi-scale representation of the descending citation curve. In the above discussion, we fix the citation curve $y = g(x)$ but change the correlations functions with varying values of $k$. Alternatively, we can also fix all the correlation function $y = f_k(x)$ as the identity function $f(x) = x$, but transform the citation curve $y = g(x)$ into multi-scale representations: $y = g_k(x) = 2^{-k}g(x)$. As a result, in the $k$-th scale, after the transformation of the citation curve, we can calculate the component $h_k$ as the classic h-index on the transformed citation curve. In this sense, we call our scheme as multi-scale (MS) h-index. We define two versions of multi-scale h-index. As the basic multi-scale h-index (MH-index), we impose that $k$ is non-negative, as illustrated in Fig. 2(a). Based on that, we extend it by keeping the full component vector with all possible $k$ and call it the extended multi-scale h-index abbreviated as MH(ext)-index, as illustrated in Fig. 2(b).

To generate a global number for convenient of evaluation and comparison, the multi-scale (MS) h-index is defined as follows,

$$MS = \sqrt{\sum_k w_k h_k},$$

where $w_k$ is a weighting constant to discriminate the component $h_k$ is different scale. Considering the above multi-scale formulation, $w_k$ is defined as $\alpha^k$, where $\alpha > 1$, to give more credit to more highly cited article. In our experiments, we set $\alpha = \sqrt{2}$.

![Figure 2. Schematic illustration of our proposed (a) multi-scale h-index and (b) the extended multi-scale h-index](image)

</tbody>
</table>
To illustrate the advantage of our proposed multi-scale h-index, we compare with h-index, iterative-weighted h-index (iw(h)-index) and EM-index on four synthetic examples in Table 1. Intuitively, the author with citation count C1 has less scientific impact than the author with C2. However, both h-index and iterative-weighted h-index get the same index values for both authors and fail to discriminate them. In contrast, our multi-scale h-index distinguish C1 from C2 with notable difference. On the other hand, it is obvious that the scientific impact of C1 is less than that of C3 but greater than that of C4. However, the EM-index assigns them with identical index values while our multi-scale h-index clearly differentiate them with the correct impact rank.

Experiments
To evaluate our proposed multi-scale h-index scheme, we collect the citation data of 82 scholars (Bihari and Tripathi 2017) in the scientometrics and bibliometrics fields from Google Scholar. The total citation counts of those scholars range from 390 to 128,909, while the publication article number varies from 27 to 598. This dataset contains scholars with both high productivity and high citation count, scholars with high productivity and less citation count, and scholars with average productivity and average citation count. The total publication and citation together with the h-index of the 82 authors are illustrated in Fig. 3.

![Figure 3. The total citation number, paper number and h-index of the studied 82 authors. The authors are sorted based on their MH-index scores in descending order. The data collection date from Google Scholar is April 26, 2017.](image_url)

We compare our proposed MH-index with h-index, iterative-weighted h-index, and EM-index. The results of each index scheme on the 82 scholars are listed in Table 2. In Table 3, we show the rank of the authors based on the index scores calculated with each methods. Our proposed MH-index provides a more fine-grained representation on the publication and citation records. Distinguished from h-index, multi-dimensional h-index and iteratively weighted h-index, our approach gives credit to those highly cited articles. On the other hand, our MH-index is different from EM-index in that, we calculate the significance index factor in a multi-scale paradigm and assigns more weight to the significance factor from articles of larger citations. The above properties make our MH-index produce more consistent and better ranking results on the scholar’s scientific impact. More case study results are discussed below.

For instance, for the scholars Linton C. Freeman and Stan Wasserman, their h-index values are 49 and 45, respectively, while their iw(h)-index values are 66.47 and 61.41, respectively. As a result, they are ranked to no. 23 and no. 29 by h-index, and no. 33 and no. 38 by iw(h)-index. In fact, compared with the top-ranking authors, the publication article number of Linton C. Freeman (109 articles) and Stan Wasserman (106 articles) is relatively few. However, both of them have quite a few very highly cited articles with remarkable total citation (35424 and...
Their top 1 citation counts are 27,680 and 11,329, respectively. Those extremely high citations are ignored by h-index and iteratively weighted h-index. In contrast, our MH-index makes a full consideration of this fact and rank them to no. 2 and no. 4, respectively. Another interesting example is Heidi Winklhofer, whose h-index is 22 but EM-index is 63.46. As a result, the scholar is ranked to as high as no. 9 by EM-index, which is unreasonable considering the relatively less publication article number (31) and total citation (6270). That is due to the fact that EM-index extremely favours the case like Heidi Winklhofer, whose top 1 citation is 4027 but the following one takes a cliff-like drop to 433. Our MH-index well address such cases and rank Heidi Winklhofer to no. 38.

Table 2. Comparative result of h-index, iteratively weighted h-index, EM-index, MH-index and the extended MH-index

Conclusion
In this paper, we propose a novel multi-scale h-index to measure the scientific impact of individual scholars. We mathematically formulate the index scheme from the perspective of correlation function to collaboratively investigate the publication and citation record. With a multi-scale paradigm, a multi-dimension index factor is generated, which is further summarized by adaptive weighting into a global index number. The proposed MH-index makes a fine-grained measure and gives adaptive credit based on the significance level of the publication article citation count. We evaluate our index scheme with comprehensive study on the real scholars and quantitatively demonstrate the advantage of the proposed MH-index over the comparison indices.

Abstract
There are many different relatedness measures, based for instance on citation relations or textual similarity, that can be used to cluster scientific publications. We propose a principled methodology for comparing relatedness measures and for evaluating the accuracy of clustering solutions resulting from these measures. Our empirical results, based on publications in the field of condensed matter physics, suggest that bibliographic coupling relations yield more accurate clustering solutions than direct citation relations and co-citation relations. The so-called extended direct citation approach is competitive with bibliographic coupling in terms of the accuracy of the resulting clustering solutions. Our results also suggest that BM25 yields more accurate clustering solutions than other text-based relatedness measures.

Conference topic
Citation and co-citation analysis; methods and techniques

Introduction
Clustering of scientific publications is an important bibliometric problem. Bibliometricians have employed many different clustering techniques (e.g., Gläser, Scharnhorst, & Glänzel, 2017). Moreover, they have also used various different relatedness measures to cluster publications. These relatedness measures are typically based on either citation relations (e.g., direct citation relations, bibliographic coupling relations, or co-citation relations) or textual similarity, or sometimes a combination of the two.

Which relatedness measure yields the most accurate clustering of publications? Two perspectives can be taken on this question. One perspective is that there is no absolute notion of accuracy (e.g., Gläser et al., 2017). Following this perspective, each relatedness measure yields clustering solutions that are accurate in their own right, and it is not meaningful to ask which clustering solutions are the overall most accurate ones. Different citation-based and text-based relatedness measures for instance each emphasize different aspects of the way in which publications relate to each other, and the corresponding clustering solutions each provide a legitimate viewpoint on the organization of the scientific literature. The other perspective is that for some purposes it is useful, and perhaps even necessary, to assume the existence of an absolute notion of accuracy. When this perspective is taken, it is possible, at least in principle, to say that some relatedness measures yield more accurate clustering solutions than others.

We believe that both perspectives are useful. From a purely conceptual point of view, the first perspective is probably the more satisfactory one. However, from a more applied point of
view, the second perspective is highly important. In many practical applications, users expect to be provided with a single clustering of publications. Users typically have some intuitive idea of accuracy and, based on this idea of accuracy, they expect the clustering provided to them to be as accurate as possible. In this paper, we take the applied viewpoint and we therefore focus on the second perspective.

Identifying the relatedness measure that yields the most accurate clustering of publications is challenging because of the lack of a ground truth. There is no perfect clustering of publications that can be used to evaluate the accuracy of different clustering solutions. As an alternative, the accuracy of clustering solutions can be evaluated by domain experts who assess the quality of different clustering solutions in a specific scientific domain (e.g., Šubelj, Van Eck, & Waltman, 2016). The difficulty of this approach is that it is hard to find a sufficiently large number of experts who are willing to spend a considerable amount of time to make a detailed assessment of the quality of different clustering solutions. Moreover, the knowledge of experts will often be restricted to relatively small domains, and it will be unclear to what extent the conclusions drawn by experts generalize to other domains.

In this paper, we take a large-scale data-driven approach to compare different relatedness measures based on which publications can be clustered. The basic idea is to cluster publications based on a number of different relatedness measures and to use another more or less independent relatedness measure to evaluate the accuracy of the clustering solutions. This approach has already been used extensively in a series of papers by Kevin Boyack, Dick Klavans, and colleagues. They compared different citation-based relatedness measures (Boyack & Klavans, 2010; Klavans & Boyack, 2017), including relatedness measures that take advantage of full-text data (Boyack, Small, & Klavans, 2013), as well as different text-based relatedness measures (Boyack et al., 2011). To evaluate the accuracy of clustering solutions, they used grant data and textual similarity (Boyack & Klavans, 2010; Boyack et al., 2011, 2013) and more recently also the reference lists of ‘authoritative’ publications, defined as publications with at least 100 references (Klavans & Boyack, 2017).

Our aim in this paper is to introduce a more principled methodology for performing analyses similar to the ones mentioned above. We restrict ourselves to the use of one specific clustering technique, namely the technique introduced in the bibliometric literature by Waltman and Van Eck (2012), but we allow the use of any measure of the relatedness of publications. For two relatedness measures $A$ and $B$, our proposed methodology offers a principled way to evaluate the accuracy of clustering solutions obtained using the two measures, where a third relatedness measure $C$ is used as the evaluation criterion.

**Methodology**

To introduce our methodology for evaluating the accuracy of clustering solutions obtained using different relatedness measures, we first discuss the quality function that we use to cluster publications. We then explain how we evaluate the accuracy of a clustering solution, and we analyze the consistency of our evaluation framework. Finally, we discuss the importance of using an independent evaluation criterion.

**Quality function for clustering publications**

Consider a set of $N$ publications. Let $r_{ij}^X \geq 0$ denote the relatedness of publications $i$ and $j$ (with $i = 1,\ldots,N$ and $j = 1,\ldots,N$) based on relatedness measure $X$, and let $c_i^X \in \{1,2,\ldots\}$ denote the cluster to which publication $i$ belongs when publications have been clustered based on relatedness measure $X$.

Publications are assigned to clusters by maximizing a quality function. We focus on the quality function of Waltman and Van Eck (2012). This quality function is given by
\[ Q = \sum_{i,j} I(c_i^X = c_j^X)(r_{ij}^X - \gamma), \]  

(1)

where \( I(c_i^X = c_j^X) \) equals 1 if \( c_i^X = c_j^X \) and 0 otherwise and where \( \gamma \geq 0 \) denotes a so-called resolution parameter. The higher the value of this parameter, the larger the number of clusters that will be obtained. Hence, the resolution parameter \( \gamma \) determines the granularity of the clustering.

The quality function in (1) can also be written as

\[ Q = \sum_{i,j} I(c_i^X = c_j^X)r_{ij}^X - \gamma \sum (s_k^X)^2, \]  

(2)

where \( s_k^X \) denotes the number of publications belonging to cluster \( k \), that is,

\[ s_k^X = \sum_i I(c_i^X = k). \]  

(3)

We also refer to \( s_k^X \) as the size of cluster \( k \).

In the network science literature, the above quality function was proposed by Traag, Van Dooren, and Nesterov (2011), who referred to it as the constant Potts model. The quality function is closely related to the well-known modularity function introduced by Newman and Girvan (2004) and Newman (2004), but it has the important advantage that it does not suffer from the so-called resolution limit problem (Fortunato & Barthélémy, 2007). Waltman and Van Eck (2012) introduced the above quality function in the bibliometric literature.

**Evaluating the accuracy of a clustering solution**

Suppose that we have three relatedness measures \( A, B, \) and \( C \), and suppose also that we have used relatedness measures \( A \) and \( B \) to cluster a set of publications. Furthermore, suppose that we want to use relatedness measure \( C \) to evaluate the accuracy of the clustering solutions obtained using relatedness measures \( A \) and \( B \). Let \( A^{X|C} \) denote the accuracy of a clustering solution obtained using relatedness measure \( X \) (with \( X = A \) or \( X = B \)), where the accuracy is evaluated using relatedness measure \( C \). We define \( A^{X|C} \) as

\[ A^{X|C} = \frac{1}{N} \sum_{i,j} I(c_i^X = c_j^X)r_{ij}^C. \]  

(4)

The clustering solution obtained using relatedness measure \( A \) is considered to be more accurate than the clustering solution obtained using relatedness measure \( B \) if \( A^{A|C} > A^{B|C} \), and the other way around.

The above approach for evaluating the accuracy of a clustering solution favors less granular solutions over more granular ones. Of all possible clustering solutions, the least granular solution is the one in which all publications belong to the same cluster. According to (4), this least granular clustering solution always has the highest possible accuracy. There can be no other clustering solution with a higher accuracy. In order to perform meaningful comparisons, (4) should be used only for comparing clustering solutions that have the same granularity.

How do we determine whether two clustering solutions have the same granularity? We could require that both clustering solutions have been obtained using the same value for the resolution parameter \( \gamma \). Alternatively, we could require that both clustering solutions consist of the same number of clusters. We do not take either of these approaches. Instead, we require that the sum of the squared cluster sizes is the same for two clustering solutions. In other words, two clustering solutions obtained using relatedness measures \( A \) and \( B \) have the same granularity if
\[ \sum_k (s_k^A)^2 = \sum_l (s_l^B)^2. \]  

(5)

If (5) is satisfied, (4) can be used to compare in an unbiased way the clustering solutions obtained using relatedness measures \( A \) and \( B \). On the other hand, if (5) is not satisfied, a comparison based on (4) will be biased in favor of the less granular clustering solution. In practice, obtaining two clustering solutions that satisfy (5) typically will not be trivial. For each of the two clustering solutions, it may require a significant amount of trial and error with different values of the resolution parameter \( \gamma \). In the end, it may turn out that (5) can be satisfied only approximately, not exactly. We will get back to this issue in the discussion of our empirical results.

Consistency of the evaluation framework

The choice of the accuracy measure defined in (4) and the granularity condition presented in (5) may seem quite arbitrary. However, provided that we use the quality function defined in (1), this choice has an important justification. When the accuracy of clustering solutions is evaluated using some relatedness measure \( X \), our choice of the accuracy measure in (4) and the granularity condition in (5) guarantees that of all possible clustering solutions of a certain granularity the solution obtained using relatedness measure \( X \) will be the most accurate one. In other words, it is guaranteed that \( A^X|X \geq A^Y|X \) for any relatedness measure \( Y \). This is a fundamental consistency property that we believe should be satisfied by any sound framework for evaluating the accuracy of clustering solutions obtained using different relatedness measures.

Suppose for instance that we have three clustering solutions, all of the same granularity, one solution obtained based on direct citation relations between publications, another one obtained based on bibliographic coupling relations, and a third one obtained based on co-citation relations. Suppose also that the accuracy of the clustering solutions is evaluated based on direct citation relations. It would then be a rather odd outcome if the clustering solution obtained based on bibliographic coupling or co-citation relations turned out to be more accurate than the solution obtained based on direct citation relations. In our evaluation framework, it is guaranteed that there can be no such inconsistent outcomes. When the accuracy of clustering solutions is evaluated based on direct citation relations, the clustering solution obtained based on direct citation relations will always be the most accurate one.

Independent evaluation criterion

As already mentioned, the approach that we take in this paper is to cluster publications based on a number of different relatedness measures and to use another more or less independent relatedness measure to evaluate the accuracy of the clustering solutions. More specifically, we use a text-based relatedness measure to evaluate the accuracy of different clustering solutions obtained using citation-based relatedness measures, and the other way around, we use a citation-based relatedness measure to evaluate the accuracy of different clustering solutions obtained using text-based relatedness measures.

Importantly, we do not evaluate citation-based clustering solutions using a citation-based relatedness measure or text-based clustering solutions using a text-based relatedness measure. Such evaluations do not provide much information, because the relatedness measure used for evaluation is not sufficiently independent from the relatedness measures being evaluated. For instance, when direct citation relations are used to evaluate the accuracy of different clustering solutions obtained using citation-based relatedness measures, the clustering solution obtained based on direct citation relations can be expected to be the most accurate one. We do not learn much from this. The evaluation simply shows that the clustering
solution obtained based on direct citation relations is best aligned with an evaluation criterion based on direct citation relations, which of course is not surprising at all. This illustrates the importance of using an independent evaluation criterion. The more the relatedness measure used for evaluation can be considered to be independent of the relatedness measures being evaluated, the more informative the evaluation will be.

**Relatedness measures**

We now discuss the relatedness measures that we consider in this paper. We first discuss relatedness measures based on citation relations, followed by relatedness measures based on textual similarity. We also discuss the idea of the so-called top M relatedness approach combined with the idea of normalized relatedness measures.

**Citation-based relatedness measures**

Below we discuss a number of citation-based approaches for determining the pairwise relatedness for a set of $N$ publications. We use $c_{ij}$ to indicate whether publication $i$ cites publication $j$ ($c_{ij} = 1$) or not ($c_{ij} = 0$). The relatedness of publications $i$ and $j$ based on direct citation relations is given by

$$r_{ij}^{DC} = c_{ij} + c_{ji}. \quad (6)$$

Hence, $r_{ij}^{DC} = 1$ if either publication $i$ cites publication $j$ or the other way around and $r_{ij}^{DC} = 0$ if neither publication cites the other.

The relatedness of publications $i$ and $j$ based on bibliographic coupling relations equals the number of common references in the two publications. This can be written as

$$r_{ij}^{BC} = \sum_k c_{ik} c_{jk}, \quad (7)$$

where the summation extends over all publications in the database that we use, not only over the $N$ publications for which we aim to determine their pairwise relatedness.

As is well known, co-citation can be seen as the opposite of bibliographic coupling. The relatedness of publications $i$ and $j$ based on co-citation relations equals the number of publications in which publications $i$ and $j$ are both cited. In mathematical terms,

$$r_{ij}^{CC} = \sum_k c_{ki} c_{kj}, \quad (8)$$

where the summation again extends over all publications in the database that we use.

The above approaches for determining the relatedness of publications may also be combined. This results in

$$r_{ij}^{DC-BC-CC} = \alpha r_{ij}^{DC} + r_{ij}^{BC} + r_{ij}^{CC}, \quad (9)$$

where $\alpha$ denotes a parameter that determines the weight of direct citation relations relative to bibliographic coupling and co-citation relations. A direct citation relation may be considered a stronger signal of the relatedness of two publications than a bibliographic coupling or co-citation relation (Waltman & Van Eck, 2012), and therefore one may want to give more weight to a direct citation relation than to the two other types of relations. This can be achieved by setting $\alpha$ to a value above 1.

In addition to the above citation-based approaches for determining the relatedness of publications, we also consider a so-called extended direct citation approach. Like the ordinary
direct citation approach, the extended direct citation approach takes into account only direct citation relations between publications. However, direct citation relations are considered not just within the set of $N$ focal publications but within an extended set of publications. In addition to the $N$ focal publications, the extended set of publications includes all publications in our database that have a direct citation relation with at least two focal publications. The technical details of the extended direct citation approach are somewhat complex. Because of space limitations, we do not discuss these details. We note that an approach similar to our extended direct citation approach was also used by Boyack and Klavans (2014) and Klavans and Boyack (2017).

**Text-based relatedness measures**

We consider two text-based approaches for determining the relatedness of publications. We use $o_{il}$ to denote the number of occurrences of term $l$ in publication $i$. To count the number of occurrences of a term in a publication, only the title and abstract of the publication are considered, not the full text. Part-of-speech tagging is applied to the title and abstract of the publication to identify nouns and adjectives. A term is defined as a sequence of nouns and adjectives, with the last word in the sequence being a noun. No distinction is made between singular and plural nouns, so *neural network* and *neural networks* are regarded as the same term. Furthermore, shorter terms embedded in longer terms are not counted. For instance, if a publication contains the term *artificial neural network*, this is counted as an occurrence of *artificial neural network* but not as an occurrence of *neural network* or *network*. Finally, no stop word list is used, so there are no terms that are excluded from being counted. A straightforward text-based measure of the relatedness of publications $i$ and $j$ is given by

$$ r_{ij}^{CT} = \sum_l \frac{o_{il}o_{jl}}{\left(\sum_k o_{kl}\right)^{\beta}}. \quad (10) $$

We refer to this as relatedness based on common terms. The denominator in (10) aims to reduce the influence of frequently occurring terms. The parameter $\beta$ in the denominator determines the extent to which the influence of these terms is reduced. If $\beta = 0$, no reduction in the influence of frequently occurring terms takes place. On the other hand, if $\beta = 1$, the influence of frequently occurring terms is strongly reduced, following a so-called fractional counting approach (Perianes-Rodriguez, Waltman, & Van Eck, 2016).

Boyack et al. (2011) identified BM25 as one of the most accurate text-based relatedness measures for clustering publications. We therefore also include BM25 in our analysis. BM25 originates from the field of information retrieval, where it is used to determine the relevance of a document for a search query (Sparck Jones, Walker, & Robertson, 2000a, 2000b). Following Boyack et al. (2011), we use BM25 as a text-based measure of the relatedness of publications. The BM25 relatedness measure is defined as

$$ r_{ij}^{BM25} = \sum_l I(o_{il} > 0) \text{IDF}_l \frac{o_{jl}(k_1+1)}{o_{jl+k_1}\left(1-b+bd\right)}, \quad (11) $$

where $I(o_{il} > 0)$ equals 1 if $o_{il} > 0$ and 0 otherwise and where $d_j$ and $\bar{d}$ denote, respectively, the length of publication $j$ and the average length of all $N$ publications. We define the length of a publication as the total number of occurrences of terms in the publication. This results in

$$ d_i = \sum_l o_{il} \quad \text{and} \quad \bar{d} = \frac{1}{N} \sum_i d_i. \quad (12) $$

IDF$_l$ in (11) denotes the inverse document frequency of term $l$, which we define as

$$ \text{IDF}_l = \log \left(\frac{N}{\# \text{of documents containing } l}\right), $$

where $\# \text{of documents containing } l$ is the number of publications containing term $l$. The constant $k_1$ is set to 1.2 and $b$ is set to 0.75. The length of a publication is defined as the total number of occurrences of terms in the publication.
\[
\text{IDF}_l = \log \frac{N - n_l + 0.5}{n_l + 0.5},
\]

where \( n_l \) denotes the number of publications in which term \( l \) occurs, that is,

\[
n_l = \sum_i I(o_{il} > 0).
\]

The BM25 relatedness measure in (11) depends on the parameters \( k_1 \) and \( b \). Following Boyack et al. (2011), we set these parameters to values of 2 and 0.75, respectively. We note that, unlike all other relatedness measures that we consider in this paper, the BM25 relatedness measure is not symmetrical. In other words, \( r_{ij}^{BM25} \) does not need to be equal to \( r_{ji}^{BM25} \).

**Top M relatedness approach and normalized relatedness measures**

Our interest focuses on large-scale clustering analyses that may involve hundreds of thousands or even millions of publications. These analyses impose significant challenges in terms of computing time and memory requirements. In particular, it may not be feasible in these analyses to store all non-zero relatedness values in a computer’s main memory.

To deal with this problem, we use the top \( M \) relatedness approach. This approach is quite similar to the idea of similarity filtering typically used by Kevin Boyack and Dick Klavans (e.g., Boyack & Klavans, 2010; Boyack et al., 2011). In the top \( M \) relatedness approach, only the top \( M \) strongest relations per publication are kept. The remaining relations are discarded.

We use \( \hat{r}_{ij}^X \) to denote the relatedness of publications \( i \) and \( j \) based on relatedness measure \( X \) after discarding relations that are not in the top \( M \) per publication. This means that \( \hat{r}_{ij}^X = r_{ij}^X \) if publication \( j \) is among the \( M \) publications that are most strongly related to publication \( i \) and that \( \hat{r}_{ij}^X = 0 \) otherwise. Relatedness of a publication with itself is ignored. Hence, \( \hat{r}_{ij}^X = 0 \) if \( i = j \). We note that even if \( r_{ij}^X \) is symmetrical, \( \hat{r}_{ij}^X \) does not need to be symmetrical.

In the analyses presented in this paper, we use a value of 20 for \( M \). We apply the top \( M \) relatedness approach to all our relatedness measures except for the measures based on direct citation relations. As pointed out by Waltman and Van Eck (2012), the use of direct citation relations has the advantage of requiring only a relatively limited amount of computer memory, and therefore there is no need to use the top \( M \) relatedness approach when working with direct citation relations. Applying the top \( M \) relatedness approach in the case of direct citation relations would also be problematic because all relations are equally strong, making it difficult to decide which relations to keep and which ones to discard. Hence, in the case of direct citation relations, we simply have \( \hat{r}_{ij}^{DC} = r_{ij}^{DC} \) for all publications \( i \) and \( j \).

We also normalize all relatedness measures. The normalized relatedness of publication \( i \) with publication \( j \) equals the relatedness of the publications divided by the total relatedness of publication \( i \) with all other publications. Hence, the relatedness of publication \( i \) with publication \( j \) based on relatedness measure \( X \) is given by

\[
\hat{r}_{ij}^X = \frac{\hat{r}_{ij}^X}{\sum_k \hat{r}_{ik}^X}.
\]

This normalization was also used by Waltman and Van Eck (2012). The idea of the normalization is that relatedness values of publications in different fields of science should be of the same order of magnitude, so that clusters in different fields will be of similar size. Without the normalization, citation-based relatedness values for instance can be expected to
be much higher in the life sciences than in the social sciences. In a clustering analysis that involves both publications in the life sciences and publications in the social sciences, this would result in life science clusters being systematically larger than social science clusters. The normalization in (15) can be used to correct for these kinds of differences between fields. All results presented in the next section are based on normalized relatedness measures.

Results
We start the discussion of the results of our analyses by explaining the data collection and the way in which publications were clustered. We then introduce the idea of granularity-accuracy plots. Next, we present a comparison of different citation-based relatedness measures that can be used to cluster publications. This is followed by a comparison of different text-based relatedness measures.

Data collection and clustering of publications
Data was collected from the Web of Science database. We used the in-house version of the Web of Science database available at the Centre for Science and Technology Studies at Leiden University. This version of the database includes the Science Citation Index Expanded, the Social Sciences Citation Index, and the Arts & Humanities Citation Index. Like in our earlier work (e.g., Klavans & Boyack, 2017; Waltman & Van Eck, 2012), our final interest is in clustering all publications available in the database that we use, without restricting ourselves to certain fields of science. However, to keep the analyses presented in this paper manageable, we did restrict ourselves to one specific field. We selected all publications of the document types article and review that appeared in the period 2007–2016 in journals belonging to the Web of Science subject category Physics, condensed matter. The number of selected publications is 272,935.

The citation-based and text-based relatedness measures discussed above were calculated for the selected publications. Two comments need to be made. First, in determining bibliographic coupling relations between publications, only common references to publications indexed in our database were considered. Common references to non-indexed publications (e.g., books, conference proceedings publications, and PhD theses) were not taken into account. Non-indexed publications were not considered in the extended direct citation approach either. Second, our database included a limited number of publications from 2017. These publications were not used in determining co-citation relations between publications. They also were not considered in the extended direct citation approach.

The selected publications were clustered based on each of our relatedness measures. Clustering was performed by maximizing the quality function presented in (1). To maximize the quality function, we used an iterative variant (Waltman & Van Eck, 2013) of the well-known Louvain algorithm (Blondel, Guillaume, Lambiotte, & Lefebvre, 2008). Five iterations of the algorithm were performed. In addition, to speed up the algorithm, we employed ideas similar to the pruning idea of Ozaki, Tezuka, and Inaba (2016) and the prioritization idea of Bae, Halperin, West, Rosvall, and Howe (2017). Our algorithm usually will not be able to find the global maximum of the quality function, but it can be expected to get close to the global maximum.

Different levels of granularity were considered. For each relatedness measure, we obtained ten clustering solutions, each of them for a different value of the resolution parameter $\gamma$. The following values of $\gamma$ were used: 0.00001, 0.00002, 0.00005, 0.0001, 0.0002, 0.0005, 0.001, 0.002, 0.005, and 0.01.
Granularity-accuracy plots

A difficulty of our evaluation framework is the requirement that the clustering solutions being compared have exactly the same granularity. This requirement, which is formalized in the condition in (5), is hard to meet in practice. Clustering solutions obtained using different relatedness measures but the same value of the resolution parameter $\gamma$ will approximately satisfy (5), but the condition normally will not be satisfied exactly.

To deal with this problem, we propose a graphical approach based on the idea of granularity-accuracy (GA) plots. Using a GA plot, relatedness measures can be compared despite differences in granularity between clustering solutions. The horizontal axis in a GA plot represents the granularity of a clustering solution. We define the granularity of a clustering solution obtained using relatedness measure $X$ as

$$\frac{N}{\sum_k (s_{X,k})^2}.$$  \hspace{1cm} (16)

We note that two clustering solutions that have the same granularity according to (16) indeed satisfy the condition in (5). The vertical axis in a GA plot represents the accuracy of a clustering solution as defined in (4). Clustering solutions are plotted in a GA plot based on their granularity and accuracy. Lines are drawn between clustering solutions obtained using the same relatedness measure but different values of the resolution parameter $\gamma$. In this paper, we use a logarithmic scale for both the horizontal and the vertical axis in a GA plot.

In the interpretation of a GA plot, one should be aware that for any relatedness measure an increase in granularity will always cause a decrease in accuracy. This is a mathematical necessity in our evaluation framework, and therefore it is not something that one should be concerned about. A GA plot can be interpreted by comparing the accuracy of different relatedness measures at a specific level of granularity. As explained above, clustering solutions obtained using different relatedness measures normally do not have exactly the same granularity. However, in a GA plot, lines are drawn between different clustering solutions obtained using the same relatedness measure, providing interpolations between these solutions. Based on such interpolations, the accuracy of different relatedness measures can be compared at a specific level of granularity. These comparisons can be performed at all levels of granularity. Sometimes different levels of granularity will yield inconsistent results, with for instance relatedness measure $A$ outperforming relatedness measure $B$ at one level of granularity and the opposite outcome at another level of granularity. In other cases, consistent results will be obtained at all levels of granularity. For instance, relatedness measure $C$ may consistently outperform relatedness measure $D$, regardless of the level of granularity.

In the next two subsections, GA plots will be used to compare different citation-based and text-based relatedness measures.

Comparison of citation-based relatedness measures

Figure 1 presents a GA plot for comparing the DC, BC, CC, DC-BC-CC, and EDC citation-based relatedness measures. In the case of the DC-BC-CC relatedness measure, two values of the parameter $\alpha$ are considered, $\alpha = 1$ and $\alpha = 5$. The BM25 text-based relatedness measure is used as the evaluation criterion. Results obtained when this relatedness measure is used to cluster publications are also included in the GA plot. These results provide an upper bound for the results that can be obtained using the citation-based relatedness measures. (Recall that the highest possible accuracy is obtained when publications are clustered based on the same relatedness measure that is also used as the evaluation criterion.)

To interpret the GA plot in Figure 1, it is important to have some understanding of the meaning of the different levels of granularity. When the granularity is around 0.001, a
clustering solution typically has about 500 significant clusters, defined as clusters that include at least ten publications. A granularity around 0.01 corresponds with a typical number of about 4,500 significant clusters. Finally, when the granularity is around 0.1, there typically are about 8,000 significant clusters. We emphasize that these statistics have a limited accuracy. The number of significant clusters depends quite strongly on the relatedness measure that is used.

Figure 1 shows that, when BM25 is used as the evaluation criterion, CC has the worst performance of all citation-based relatedness measures. This is not surprising. Uncited publications have no co-citation relations with other publications and therefore cannot be properly clustered. This is an important explanation of the bad performance of CC. The bad performance of CC is also in line with recent results of Klavans and Boyack (2017). DC outperforms CC but is outperformed by all other citation-based relatedness measures. The somewhat disappointing performance of DC is an important finding, especially given the increasing popularity of DC in recent years. BC, DC-BC-CC, and EDC all perform about equally well. DC-BC-CC and EDC seem to slightly outperform BC, but the difference is tiny. Likewise, there is hardly any difference between the parameter values $\alpha = 1$ and $\alpha = 5$ for DC-BC-CC. Our finding that BC and EDC perform about equally well differs from results of Klavans and Boyack, who found that an approach similar to EDC significantly outperforms BC. Our results are based on a more principled evaluation framework and a different evaluation criterion than the results of Klavans and Boyack, which explains why our findings are different from theirs.

Comparison of text-based relatedness measures

Figure 2 presents a GA plot for comparing the BM25 and CT text-based relatedness measures. In the case of the CT relatedness measure, three values of the parameter $\beta$ are considered, $\beta = 0.0$, $\beta = 0.5$, and $\beta = 1.0$. The DC-BC-CC citation-based relatedness measure (with $\alpha = 1$) is used as the evaluation criterion. Results obtained when this relatedness measure is used to cluster publications are also included in the GA plot. These results provide an upper bound for the results that can be obtained using the text-based relatedness measures.
The results presented in Figure 2 are quite clear. Using DC-BC-CC as the evaluation criterion, BM25 outperforms CT, regardless of the value of the parameter $\beta$. The good performance of BM25 is in agreement with the results of Boyack et al. (2011). By far the worst performance is obtained when CT is used with the parameter value $\beta = 0.0$. This confirms the importance of reducing the influence of frequently occurring terms.

Figure 2. GA plot for comparing text-based relatedness measures. The DC-BC-CC citation-based relatedness measure (with $\alpha = 1$) is used as the evaluation criterion.

Conclusions
The problem of clustering scientific publications involves significant conceptual and methodological challenges. In this paper, we have introduced a principled methodology for evaluating the accuracy of clustering solutions obtained using different relatedness measures. Our methodology can be applied to evaluate the accuracy of clustering solutions obtained using two relatedness measures $A$ and $B$, where a third relatedness measure $C$ is used as the evaluation criterion. Preferably, relatedness measure $C$ should be as independent as possible from relatedness measures $A$ and $B$. Relatedness measures $A$ and $B$ for instance may be citation-based relatedness measures, and relatedness measure $C$ may be a text-based relatedness measure (or the other way around).

The empirical results that we have presented are based on a large-scale analysis of publications in the field of condensed matter physics indexed in the Web of Science database. We have used our proposed methodology, complemented with a graphical approach based on so-called GA plots, to compare different citation-based relatedness measures that can be used to cluster publications. Using the BM25 text-based relatedness measure as the evaluation criterion, we have found that co-citation relations and direct citation relations yield less accurate clustering solutions than a number of other citation-based relatedness measures. Bibliographic coupling relations, possibly combined with direct citation relations and co-citation relations, can be used to obtain much more accurate clustering solutions. The accuracy of these clustering solutions is similar to the accuracy of clustering solutions obtained using the so-called extended direct citation approach. The other way around, we have compared different text-based relatedness measures using a citation-based relatedness measure (obtained by combining direct citation relations, bibliographic coupling relations, and co-citation relations) as the evaluation criterion. BM25 has turned out to yield more accurate clustering solutions than the other text-based relatedness measures that we have studied.

Abstract
Diversity indicators have recently taken into account the similarity between classes. Among those new indicators, the Leinster-Cobbold diversity measure is the most promising. However, two issues remain with this indicator: the use of a free sensitivity parameter that must be arbitrarily set depending on the studied system, and the absence of a standard for a classification and class similarities. This paper proposes a new reference-based diversity indicator to measure the interdisciplinarity of research papers that aims at solving these two issues, based on the expansion of the Gini coefficient to take class similarity into account. Since it contains no free parameter, our indicator can be used to compare different systems. In addition, our indicator provides a framework for the quantitative measurement of the quality of a classification.

Conference Topic
Indicators

Introduction
Since the publication of Gibbons et al. (1994) seminal book, interdisciplinary has been on the science policy agenda of several governments, research councils and universities. Indeed, many of these believe that, by combining the knowledge and methodologies of more than one discipline, greater scientific advances can be obtained (Frodeman, Klein, & Dos Santos Pacheco, 2017; Wagner et al., 2011). In this context, several bibliometric indicators have been developed to measure the extent to which a given body of research is interdisciplinary. However, the construction of appropriate indicators of interdisciplinarity—which can be considered as indicators of diversity—is a fair challenge, as exemplified by the several advanced indicators developed over the last decade (e.g. Stirling, 2007; Wang, Thijs & Glänzel, 2015; Yegros-Yegros, Rafols & D’Este, 2015; Mugabushaka, Kyriakou & Papazoglou, 2016; Zhang, Rousseau & Glänzel, 2016). Even the most advanced interdisciplinarity indicators—such as the Leinster-Cobbold and the Rao-Stirling—suffer from two main problems: the presence of free parameters, and the lack of standards for defining classes. This paper proposes a new interdisciplinary indicator which aims at correcting these two issues. It first describes the issue with existing indicators, and then presents of our new indicator, based on the expansion of the Gini coefficient, in which those issues are addressed.

Background
In its broadest sense, a diversity indicator is applied to an element, which is normally a set of different classes. Most diversity indicators were developed in disciplines such as biology and economics (Stirling, 2007). For example, an application of a diversity indicator would be if the element is a set of animals, and the classes are the animals’ species. Figure 1 shows an example
of an element, which could be represented as the set \( x = \{ \text{Class A} = 40 \%, \text{Class B} = 40 \%, \text{Class C} = 20 \% \} \), or \( x = \left[ \frac{2}{5}, \frac{2}{5}, \frac{1}{5} \right] \) for simplicity.

![Diagram of an element as a set of classes.]

Figure 1. Representation of an element as a set of classes.

In bibliometrics, the element is typically an article, or a set of articles, and classes are typically disciplines. The diversity of an element can then be calculated based on the bibliographic references, with each of the references belonging to one or multiple classes (or disciplines). Figure 2 shows, as an example, an article with five references: two in mathematics, two in chemistry, and one in physics.

![Diagram of an article as an element where the references’ domains are used as the studied set of classes.]

Figure 2. Representation of an article as an element where the references’ domains are used as the studied set of classes.

Once classes have been defined\(^1\), multiple properties can be taken into account for measuring the diversity of elements. As discussed by Stirling (2007), the three main properties are 1) the number of classes in the element (variety), 2) the evenness of the class distribution within the element (balance), and 3) the similarity between the classes (disparity). While considering these properties distinctively is crucial to understand the complex diversity of a single system, combining them in a single indicator is useful to compare different systems and correlate diversity to other variables on a larger scale.

While an abundance of diversity indicators that take into account only the balance (e.g., Simpson diversity, Shannon entropy and Gini coefficient) have been developed over the past decades, other indicators (e.g., Rao-Stirling diversity) have integrated disparity (Stirling, 2007). Among those new indicators, the Leinster-Cobbold measure of diversity (Leinster, & Cobbold, 2012) is one of the most promising, as it incorporates the three main properties: variety, balance and disparity. The Leinster-Cobbold formula is as follows:

\[^{1}\text{It is worth mentioning here that the notion of disciplines as classes can be problematic, since several disciplinary classifications cohabit in the literature, and ad-hoc definition of classes could in principle be just as valid as any other (Rafols, 2014).}\]
where $s_{ij}$ is the similarity between class $i$ and class $j$. It is through this similarity matrix that disparity is incorporated in the indicator. The strength of the Leinster-Cobbold indicator is that almost all relevant measures are derived from the sensitivity parameter $q$. However, because different values of $q$ provide significantly different results, and the ideal value of $q$ depends on the effect one wants to measure. For example, cases with a large number of rare classes require a higher value of $q$ to capture the effect of the transfer from one class to another. This creates a problem when we want to easily compare the diversity between systems from different regimes. This problem is made worse when we compare the diversity of a very large number of systems, like scientific articles. For this purpose, we need a new indicator that possesses the properties and advantages of the Leinster-Cobbold indicator without having to rely on a free parameter which optimal value depends on the studied system.

Any diversity indicator must satisfy two essential properties. First, the effective number property states that the diversity of a community of $N$ equally abundant, totally dissimilar classes must be $N$. The second essential property is Dalton’s transfer principle, which states that transferring unit abundance from a small class to a larger one should decrease diversity (Jost, 2009). The Leinster-Cobbold indicator does not respect Dalton’s transfer principle for every possible value of the similarity matrix $s_{ij}$. For some values of $s_{ij}$, adding a new class might decrease diversity. The new indicator we propose here adds a linear component to Dalton’s transfer principle, so that transferring a unit abundance from a small class to a larger one should decrease diversity linearly. Therefore, our indicator has no free parameter (e.g., the $q$ parameter in Leinster-Cobbold), which facilitates comparison between systems from different regimes. While the Gini coefficient (Gini 1997) already offers a linear behaviour when transferring units, it only measures the variety and balance of perfectly distinct classes, and therefore does not consider the similarity between classes (i.e., disparity), which makes the indicator weaker than Leinster-Cobbold. The proposed indicator is in fact an expansion of the Gini coefficient to include similarity.

The expansion of the Gini coefficient

The first step of the indicator is to renormalize the Gini coefficient so that it respects the effective number property. In other words, the Gini coefficient has a value between 0 and 1, while the renormalized coefficient should have a value between 1 and $N$. Let us consider a set of $N$ classes where $x_i$ is the share of elements of class $i$ in the set. For example, the values of $x_i$ for the case in Figure 1 would be $x_1 = 0.4, x_2 = 0.4$ and $x_3 = 0.2$. A renormalized Gini coefficient can be expressed as an ordered sum over all classes as shown in Equation (2).

$$
(2) \quad \sum_{i=1}^{N} (x_i - x_{i+1})^2 \quad \text{where } x_i > x_{i+1} \text{ and } x_i = 0 \text{ if } i > N
$$

One can see that Equation (2) satisfies both the effective number property and the linear version of Dalton’s transfer principle. Furthermore, its main advantage is that it can be interpreted as a linear combination of sets of equally abundant classes. In our example case, we express the Gini coefficient in terms of the diversity of a case where $x_1 = 0.5$ and $x_2 = 0.5$, and another
where \( x_1 = 0.33, \ x_2 = 0.33 \) and \( x_3 = 0.33 \). Indeed, assuming that the equally abundant set of the most frequent \( i \) classes has a diversity of \( D_i \), Equation (2) can be rewritten as:

\[
(3) \quad \sum_{i=1}^{N} i(x_i - x_{i+1})D_i
\]

In the case of totally dissimilar classes, \( D_i = i \) because of the effective number property, and we reobtain Equation (2). However, by changing this definition of \( D_i \) in Equation (3), we can obtain a version of the Gini coefficient that takes into account the similarity between classes. We can therefore attribute a value \( D_i \) for sets of equally abundant but not totally dissimilar classes, and our indicator can correct for disparity while considering the evenness of the distribution linearly. Here, the value of \( D_i \) will be defined by citations between classes. We consider the following hypothesis for \( D_i \): the proportion of all the references to a class \( A \) in articles of a class \( B \) are considered redundant information if class \( A \) was already considered in our set.

Let us consider a specific case. Because of the effective number property, we know that a set only comprised of class \( A \) must have a diversity of 1. If 10% of class \( B \) refers to class \( A \), then a set comprised equally of class \( A \) and class \( B \) should have a diversity of \( 1 + 1*(100\% - 10\%) = 1.9 \). However, for the process to be symmetrical, we also consider the references to class \( B \) in articles of class \( A \), and average the two values. Therefore, for \( i = 2 \) classes, the diversity \( D_i \) is equal to:

\[
(4) \quad D_{i=2} = 2 - \frac{1}{2} (r(A, B) + r(B, A))
\]

where \( r(A, B) \) is the proportion of the references of class \( A \) citing articles of class \( B \) and vice versa. If we consider more than two classes, we need to consider the average over all the possible combinations of classes, and the general formula becomes:

\[
(5) \quad D_i = N - \frac{1}{2} \sum_{j \neq k} r(j, k)
\]

where \( r(j, k) \) is the proportion of the references to class \( k \) in articles of class \( j \). Equation (6) shows that this can be expressed as the sum of all elements of a matrix if the diagonal elements are equal to 1 instead of the self-references of a class \( r(i, i) \). This apparent discontinuity is due to the effective number property that forces the diversity of a single class to be equal to 1.

\[
(6) \quad D_i = \sum_{j,k} M_{jk}
\]

\[
M_{jj} = 1
\]

\[
M_{jk} = -\frac{1}{2} r(j, k) \quad \text{if} \ j \neq k
\]

One should note that this formula does not respect Dalton’s transfer principle for all values of \( M_{jk} \). Indeed, a consequence of that principle is that adding a new class to an element should never decrease diversity. For example, if we consider the following \( M \):

\[
(7) \quad M = \begin{bmatrix}
1 & 0 & -\frac{1}{2} \\
0 & 1 & -\frac{1}{2} \\
-\frac{1}{4} & -\frac{1}{4} & 1
\end{bmatrix}
\]
We note a decrease in diversity from $D = 2$ for $x = [1 \, 1 \, 2]$ to $D = 1.5$ for $x = [1 \, 1 \, 3]$. This should not be too surprising since even the Leinster-Cobbold formula does not respect Dalton’s transfer principle for all values of the similarity matrix. Moreover, our indicator does not satisfy the Dalton’s transfer principle only in extreme cases where the sum of the relative references to a single class is greater than 1. The simple way to correct the formula is by modifying the diagonal of the matrix $M$ in the following way:

\[
M_{jj} = \max \left\{ 1, \sum_{k \neq j} r(k, j) \right\} = \omega_j
\]

This weight factor $\omega_j$ allows the indicator to respect Dalton’s transfer principle for all cases, and is justified by the fact that it corrects an inadequate classification. We consider that references from one class to another indicate their similarity and that those other classes have an intrinsic diversity value of 1 according to the effective number principle. Therefore, if the sum of references to a single class is greater than 1, then this class has technically been recognized by the other classes as too large and should theoretically be split in subclasses. Thus, even if this weight factor implies that the effective number principle is not satisfied, we can indirectly satisfy it by interpreting all the classes where $\omega_j$ is greater than 1 as a group of subclasses with a weight factor equal to 1.

We should note here that the absence of a recognized standard disciplinary classification creates a lot of possible choices defining classes (e.g., WoS subject categories, NSF journal classification, institutions, journals, etc.). Defining classes raises the question of the equilibrium between the number of classes and their similarity: is it better to have a large number similar classes, or a smaller number of dissimilar classes? We can solve this problem since we now have a quantitative bibliometric measure for the quality of a classification. A high number of classes provides a higher resolution of interdisciplinarity, which would increase the granularity of our indicator. Indeed, since all articles in the same class are considered to have the same characteristics, increasing the number of classes allows us to better account for differences between articles. However, classes should reflect reality regarding the effective number property, and we should therefore aim for all classes to have a value of $\omega_j = 1$. Since we already have multiple existing classifications to choose from, then a look at the average of $\omega_j$ can help us determine which one is the best. Therefore, to make our indicator as fine-grained as possible, we need a classification with the lowest average value of $\omega_j$ but the highest number of classes.

**Discussion and conclusion**

We developed a new indicator to measure the interdisciplinarity of an article or a group of articles based on the set of their references. It is an expansion of the Gini coefficient that takes into account the similarity between classes. Assuming the relative distribution of $n$ classes:

\[
\begin{bmatrix}
x_1 & x_2 & \ldots & x_n
\end{bmatrix}
\]

where $\sum_{i=1}^{N} x_i = 1$ and $x_i = 0$ if $i > N$

the diversity $D$ of our distribution is given by

\[
D = \sum_{i=1}^{N} i(x_i - x_{i+1}) \sum_{j=1, k=1}^{N} M_{jk}
\]

\[
M_{jk} = -\frac{1}{2} r(j, k) \quad \text{if } j \neq k
\]

\[
M_{jj} = \max \left\{ 1, \sum_{k=1, k \neq j} r(k, j) \right\} = \omega_j
\]
where $r(j,k)$ is the proportion of the references of class $j$ that cites articles of class $k$.

This formula offers a clear quantitative measure of the concept of diversity, defined as how a given element links—in this case, through references—classes that are not themselves strongly linked. Therefore, it is important that the measured element be independent from the process that establishes the similarity of the classes. Our diversity indicator is thus best suited for evaluating the diversity of a single article, or the articles of an author, an institution or a country. It possesses the inclusion of similarity effects of previous indicators such as the Leinster-Cobbold without relying on a free parameter, and provides a quantitative measure of the quality of a classification to establish a standard in that regard, while still satisfying all the essential properties of diversity indicators.

Further research will aim at comparing our new indicator with existing ones on empirical samples, reanalyzing patterns of interdisciplinarity as measured by our expanded Gini coefficient, and correlating its results with indicators of productivity, scholarly impact, or collaboration.

Abstract
The purpose of this study is to reveal the differences both in research output and research preferences of the G20 countries. The research outputs of the nineteen G20 countries (excluding the European Union) are measured based on their publications indexed in Web of Science Core Collection. The research preferences of the G20 countries were investigated by comparing their research output in each research subject. Clustering method was then employed to classify the countries according to their research preferences. Nineteen countries are classified into four clusters. Countries assigned in same cluster are similar in distribution of research subjects. In the end, by VOSviewer, we showed research pattern of each cluster. For example, USA in Cluster A is characterized by the emphasis on the medical sciences; while China in Cluster C is characterized by paying more attention to physical sciences.

Conference Topic
Country-level studies

Introduction
The G20 is initially an international economic cooperation forum established on 1999. After almost twenty-year development, the G20 has become a major platform for international affairs and has played an increasingly important role in all kinds of global issues, including scientific research (Callaghan, Ghate, Pickford, & Rathinam, 2014). The G20 countries account for about 60% of the world's land area, 66.7% of the world population, and more than 90% of the sum of Gross Domestic Product. They are also the dominated producers of scientific research output, and served as the major engines to drive further development in science and technology.

However, the driving effects of the G20 countries vary sharply, both in their strength and their preferential research areas. Yang et al (2012) studied the research preference of the G7 countries, and found that life sciences are the main focuses of these developed country. Bouabid et al (2016) addressed the issue of the scientific collaboration between the G7 countries, theirs research showed that the G7 countries had intensive intra-collaboration activities. Thomson Reuters (now named Clarivate Analytics) investigated the research and innovation performance of the G20 in a report in 2014 (Thomson Reuters, 2014), and list the amount and world share of each G20 country’s publications in the select OECD research fields. Hu et al (2017) explored research preferences of the provinces of China by the method of cosine similarity and hierarchical clustering, and mapped different province’s research hotspots using VOSviewer (Hu, Guo, & Hou, 2017). Almeida et al (2009) performed an analysis on the way how the European countries are clustered according to their similarity (Almeida, Pais, & Formosinho, 2009).
In this research, we systematically examined research output and preference of the G20 countries. The following questions will be addressed below: (a) how great is the differences among the G20 countries in their research output? (b) what is the research preference for each country? (c) which countries have the similar/different research preferences? (d) does a country’s economic level have influence on its research preferences?

Data and methods

Data collection

The G20 countries’ publications were retrieved in Web of Science™, one of the world’s most comprehensive bibliometrics database. WoS Core Collection is consisted of three core journal databases, namely Science Citation Index (SCI), Social Sciences Citation Index (SSCI), and Arts & Humanities Citation Index (A&HCI). Together they cover more than 10,000 journals of the research subjects of natural sciences, social sciences and humanities. WoS Core Collection also integrated two important conference databases, CPCI-S and CPCI-SSH. All these journals and proceeding books are assigned into one or more research subjects, such as Engineering Electrical Electronic, Materials Science, Oncology, etc. In WoS, we retrieved the amount of publications of the G20 countries for each research subject in 2015. To exclude non-research articles, only Article, Proceedings Paper and Review are included, and all the other data type, such as Letter, Note, and Edictal Martial are ignored. It also should be noted that the WoS subject categories overlap in coverage and therefore some publications have been double counted.

Similarity Measurement between G20 countries

Two countries are similar in research preference if their cosine distance is close(Singhal, 2001). Since this study is intended to compare the research preference instead of absolute research output, the cosine distance is more appropriate than Euclidean distance. After calculating the similarity of the G20 countries, we further classified them into four clusters using the method of hierarchical clustering. Hierarchical clustering shows not only the result of clustering but also the clustering process through a tree diagram. The most similar two countries are merged firstly. The process continues until all nineteen countries are merged(B & Suzuki, 2015).

Research Hotspot of the G20 countries

To illustrate research preference vividly, we draw research hotspots for several typical countries using the visualization technology in the end. VOSviewer, a software tool developed by Van Eck and Waltman for constructing bibliometrics networks (Eck & Waltman, 2013, 2014; Hu et al., 2017; van Eck & Waltman, 2010), is employed in this research. Figure 1 is the global map of research subjects, which provides a foundational research hotspot in the world today. This map is derived from the official website of VOSviewer. In this map, all the Web of Science’ research subjects are located based on their citation relations to each other. Five research fields are clustered and assigned with distinguished colours. They are the field of Social Sciences and Humanities in red, the field of Health Sciences in green, the field of Life Sciences in yellow, the field of Physical Sciences and Engineering in blue, and the field of Mathematics and Computational Sciences in purple. Of particular note is that Health Sciences and Life Sciences are allied research fields overlapping with each other. Health Sciences mainly refer to the subjects related with medicine, nursing and pharmaceutical science; while Life Sciences mainly refer to agricultural and environmental sciences.
Based on the research map, we generated network maps for different G20 countries by keeping the layout of map constant. The size of each node was redrew according to the amount of publications of and the country in the corresponding research subject. The research network is able to show the relatedness of nodes and the weight of the item in the network. The VOSviewer maker notes that for some items the label may not be visible. This is done in order to avoid overlapping labels (Eck & Waltman, 2013).

Cluster analysis of the G20 countries

Research output of the G20 countries

The publication amount of the G20 countries in 2015 is listed in Table 1. The United States, not surprisingly, ranks first with about 0.45 million publications. China ranks second with about 0.36 million publications. They are the undisputed leaders in research output, far beyond anyone else in the G20 countries. The sum of publications from the third ranked UK, the fourth ranked Germany and the fifth ranked Japan are still less than China’s research output, let alone the US. Obviously, the G20 countries vary greatly in terms of counts of publications. The research output of the US is almost 81 times that of Indonesia, the least producer in the G20.

Generally, a country's scientific research output is proportional to its economic level. The USA and China, which produced the most research publication, are also the bigger economic powers. UK, German and Japan contribute the third to fifth research publications, their GDP are also ranked from the third to fifth, just in reversed order. France, India and Canada ranks the sixth to eighth both in research publications and GDP. The top 13 research producers are exactly the same with the richest countries, only in somehow different sequence.

The scatter plot chart in Figure 2 shows the correlation between the research output and the GDP of the G20 countries. For each country, coordinate X represents its GDP in 2015, and Y represents its publication count. It shows that a country’s GDP is significantly \((R^2=0.9517)\) correlated with its research output.

![Fig. 2 The relationship between GDP and the amount of publications (2015)](image)

Publications of research subjects

In Table 2, the publication amounts of 252 research subject are listed. “Engineering Electrical Electronic” is the largest subjects. It involved 163,833 publications, and was 68.7% higher than the second-placed “Materials Science Multidisciplinary”. The subjects of “Physics Applied”, “Chemistry Multidisciplinary” and “Chemistry Physical” rank third to fifth respectively. The top 5 research subjects contributed more than 1/4 of all publications. Correspondingly, the publications in the subjects of “Literature African Australian Canadian” and “Poetry”, are only less than 200, merely account for 0.0008%.

Table 2 Publications of Research subjects in Web of Science (2015)
Research preferences of the G20 countries

By listing top research subjects of each G20 country, we uncovered the research preferences in Table 3. In 2015, the USA researchers published the most publications in the subjects of “Engineering Electrical Electronic”, “Multidisciplinary Sciences”, “Materials Science Multidisciplinary”, “Biochemistry Molecular Biology” and “Neurosciences”. Chinese researchers did well in the subjects of “Engineering Electrical Electronic”, “Materials Science Multidisciplinary”, “Chemistry Multidisciplinary”, “Physics Applied” and “Chemistry Physical”. Compared with the USA and China, UK paid more attention to “Astronomy Astrophysics”, and Indonesian preferred published more papers in the subject of “Computer Science Information Systems”, “Computer Science Theory Methods” and “Telecommunications”.

The similarity of the G20 countries in research preferences

The cosine distances between each two countries were calculated based on the data in Table 3. As it shown in Table 4, the resulting adjacency matrix represents the level of similarity between every two countries. For example, the cosine similarity between Australia and China is 0.7991; while that between Australia and France is 0.8906. It means Australia is more similar with France than China in the distribution of research subjects.

Table 5 lists the country pairs with the most and the least similarity. France and Germany, two adjacent countries located in the Western Europe, are closest in the vector space of research subjects. Their similarity is 0.9797. This similarity between them also show in Almeida's research (Almeida et al., 2009). The next closest countries pairs are between UK and USA, both important developed countries in the word with similar economic status and structure. The third pairs are Canada and USA. Although the absolute count of publications varies a lot between Canada and USA, both of them have a homogeneous disciplinary structure and research preferences. The most dissimilar countries pairs are Argentina and Indonesia. Their similarity is only 0.5005.

Cluster analysis of the G20 countries

The dendrogram of the cluster analysis is shown in Fig. 3. This is a pictorial representation of the data structure, indicating the merging objects and the merging distances.

Cluster A is composed of eight countries: France, Germany, Italy, USA, UK, Canada, Australia and Turkey. Besides Turkey, all the others are all developed countries and located in Europe and North America.

Cluster B is composed of four countries: Brazil, Mexico, Argentina and South Africa. They are all former European colonies, located in either Latin America or Africa.
Cluster C consists of six countries: Japan, South Korea, China, Saudi Arabia, India, and Russia. These six countries are mainly Asian countries, with different cultures and languages from the West.

Cluster D contains only one country, namely, Indonesia, the smallest research producer in the G20. Indonesia is famous for its superior natural conditions and abundant marine resources. It contains more than seventeen thousand islands. The electronics industry is Indonesia’s most important engine of economic development.

At a highest level, the eleven countries in Clusters A and B merged into Group I; while the other seven countries in Cluster C and D merged into Group II. Group I is composed of developed countries mainly from the West. Compared with those in Group I, the countries in Group II are almost located in Asia, and most of them are developing countries.

Although economic level has a significance effect on discipline structure and subject development, geographical locations might have a greater influence on research preferences. For example, Japan and South Korea, two developed countries, both belong to Group II instead of Group I.

Research mapping of the clusters

Each cluster is featured by its unique research preference. In the following section, we selected one typical country of each cluster. They are the USA in Cluster A, Brazil in Cluster B, China in Cluster C, and Indonesia in Cluster D. We will map their research hotspots using VOSviewer.

a. Research map of the USA

The research map of the USA is shown in Figure 4. Health Sciences is the hottest field in the USA. Specifically, the researchers of the USA focus on the subjects of “Biochemistry Molecular Biology”, “Neurosciences”, “Oncology”, “Public Environmental Occupational Health” and “Surgery”, “Cell Biology”, etc.

Another field preferred by the USA are Physical Sciences and Engineering. In this field, “Materials Science Multidisciplinary”, “Physics Applied”, “Chemistry Physical”, “Chemistry Multidisciplinary” and “Optics” are the most dominant subjects. Besides, the USA also an
important producer of the research papers in the subject of “Engineering Electrical Electronic” and other subjects in the field of Computational Sciences.

Compared with the countries in other clusters, the USA also contribute a lot in the field of Social Sciences and Humanities, in which field the most primary subjects are “Psychiatry”, “Economics”, “Education Educational Research”, “Psychology Clinical”, etc. The USA is less productive in the field of Life Sciences, which is mainly involved with Agriculture sciences and Environmental Sciences.

The USA shows a typical research maps for North American and European countries, which was called “Western Model” by a report published in 1997 (REIST-2, 1997). In this report, “Western Model” is defined by focusing on the research in clinical medicine and biomedical sciences.

b. Research map of Brazil

Brazil is featured by its advantage in the field of Life Sciences. Brazil mainly focus on the subjects of “Plant Sciences”, “Agronomy”, “Food Science Technology”, “Environmental Sciences” and “Agriculture Multidisciplinary”. Abundant natural resources and agricultural production provide an essential necessity and condition for Brazil and other countries in Cluster B.

Health Sciences is also a preferential research field of Brazil. In this field, the subjects of “Biochemistry Molecular Biology”, “Public Environmental Occupational Health”, “Pharmacology Pharmacy”, “Dentistry Oral Surgery Medicine”, “Neurosciences” are the most primary subjects.

In the research fields of Physical Sciences and Engineering or Mathematics and Computational Sciences, Brazil also had good performance. But The Brazilian researchers seemingly pay less attention to Social Sciences and Humanities, in which field an only primary subject of the Brazil is Psychiatry.
The Brazil’s research map is in accordance with the result of the report (REIST-2, 1997). As we find, Brazil is still following the “Bio-Environmental Model” with Biology, Earth and Space sciences in the main focus. The finding is also confirmed by a study of GLÄNZEL (GLÄNZEL, LETA, & THIJS, 2006).

c. Research map of China

China is the typical developing country. Chinese researchers have been more active in the field of Physical Sciences and Engineering, as well as Mathematics and Computational Sciences. The emphasizing on physical sciences is also stated by previous research (Fu, Chuang, Wang, & Ho, 2011). In comparison, Health sciences and Life sciences are not so preferential in China as the USA and Brazil.

“Materials Science Multidisciplinary”, “Chemistry Multidisciplinary” and “Physics Applied”, in the field of Physical Sciences, “Engineering Electrical Electronic”, “Computer Science Theory Methods” and “Automation Control Systems” in the field of Mathematics and Computational Sciences are the most productive subjects in China.

In the field of Health Sciences, China focuses on the subjects of “Oncology”, “Biochemistry Molecular Biology” and “Medicine Research Experimental”. In the field of Life Sciences, “Plant Sciences”, “Agronomy”, “Food Science Technology” are the most preferential subjects. China’ mainly concerned with the subjects of “Social Sciences Interdisciplinary”, “Education Educational Research” and “Folklore” in the field of Social Sciences and Humanities.

The heavy emphasis on classical sciences (chemistry, physics, engineering etc) in China was similar three decades ago. Although China has increased investment in and policy support for emerging industries of strategic importance, such as biotechnology and pharmaceutics, their development are currently facing key issues such as lack of innovation of the driving force and endogenous growth fatigue.
d. Research map of Indonesia

The field of Physical Sciences and Engineering is another important research fields for Indonesia, “Physics Applied”, “Materials Science Multidisciplinary” and “Energy Fuels” are the most dominant subjects.

Indonesia also focused on the field of Social Sciences Interdisciplinary, such as “Social Sciences Interdisciplinary”, “Business”, “Management”, “Education Educational Research”, etc. Compared with Health Sciences, Indonesia prefers to conduct research in the field of Life Sciences.

In the end, we drew radar charts for each country above, and reveal the difference in their research maps, as shown in Figure 8. By comparing the shape of radar charts, we are able to
distinguish the research spotlights of each country or cluster more clearly. The different clusters’ different characteristics in research preferences could be identified obviously.

Conclusions
We compared the research performances of the nineteen G20 countries in this research. As we found, different countries vary greatly not only in research outputs, but also in research preferences. The research publications of the USA could be 80 times as that of Indonesia. The difference in terms of research preferences is as well. By clustering method, the nineteen G20 countries are classified into four clusters firstly and then two groups at a higher level. Each cluster is featured with a particular research preference. For example, the countries in Cluster A, e.g., the USA, prefer the research area of Health Sciences; while those in Cluster C, e.g., China, put a greater emphasis on the research area of Physical Sciences and Engineering. The research also found that there is significant correlation between a national research performance and its economic level or geographic location. If some countries have similar economic levels or their locations are close to each other, their research preferences tend to be similar. The developed countries conduct more research in the biology and medical sciences; while the developing countries’ emphasises go to physical sciences and computer sciences. Using VOSviewer and Radar Charts, we provide research maps of four typical countries in each cluster. It allows us compare research preferences of different clusters more intuitively.

Acknowledgments
The research was supported by the Natural Science Foundation of China (NSFC) under Grant 71503031 and China Postdoctoral Science Foundation under Grant 2016M591435.

Abstract
This study investigates the interdisciplinary relations of nanotechnology (Nano), biotechnology (Bio), information technology (Info), and cognitive science (Cogno) (together known as NBIC converging technologies) at the science level using a range of different bibliometric techniques and measures. The study applied journal citation, author citation, keyword analysis, and authorship analysis on all Iranian NBIC international articles (2001-2015). Spanning tree, inclusion index, import and export of concepts, and inward and outward interactions were used to measure the interdisciplinary relations. The results showed that Bio and Nano had the highest level of interdisciplinary relations in terms of journal citations, shared keywords, and the exchange of authorship. On the other hand, Cogno had no journal citation relation with Bio, and it had very low exchange of concepts with Bio. Cogno also had the weakest link to Nano in terms of authorship as well as author citations. The study suggests using a combination of techniques and measures for the study of interdisciplinarity and convergence.

Conference Topic
Science communication; Participation in science

Introduction
Interdisciplinary relations are interactions between two or more disciplines. These interactions could be as simple as the exchange of ideas or as complex as mutual integration of methods, terminologies, data and epistemology of disciplines. Interdisciplinary relations play an important role in the progress of science and the study of interdisciplinary relations has gained a great deal of importance in recent years. In the bibliometric tradition, interdisciplinarity has remained a difficult issue despite its high policy-relevance (Wagner et al., 2011). However, access to high-volume and high-quality data sets of scientific output (e.g., publications, patents, grants) and computers and algorithms capable of handling this enormous stream of data has made it possible for bibliometricians to deeply study the phenomenon of interdisciplinarity (Borner, Maru and Goldstone, 2004).

Interdisciplinary research is considered a kind of convergence phenomenon (Jeong, Kim and Choi, 2015). There are four areas that their convergence is particularly considered important, especially in terms of technology convergence. They include nanotechnology, biotechnology, information technology, and cognitive science (together known with the acronym of NBIC) (Jeong, Kim and Choi, 2015). This technological convergence might manifest itself in the early stages as the interdisciplinary relations and interactions among these four fields. Technology convergence has different levels that starts with convergence in science and moves to convergence in technology, market and then in industry (Jeong, Kim and Choi, 2015). Although, individual fields from NBIC, especially nanotechnology and nanoscience, have received considerable attention in bibliometric studies, there is not much research on the
interdisciplinary relations of these four areas. It is critical to know how these converging fields rely on each other, how similar they are and how much scientific exchange and interactions occur among them. All of these four fields have been especially emphasised in the Iranian Scientific Roadmap and the Iranian government has invested in research in these areas. This article aims to investigate the convergence of these four fields at the science level by focusing on the relations between them. The focus of the article is on Iranian international publications in these areas. There are different bibliometric techniques for studying interdisciplinary relations and this article uses a combination of techniques including journal citations, author citations and keyword analysis.

Literature review

Techniques and methods for measuring similarity and interdisciplinary relations in science have been laboriously developed over the past several decades using bibliometric analysis (Rafols, Porter and Leydesdorff, 2010). There have been already a few reviews and discussions of the methods used for this purpose including Van Raan (1999) and Wagner et al. (2011). Generally, we can divide studies on the interdisciplinary relations of scientific fields into five groups based on the techniques they have used.

The first group include studies that have used citation analysis. These studies focus on the cross references between scientific fields with the assumption that if two fields of science cite publications of one another, they are related. For instance Goldstone and Leydesdorff (2006) studied how much cognitive science cite other fields of science and how much it is cited by other fields. The results showed that cognitive science cited neurology (13.4%) more than other fields and it received the highest rate of interdisciplinary citations from computer and artificial intelligence (15.2%). In another study Porter and Youtie (2009) studied interdisciplinarity of nanotechnology and found that nanotechnology had some level of convergence with medicine, biotechnology, neurosciences, physics and maths. In a more recent study on nanotechnology and nanoscience, Stopar et al. (2016) found out that nanosciences showed characteristics of a distinct discipline.

The second group are studies that focus on co-classification analysis which looks at the co-occurrence of different subject-classification headings assigned to research publications. An example from this group is the study by Rafols and Meyer (2010) on bionanoscience.

The third group have used co-word analysis. Milojević (2012) in his study of nanotechnology found that some 85% of Nano research was multidisciplinary. Wang, Notten and Surpatean (2013) in their study of nanotechnology also found that nanotechnology has developed to a relatively mature stage and has become a standardized and codified technology.

The fourth group have used co-authorship analysis techniques. Bergmann et al. (2016) investigated how interdisciplinary collaboration in cognitive science was and they found a high level of interdisciplinary collaboration in cognitive sciences.

The fifth group are those that have applied co-citation and bibliographic coupling analysis techniques. For instance, Bassecoulard, Lelu and Zitt (2007) used bibliographic coupling analysis for nanosciences and found out that observed moderate multi-disciplinarity is based on a real inter-disciplinarity at the paper level. Chen et al. (2015) used a co-citation matrix to study the interdisciplinary evolution of biochemistry and molecular biology. Their study showed that interdisciplinarity evolves mainly from neighbouring fields to distant cognitive areas and provides evidence of an increasing tendency of biochemistry and molecular biology researchers to cite literature from other disciplines.

Overall, there is a wide range of research on interdisciplinary relations as well as on identifying converging fields (such as Buter, Noyons and Van Raan, 2010). Several studies in the past have focused on nanotechnology and nanoscience and a few on cognitive sciences. However, there
seems to be no study on the relations between all of the four areas of NBIC and the present study contributes in this area.

**Methods and measures**

Data for the Iranian articles were obtained from Scopus database. Any English article with at least one author affiliated to an Iranian institute was retrieved in four fields of nanotechnology (Nano), biotechnology (Bio), information technology (Info), and cognitive science (Cogno) for the period 2001-2015. The data were searched and obtained in 6 September 2016 as batches of 2000 records (the maximum number Scopus allows downloading). The year of publication was used to break the search results into smaller sets in order to be able to download the records. They were then imported into a database for the analysis. Table 1 shows the number of Iranian records for each subject area.

<table>
<thead>

</tr>
</tbody>
</table>

Four analysis techniques were used: journal citations, author citations, keyword analysis and authorship.

- **Journal citations**: citations to journals by publications of each field were analyzed and then the amount of overlap between the cited journals (journals jointly cited by each pair of fields) was calculated.
- **Author citations**: citations to authors by publications of each field were analyzed and then the amount of overlap between the cited authors (authors jointly cited by each pair of fields) was calculated.
- **Keywords analysis**: VOSviewer (vosviewer.com) was used to do a keyword analysis on the titles of the articles for each field. For each field, keywords with at least five occurrences were extracted and then the amount of keywords shared by each pair of fields was calculated. VOSviewer was used to extract the keywords from titles of each field. The results were presented to a panel of experts who identified common terms to be removed. The remaining sets were used for comparison of the four fields as pairs or triads.
- **Authorship analysis**: the number of authors who have published articles in each pair of fields were calculated. Author analysis was only done on Iranian authors and foreign co-authors were removed from the sets. Affiliations were used to do some control for homonyms.

Four measures were used in this study: inclusion index, import/export of concepts, inward/outward interactions and spanning tree.

- **Spanning tree**: spanning tree calculation was used to show the strongest (maximum spanning tree) and weakest (minimum spanning tree) ties between the subject fields.
- **Inclusion index**: inclusion index is a simple measure for asymmetric similarity. It was used because among three indexes that have been suggested for measuring similarity of
documents (including Salton’s Cosine formula, the Jaccard Index, and the Inclusion Index), inclusion index reveals better results (Sternitzke & Bergmann, 2009). In asymmetric similarity, the similarity of set A to set B is different from the similarity of set B to set A (Qin, 2000). Inclusion index here indicate the extent by which keywords from one field have been used in a second field. The formula used here was $100 \times \frac{A}{M}$ in which A is the number of keywords common in both fields of B and C, and M is the number of keywords from field B that do not exist in field C.

- Import and export of concepts: this measures (used only for keyword analysis) shows how many concepts from one field are used in other fields (exporting) and how many concepts from other fields are used in the given field (importing). Concepts here are represented with keywords.
- Inward and outward interactions: this measure (used only for author analysis) was used to see the percentage of authors of a given field that have authored articles in other fields (outward interaction) and the percentage of authors from other fields that have authored articles in the given field (inward interactions).

**Findings**

**Journal citations**

Table 2 shows the amount of overlap in each pair of fields in their citations to journals. For instance the first row shows the overlap between Nano and Cogno. It shows that 17 journals have been cited by the articles of both fields. There have been 223 citations to these 17 journals in Nano articles, accounting for 9.9 per cent of all of citations. Cogno articles included 4,424 citations (12%) to these 17 journals. The largest number of journals jointly cited by two fields belongs to Nano and Bio with 297 journals cited by both fields. While these journals accounted for 65.4 percentage of citations from Bio articles, they only were 18 per cent of citations from Nano articles. The smallest overlap is between Bio and Cogno (no overlap) and then between Info and Bio, and Info and Cogno respectively.

Figure 1 shows the weighted graph of the spanning tree representing the journal citation similarities between the four fields. The numbers shown for edges are percentages. The number inside nodes are the total number of journals cited in the articles of that field. The maximum spanning tree is shown with dashed line and the minimum spanning tree is shown with dotted line. The strongest relation is between Bio and Nano where 65.4 per cent of citations in Bio articles are to sources that have been cited in Nano articles too. The weakest relation is between Bio and Cogno where Bio has no common cited sources with Cogno articles.

Inclusion index was calculated for overlap in citations to journals. Table 3 shows that for instance the similarity of journal citations in Nano articles to Bio articles (2nd row) is 18.6%, while the similarity of journal citations in Bio articles to Nano articles is higher (22.1%). The smallest number is the similarity of journal citations in Cogn articles to journal citations in Bio articles.

Author citations
Another way of measuring the relation between two fields or their similarity is to look at their overlap in citations to authors. Table 4 shows the overlap between each pair of fields in their author citations. For instance there were 1,494 authors that were cited by articles in both Nano and Cogn articles. In Nano articles, 32,391 citations (3.4% of all of citations in Nano articles) were made to these 1,494 authors, while this figure for Cogn science articles was 45,334 citations (23.5% of all of citations in Cogn articles). The strongest relation is where 72.5 percent of citations in Nano articles were made to 9,479 authors who also were cited by articles in Bio. The data are also illustrated in the spanning tree graph (Figure 2). The number inside nodes are the total number of citations to authors in the articles of that field.

Figure 1. Spanning tree of the relations of four fields based on journal citations
Inclusion index for author citations is presented in Table 5. We can see that the similarity of Nano articles to Cogno articles in terms of citing the same authors is 4.6 per cent while Cogno articles are only 3.3 per cent similar to Nano in this regard. The highest similarity is the similarity of Info articles to Bio articles (9.4%).

Shared keywords
The third way of looking at the relation or similarity of two fields here is keyword analysis. Table 6 shows the keyword similarity between pairs of subjects. In the strongest similarity we can see that 483 keywords had a total frequency of 15,855 (28.6%) in Nano articles. These 483 keywords were also used in Bio articles and they accounted for 38 per cent of keyword frequencies in Bio articles. The weakest relation is between Cogno and Bio articles, where
Cogno articles have the smallest number of shared keywords with Bio articles. Figure 3 shows the spanning tree of shared keywords. The number inside nodes are the total number of keywords in the given field.

Figure 3. Spanning tree for the relations of four subjects based on shared keywords

*Inclusion index* for the similarity of pairs of subjects in terms of shared keywords is presented in Table 7. The highest quantity is the similarity of Bio articles’ keywords (5.6%) to those of Nano articles. The lowest quantity belongs to similarity of Nano articles’ keywords (1.2%) to those of Info articles.

For keywords, we can also consider how each field imports concepts from or exports concepts to the other fields. Exporting here indicates the percentage of keywords of a given field that have been used by other fields. The percentage of concept export for Cogno articles here is 56
per cent (i.e. 1241+1216+755)/5725*100 = 56%). To calculate import percentage for Cogno articles, the sum of all of its join keywords with the other three fields is divided by the total number of its keywords. The concept import percentage for Cogno articles is 79 per cent. The ratio of import to export (59/79) is 0.7 for Cogno. This ratio indicates that Cogno exports more concepts to the other fields than it imports. Nano seems to have the largest import to export ratio.

Authorship analysis

Authors of one subject field might publish articles in the journals of another subject field. Table 9 shows the number and percentage of authors who published in each pair of subject fields. In the pair of Nano and Bio, 9,478 authors published in the journals of both fields. These authors, given the frequency of their appearance in the articles (counting was not unique counting) were 67.4 per cent (or 50,131 authorships) of Nano articles. The same 9,478 authors accounted for 40.7 per cent or 50,915 authorships in Cogno articles. Figure 4 shows the spanning tree graph of authorship. The number inside nodes are the total number of authors in the given field.

</tr>
</tbody>
</table>

For authorship, we can also consider inward and outward interactions. Outward interaction is the percentage of authors from a given field that have contributed in the articles of any of the other three fields. Inward interaction is the percentage of authors from any of the other three fields that have contributed in the articles of the given field. Table 11 presents the data. We can see that inward interaction of authors in Nano is 91.6 which was calculated by dividing the sum of contributions of authors of the other fields in Nano articles by the total number of authors of Nano articles. Nano has a larger percentage of outward interactions. The ratio of inward to outward interactions (inward/outward) shows whether the authors of a field contribute to the other fields more than other receiving contribution from the other three fields or it is the opposite. In the case of Nano, 0.82 shows that authors of this field contribute more in the articles of the other three fields than the field receives contribution from the other three fields.

Discussion and conclusions

This study is one of the few studies, if not the only, that have looked at the interdisciplinary relations between the four fields of NBIC (nanotechnology, biotechnology, information technology, and cognitive science). These are known as converging (or convergent) technologies and there is a great deal of hope that their synergy will result in great progress in science. The first level of their convergence is at the science level, which is manifested in interdisciplinary relations. These relations were investigated in this study using a set of different techniques and measures. These combination of techniques and measures together (e.g. inclusion index and spanning tree) have not been used much in the past. The use of different techniques reveals different aspects of interdisciplinary relations. For instance while keyword analysis shows the exchange of concepts between two fields, citation analysis reveals how much...
they have in common in terms of sources of information; and authorship analysis shows something about their human interaction.

The results of the study showed that the highest exchange of citations occurs between Bio and Nano. Bio and Nano also had the strongest link in terms of shared keywords. The highest exchange of authorship was also between Nano and Bio. These results show that Bio and Nano have probably a higher level of convergence and they are more likely to be able to do joint projects. This should not be surprising as there is already a field of research named bionanoscience (Rafols and Meyer, 2010) that indicates the convergence of Nano and Bio. This result is aligned with the findings of past studies (Porter and Youtie, 2009) on high interdisciplinarity of Nano and its convergence with some other fields.

The results also showed that Cogno articles did not have any citations to the journals cited in Bio articles and the two fields of Cogno and Bio did not have any relation in this regard. Cogno also had the weakest link to Nano in terms of authorship as well as author citations. The lowest rate of exchange of concepts also belonged to Cogno and Bio. All of these indicate that cognitive science in the context of Iranian science has not been very successful in establishing relations with the other three fields in NBIC and its interdisciplinary relation with the other three fields are not as strong as it should be. The low integration of Cogno with other fields in this study was not expected for past studies (Bergman et al., 2016) found cognitive science to be very interdisciplinary.

We should note that this study has its own limitations as the data used in the study were only the data of Iranian publications. Interactions between scientific fields in the context of Iranian science is influenced by the way science is managed in Iran. There are two independent and separate ministries in Iran in charge of research. Ministry of Science, Research and Technology manages most areas of science except Medical sciences that are managed by the Ministry of Health. This might create some hindrances for the relations of certain subfield of cognitive science (such as certain areas of neuroscience that falls under the administration of the Ministry of Health) with other areas (i.e. Nano, Bio and Info). This governance aspect of science might explain the weak relationship of Cogno with the other fields in this study. It will be interesting to do the same kind of analyses on the global data to see if the relations in Iranian NBIC are different from those in the international science. The other issue is that most of the analyses in this study, similar to many other bibliometrics studies, relied on the subject categorizations of journals in Scopus database. In spite of these limitations, use of different techniques and measures helped create a better picture of the interdisciplinary relations between NBIC. Spanning tree could show the weakest and strongest connections and inclusion index showed the similarity. It is recommended that future studies use a combination of techniques for the study of interdisciplinary relations. The study also focused only on publications, and there is a need to investigate the convergence of NBIC at the technology (e.g. patent), market, and industry levels.

Mapping the development trajectory of 3D printing technologies

Abstract

Using patent and citation analysis, this study explores the development trajectory of 3 dimensional printing (3DP) technologies. Different from the existing literature, we disentangle non-3DP technologies from those in the 3DP domain. Our results show that 3D printing technologies invented by the U.S. have played in a dominating role in the main path. In particular, new branches of various types of 3D technologies have all developed from American patents. There was only one main path in 3D printing technologies during 1998 and the early 2000s. However, great diversification can be observed after the mid-2000s. China has been catching up after 2012, in technologies related to both printing materials and printing machines. By tracking technology domains in the patents cited by 3DP technologies, we find that, in the period between 2004 and 2012, technologies from non-3DP domains contributed greatly in shaping the development of 3D printing materials and printing machines. At a disaggregated level, this study provides insights on how technologies from various fields contributed to different 3D printing technology clusters. The methods carried out in this study can be also applied to exploring technological developments and knowledge flows in other fields.

Conference Topic
Patent analysis
Citation and co-citation analysis

Introduction

It is widely believed that knowledge flows can be tracked by patents and citations (Jaffé and Trajtenberg, 2005; Verspagen 2007; Hummon and Dereian 1989). Citations in one patent reveal that the knowledge in this patent has been developed from (or is related to) the knowledge described in other patents published earlier. By tracing the inventor’s name, country and year in which the patents were granted, one can also view the locations where the technological innovation took place and the year when the patent was publicly announced. There are clusters or sub-streams in the development of technological trajectory. The main path, however, provides
the most important information on the major stream of knowledge flows and represents the greatest connectivity of different technologies (Verspagen 2007; Hummon and Dereian 1989).

Three-dimensional (3D) printing, known as additive manufacturing, is a process of creating physical objects from a digital design. In the digital era, 3D printing is regarded as socially transformative technology with great socioeconomic implications (Ratto and Ree 2012). Several studies have been conducted, using citation analysis, to map the development of 3D technologies (Huang et al. 2017; Kim et al. 2016). The existing literature has examined 3D printing trajectory with citation links without disentangling technological domains (i.e. citation resources). We argue that understanding the technological contribution from other technological domains is crucial for a deeper understanding of the emergence of new technologies. To this end, our study covers two types of knowledge sources. On the one hand, we investigate the contribution of different countries in the main path of 3D printing development. This reflects the knowledge flows across geographical regions. On the other hand, we disentangle the contribution of different technological domains, including the 3D printing field itself and the domains of non-3D printing technologies.

Data and Methodology

Patent data have been collected through the Thomson Innovation (TI) platform from Derwent World Patent Index (DWPI)\(^1\). 3D printing patents were extracted based on a series of keywords, including 3D print, Additive Manufacturing, Rapid prototyping, and the key 3D printing techniques such as Stereolithography and Fused Deposition Model. The query we used is: TI=((3d) or (three ADJ dimension*) or (3 ADJ dimension*)) adj (print* or manufact*)) OR AB=((3d) or (three ADJ dimension*) or (3 ADJ dimension*)) adj (print* or manufact*)) OR TI=((Rapid ADJ protyp*) or (Rapid ADJ manufacturing) or (Additive ADJ manufacturing) or bioprint* or Stereolithograph* or (Fused ADJ Deposition ADJ Model*) or (Laser ADJ Sinter*) or (Direct ADJ Metal ADJ Deposition) or (Layered ADJ Object ADJ Manufact*) or (Select* ADJ laser ADJ melt*) or (Electron ADJ beam ADJ melt*)) OR AB=((Rapid ADJ protyp*) or (Rapid ADJ manufacturing) or (Additive ADJ manufacturing) or bioprint* or Stereolithograph* or (Fused ADJ Deposition ADJ Model*) or (Laser ADJ Sinter*) or (Direct ADJ Metal ADJ Deposition) or (Layered ADJ Object ADJ Manufact*) or (Select* ADJ laser ADJ melt*) or (Electron ADJ beam ADJ melt*))\(^2\).

Based on this query, we extracted in total 37,803 patents, which were further distributed into 19,961 patent families. The dataset covers all available patents from any year and any patent authorities covered by DWPI.

\(^2\) The final data collection was done on 7 March 2017.
Citations were gathered from Derwent Patents Citations Index (DPCI). For all the 3D printing patents collected above, we have in total 217,109 patent citations, which are from 44,664 patent families.

To track knowledge flows according to time and location, we label year and country for each patent family. The year is defined by the earliest publication year of all the patents in the same patent family. Country label is defined by the nation of inventor(s). If there are multiple inventors in one patent publication, we label only the country of the first inventor. In creating the main technological path of technological development in the long run, we follow the method proposed by Liu et al.(2013). The technological trajectory is mapped with software Pajek.

Among the cited 44,664 patent families, this study distinguishes between 3DP and non-3DP patents. The fields of non-3DP patents are examined based on the DWPI Manual Code, which was assigned by teams of Thomson Reuters analysts who have been specially trained in the application of these codes (Larner 2013). We first collect the DWPI codes at the third level (e.g. A11-A or A12-C), following which all the DWPI manual codes were aggregated at the second level (e.g. A11 or A12).

Results and discussions

Main path of 3D printing (3DP) technologies

Based on the citation linkages, the main path of 3D printing technologies is captured by Figure 1. According to the relatedness of technologies, the trajectory of 3D printing technologies is further classified into five technological clusters. The first one, shown in red squares, presents technologies related to Additive manufacturing and Stereolithography. The second cluster, shown in blue squares, includes patents that mainly introduced methods to derive data for forming high resolution three-dimensional object. The third one, in green, indicates a group of patents applying technologies such as beam Stereolithography equipment and Optical molding apparatus etc. The fourth group, in purple, consists of technologies related to 3D printing materials. And the last group, in brown, is comprised of technologies related to 3D printers.
Figure 1. Technological trajectory map of 3DP technologies
The earliest 3D printing technology is represented by EP171069A2_1985_US, which was filed in 1984. In this patent family, according to the application year, the earliest patent was US4575330A filed in 1984, which proposed a type of technology named Stereolithography. In 1986, the inventor of this patent, Hull Charles, co-funded 3D systems\(^3\) – the first 3D printing company in the world.

In the trajectory map, the arrow line illustrates citation relations between patent families, while the arrow head is directed from the cited to the citing ones. In theory, the year of citing patent families should be later than the cited ones. However, due to the fact that a patent family includes a series of patents with different publication dates, and that the year labeled on the map is defined only by the earliest publication year of all the patents in the same patent family, it can happen that a patent family seemingly cited one from an even later publication year. For instance, the earliest patent (A1) in patent family was published in 2006. Thus we labeled the publication year of patent family A as 2006. In patent family B, the earliest patent was published in 2004 and we labeled the publication year of patent family B as 2004. However, there is one patent (B2) published in 2007 that cited A1. Thus at the patent family level, we will have patent family A (labeled in the year of 2006) that was cited by patent family B (labeled in the year of 2004). Figure 2 illustrates the misalignment citations between patent families.

![Figure 2. Example of misalignment citations between patent families](image)

Apart from the few exceptional cases with misalignment citations\(^4\), the rest citation links in the main path are all with logical years. The main path (Fig.1) shows that, after 1998, 3D printing technologies formed one main stream which kept a stable path for the following two decades. However, forked technological streams are observed after 2004. Printing materials and printing machines are the two main clusters developed simultaneously in the later stage. Within either cluster, there are also sub-branches with special technological focus.

\(^3\) [https://www.3dsystems.com/our-story](https://www.3dsystems.com/our-story).

The technological path is dominated by the U.S., with an incidental presence of Japan (JP) and Germany (DE). China (CN) appeared on the map only after 2012, in both technological clusters dealing with printing materials (in purple squares) and printing machines (in brown squares). South Korea (KR) showed up also relatively late on the path, in particular in the track of printing machine related technologies (in the end of brown branch).

**Technological resources (3D printing vs. non 3D printing technologies)**

![Graph showing the share of non 3D printing citations (1986-2015)](image)

*Figure 3. Share of non 3D printing citations (1986-2015)*

Note: The year represents the publication year of the earliest patent in one 3D printing patent family.

Figure 3 shows the share of citation from non-3DP patents. After the introduction of the earliest 3DP patents in the 1980s, the share of non-3DP patent citations decreased over time till the early 2000s. This shows that, with the increasing number of 3DP technologies, more and more knowledge from this domain can be used to further develop new technologies in the following years, at least till 2003. Thus the share of citations from other technology domains remained lower. The lowest share was reached in 2003, which was around 70 per cent. This also indicates that in 2003, on average, 3DP inventions were developed 30% based on 3DP domain itself and 70% on knowledge outside. Afterwards the share of non 3DP citation increased, in particular in the period from 2004 to 2012. This interesting evidence suggests that, in spite of the growing of pool of 3DP technologies, 3DP inventors applied more extra knowledge from other technology domains after 2003. This signals that 3DP technology entered a new era after 2003, with new 3DP breakthroughs influenced by other technology domains.
Technological contribution from non-3DP

Following the trajectory map and the five technological clusters, this section analyses the contribution of non-3DP in the development of 3D printing technologies.

For the top non-3DP patents cited by the five clusters in the main path, all the assigned Derwent manual codes were collected and aggregated at the third level (e.g. A11 or A12). Table 1 provides the major non-3DP fields that have contributed to the five technology clusters.

Note: Summarized from the top non-3DP patents cited by the 3DP patents in five clusters.

In the development of 3D printing technologies, processing polymer (including equipment and applications) played a crucial role. The polymer-related processing technology, equipment, materials applications (plastic, resin, etc.) contributed to all the 3DP clusters except cluster 5.
Figure 4. Contribution of non-3DP technologies to five 3DP clusters

Knowledge flows between top non-3DP technologies to the five clusters are summarized in Figure 4. In cluster 1, the major contribution of non-3D printing technologies came from the field of digital computer processing techniques (3-dimensional image modelling), metal powder, and metal laser coating. In the second technology cluster, photosensitive material technologies played an important role in promoting the development of 3D printing. In Cluster 3, in which the earliest patents of the 3DP patent families were published mainly between 2000 and 2006, the major non-3DP technological contribution originated from the polymer field, such as condensation polymer and polymer addition. Different from Cluster 2, the non-3DP patents cited in Cluster 3 are mainly related to the polymer materials rather than polymer equipment. In cluster 4, the non-3DP citations were from various fields, including polymer processing applications, ceramic materials, computer technology, industrial equipment and so on. This facilitates the technology diversity of 3D printing technologies in this group. In cluster 5, non-3DP technologies related to image technology, computer peripherals, inkjet printers and digital transmission systems began to affect 3D printing technology.

Conclusions

Towards understanding the development of 3D printing technologies, this study maps the trajectory of 3D printing patents and explores the contribution of various knowledge sources. Different from previous studies, this paper tracks knowledge sources in contributing to the development of 3D printing technologies. On the one hand, we illustrate the contribution of different countries in the main path of 3D printing development. On the other hand, we disentangle the contribution of non-3DP technologies from that of 3DP domain.
The linkages between patent families from different countries and different years help understand the role major nations played in various stages. The trajectory map shows that the 3D printing technological path has been dominated by the U.S., with an incidental presence of Japan and Germany. After 2012, however, China witnessed a sharp rise in technologies related to 3D printing materials and 3D printing machines.

By differentiating knowledge sources from various domains, our results suggest that 3D printing technology entered into a new era after 2003. In the period of 2004 and 2012, technologies from non 3DP domains contributed greatly in shaping the development of 3D printing materials and 3D printing machines. Based on the classification of non-3D print citations, this study also provides insights on how technologies from various fields contributed to different 3D printing technology clusters.

It is noteworthy that this study defines countries of patents based on the first inventors. Thus a collaborated patent is assigned only to one country. Admittedly, various collaborations happen across the global innovation value chain. Testing such knowledge flows related to co-inventorship may be an interesting subject for future research.

Abstract
This study focuses on the knowledge spillovers in the semiconductor industry by employing patent bibliometrics and social network analysis methods. Based on the technological development of wafer diameters, the analysis is divided into three time periods: 6-inch (1976-1991), 8-inch (1989-1999) and 12-inch (1997-2011). Two types of knowledge spillover relationships between semiconductor companies are examined, of which strong ties are defined as the R&D cooperation activities between companies, while weak ties are represented by the patent citations between semiconductor companies. We apply two divisions to categorise semiconductor companies in this study. First, based on each company’s technology position in the knowledge spillovers network, companies are classified as technology leaders, technology brokers, technology followers, or technology isolated companies. Second, based on the role of each firm in the industry chain, semiconductor companies are divided into six types, which are—integrated device manufacturer (IDM), IC design, foundry, packaging & testing, IC equipment, and others. Study results indicate that technology leaders are the main sources of semiconductor knowledge spillovers among the four distinct technology positions. Furthermore, IDM and foundries are the sources of semiconductor knowledge spillovers among all roles within the industry chain. Consequently, we suggest that monitoring the development of technology leaders, such as IDMs and foundries, is important in formulating strategies for the research and development of the semiconductor industry. In addition, it is suggested that foundries transform their relationships with IDMs from vertical outsourcing manufacturing to horizontal R&D cooperation.

Conference Topic
Patent analysis

Introduction
To improve understanding of the characteristics of knowledge spillovers, it would be beneficial to systematically characterise companies when conducting research in this area. Andersen (2006) analyzed the characteristics of enterprise knowledge spillovers in European and non-European countries by positioning the technology of companies. Moreover, Podolny, Stuart and Hannan (1996) divided companies into technology leaders, technology brokers, technology followers and technology isolated companies through the calculation of two indices—technological crowding and technological prestige, which are based on the patent citations between semiconductor companies. Also, Podolny et al. (1996) inspected how the technology positions of companies affect their survival rates. Similar applications that classify companies based on their technology positions can be used to predict the formation of technology strategic alliances among companies with different technology positioning (Stuart, 1998), and be used to evaluate the shares of different technology positions in distinct industries across different countries (Andersen, 2006; Okamura & Vonortas, 2006). Apart from the classification of technology positions, many industries are categorised by their roles in the industry chain. For
instance, the semiconductor industry divides their business activities into integrated device manufacturer (IDM), IC design companies, foundries, packaging & testing companies, IC equipment companies and others (such as research institutions, terminal products manufacturing and selling companies).

The aim of this study is to discuss the channels of knowledge spillovers, considering R&D cooperation as strong ties of knowledge spillovers between companies and the patent citation connections as weak ties of knowledge spillovers (Wang, Sung, Chen & Huang, 2017). By the means of positioning companies into technology leaders, technology brokers, technology followers, and technology isolated companies, as well as categorising companies into integrated device manufacturer (IDM), IC design, foundry, packaging & testing, IC equipment and others based on their roles in the industry chain, we examine the differences in the performance of knowledge spillovers between the distinct types of companies and further analyze the degree of involvement and the receivers of knowledge spillovers.

Koka, Madhavan, and Prescott (2006) stated that two conditions affected the formation of enterprise networks, which include the uncertainty of the environment and the supply of resources. In order to fully explore the evolution of company networks within an industry, it is necessary to look for an industry that has developed for a considerable period of time and that has comprehensive data resources. Since the semiconductor industry meets the criteria mentioned above, it was selected for analysis in this study. In this paper, we analyze the knowledge spillover network of semiconductor companies over 36 years, divided into three time periods which correspond to the development of the 6-inch, 8-inch and 12-inch wafer diameters. By means of patent bibliometrics, social network analysis and statistical tests, we examine the differences between the various types of semiconductor companies as exhibited by their strong ties and weak ties of knowledge spillovers.

Knowledge Spillover Network

**Technology positions**

The relationship of patent citations between companies can be summarised and represented by two indices—technological crowding and technological prestige. We apply these indices and further divide the technology position of companies into four categories, that is, technology leaders, technology brokers, technology followers and technology isolated companies. Podolny et al. (1996) set technological crowding as the x-axis and technological prestige as the y-axis. Companies located in the first quadrant were defined as technology leaders, who have both high technological crowding and high technological prestige. Technology leaders focus on the research and development of mature technology while maintaining leading positions in the industry. Moreover, technology leaders have been considered the originators of knowledge spillovers in the semiconductor industry. Companies situated in the second quadrant represent technological brokers. Technology brokers have low technological crowding but high technological prestige. These companies tend to focus on the development of innovative and unexplored technology areas. The region in the third quadrant indicates that a certain firm is a technological isolated company, which has low technological crowding as well as low technological prestige. Technological isolated companies develop technologies that are rather out of the ordinary, and they either focus on cutting-edge technology that has not yet been adopted by the industry, or out-of-date technology that is soon to be obsolete. Companies in the fourth quadrant are defined as technology followers, who have high technological crowding but low technological prestige. Technology followers focus on the development of mature technology but rarely have innovative contribution to the industry. Related studies on the citation networks of companies classified according to their technology positions particularly focus on how the different technology positions affect a company’s survival rate (Podolny et
al., 1996); how a company’s technology position predicts its formation of technology strategic alliances (Stuart, 1998); and the distribution of countries based on their technology positions, using data from different industries (Andersen, 2006; Okamura & Vonortas, 2006).

Roles in the Industry Chain
According to the definition of companies in a semiconductor industry chain, semiconductor companies can be divided into integrated device manufacturer (IDM), IC design, foundry, packaging & testing, IC equipment and others (such as research institutions and terminal products manufacturing and selling companies). This paper classifies companies in the semiconductor industry into six roles by referring to the introduction in the companies’ official websites, Wikipedia and the Semiconductor Industry Yearbook published between 1999 and 2011. Each company can only be classified under one role with no overlapping, and the classification results were confirmed by industry experts.

Methodology
Data Collection
In this study, patents granted by the USPTO between 1976 and 2011 were gathered for analysis and data related to R&D cooperation was collected from the Semiconductor Industry Yearbook published between 1999 and 2011. Here we limit our patent citations and data sources to the United States Patent Classification (USPC) System, which is maintained by the U.S. Patent and Trademark Office (USPTO). Patents related to semiconductor technologies are categorised in the USPC under Electronic-Semiconductor Devices and its patent classes are 257, 326, 438 and 505 (Hall, Jaffe, & Trajtenberg, 2001). In addition, the R&D cooperation records between semiconductor companies were obtained and compiled from the Semiconductor Industry Yearbook, which is published by the Industrial Economics & Knowledge Center (IEK) of the Industrial Technology Research Institute in Taiwan. The yearbook has 21 volumes from 1999 up to 2011, and documents the development trajectories and issues in the semiconductor industry every year in Taiwan and other major countries. It also presents the dynamics and major changes in the industry, providing authoritative references to R&D cooperation activities in the semiconductor industry.

Patent Bibliometrics
Patent bibliometrics (or patentometrics) is a theoretical method using mathematics, statistics and logic. It studies and analyzes the quantity, quality and application of patent literature, e.g. patent counts and patent citations (Narin, 1994). Patent bibliometrics can be used to understand the development of patented technologies (including that of individuals, organisations and countries). What is more, it can be used to study the links between researchers, organisations and countries through the relationship of patent citations.

Patent analysis calculates the patent counts and the frequency distribution of patents based on the selected units of analysis (e.g. country, company/organisation, inventor and technology field), and can be used to identify the major activities of the selected units. Patent citation analysis focuses on the references (including patent and non-patent references) cited in the patent specification. As a result, potential links can be explored through patent citation counts and citation relations. Patent citations are similar, but not equal to citations in literature. The inventor/applicant might cite documents, but examiners also cite documents in their novelty reports. This study mainly focuses on the evaluation of weak ties of knowledge spillovers in the semiconductor industry using patent bibliometrics. In order to distinguish the weak ties network during the three wafer diameters periods, here we apply the Activity Index as the indicator to screen and select representative patent citation links.
Activity Index

The Activity Index (AI) is an indicator that was originally defined as the share of a given technological field among all patents held by a company, divided by the share of the given technological field among all U.S. patents. This indicator also showed the relative activeness of a company in different technological fields in order to identify which technological fields the company specialised in (Pavitt and Soete, 1980). In this study, we adjusted the indicator and applied it to measure the activeness of citing connections from one company to another. The AI is the ratio between the percentage of the patent citations to a cited company among all outbound citations of a citing company and the percentage of the patent citations to the cited company among all outbound citations of all companies. It is worth noting that the activeness, in this case, is not ‘absolute’ but ‘relative’. ‘Relative’ means that the company is more active compared with the given technological field, which does not indicate that the company has more absolute technical advantages than the other companies. The AI value ranges from 0 to $+\infty$. It indicates whether the company is relatively less active (AI < 1) or relatively more active (AI > 1) to the given field. The formula for the AI is shown as follows:

\[
\text{Activity Index (AI)} = \frac{\text{patent citation counts from the citing company to the cited company}}{\text{total patent citations from all companies to the cited company}} / \frac{\text{total outbound patent citations of the citing company}}{\text{total outbound patent citations of all companies}}
\]

Data Sampling

This study draws upon patent citation relations to analyze the knowledge spillovers between companies. However, the number of patent citations received by a company varies relative to its number of patents held, in which the likelihood of being cited increases for companies with more patents. In terms of patent citation counts, should one single citation count represent the weak ties of knowledge spillover between two companies? In order to select representative patent citation relations between companies, this study adopts not only citation counts but also the Activity Index for data sampling, explained as follows:

- **Condition 1**: The number of patent citations from the citing company to the cited company must be higher than the median of patent citations from the citing company to all companies.
- **Condition 2**: The ratio between the patent citation count from the citing company to the cited company and the total outbound citations of the citing company must be higher than the ratio between the patent citations from all companies to the cited company and the total outbound citations of all companies in the industry. In other words, the AI value of the link from one company to another must be higher than 1.

In the sampling process, patent citation relations that meet condition 1 were regarded as high ‘absolute’ citation relations of the citing companies. Those that meet condition 2 were regarded as high ‘relative’ citation relations. Therefore, sampled patent citation links that meet both conditions 1 and 2 are considered representative for measuring the knowledge spillovers between companies in this study.

Technology Positions and the Roles in the Industry Chain of Semiconductor Companies

In order to investigate the differences of strong ties and weak ties of knowledge spillovers based on the characteristics of companies in semiconductor industry, we distinguish the technology position of companies. The methodology used in this research is adopted from Podolny et al. (1996), who applied technological crowding and technological prestige to divide companies into four types of technology positions—technology leader, technology broker, technology follower and technology isolated company.
Technological Crowding

Technological crowding evaluates the niche overlap of R&D cooperation of each company, the more overlapping of R&D activities the higher the similarities in innovative capabilities between a particular company and other companies in the field. Podolny et al. (1996) applied patent citations to calculate technological crowding, while Breschi, Cassi, and Malerba (2006) extended the calculation of technological crowding to the level of organizations. The formula is defined as

\[ A_i = \sum_{j \neq i} \frac{C_{ij}}{C_i} \]

where \( C_i \) is the patent citation counts of company \( i \), \( C_{ij} \) is the number of shared references of company \( i \) and company \( j \) (i.e. bibliographic coupling). \( A_i \) therefore represents the degree of technological overlap of company \( i \) with the other companies.

Technological Prestige

Bonacich (1987) proposed a method to measure technological prestige using the power centrality index. It considers the degree centrality based on the direct paths to a company as well as the degree centrality based on indirect paths (i.e. the centrality of the neighboring companies). This shows that the advantages that a company has in the network not only depends on the centrality based on direct links, but also the centrality based on indirect links.

In social network analysis, if some of the nodes have a higher number of connections than the others, they will be considered as having dominant positions in the network due to having a greater sphere of influence. However, nodes with the same number of connections do not imply that they have the same level of influence in the network. Bonacich (1987) pointed out that the calculation of the Power Centrality Index considers both paths linked to a target node and paths that are linked to the neighbouring nodes of the target node. In other words, the calculation of power centrality is formed by the direct paths and the indirect paths of a company. For instance, assessing the power centrality of a particular node considers both the first layer of nodes linked to it and the surrounding nodes that are linked to the nodes in the first layer. Nodes in the first layer are affected by the second layer of nodes linked to them, hence, the power centrality of the central node is calculated based on all the nodes that can be linked to the central node and the relations between the nodes. The formula of power centrality is defined as

\[ C_i(\alpha, \beta) = \sum_j (\alpha + \beta C_j)R_{ij} \]

where \( R_{ij} \) is the relation matrix, representing the relations between nodes. \( \alpha \) is the number of connections with surrounding nodes. \( \beta \) is the attenuation factor and has a value between -1 and 1.

Technology Positions of Companies

Through the calculation of technological crowding and technological prestige, we further divide semiconductor companies into four categories, which are:

- Technology leaders: Companies in the first quadrant have both high technological crowding and high technological prestige. Technology leaders focus on the research and development of mature technology and maintain leading positions in the industry. These companies are often considered as the sources of knowledge spillovers in the industry. IBM, TI and Intel are examples that are considered as technology leader in the semiconductor industry in this study.

- Technology brokers: Companies in the second quadrant have low technological crowding but high technological prestige. These companies tend to focus on the development of innovative and unexplored fields. For instance, Semiconductor Energy
Lab., NEC and Philips are representatives of technology brokers in the semiconductor industry in this study.

- Technology followers: Companies in the fourth quadrant have high technological crowding but low technological prestige. Technology followers focus on the development of mature technology but rarely have innovative contributions to the industry. Cypress Semi, VLSI Technology and Integrated Device Technology are typical technological followers in the semiconductor industry.

- Technology isolated companies: Companies in the third quadrant have both low technological crowding and low technological prestige. Their development area is out of the ordinary, and they either focus on advanced technology that has not been yet been adopted by the industry, or out-of-date technology that is no longer being used, Eastman Kodak and Analog Devices represent technology isolated companies in this study.

Roles of Companies in the Industry Chain

In order to investigate knowledge spillovers in the semiconductor industry at the organization level, we further group companies by their role in the semiconductor industry chain. This way, we can examine the differences between a company’s strong ties and weak ties of knowledge spillovers based on their different roles in the industry chain.

Five common roles of companies in the semiconductor industry can be elaborated as follows:

1. Integrated Device Manufacturer (IDM): These companies are capable of vertical integration. That is to say, IDMs have capabilities in IC design, manufacturing, packaging, testing and selling of wafers. In addition, some of the IDMs release residual wafer to IC design companies, creating the IDM-Foundry business model. For instance, Micron Technology, Samsung and IBM are IDM companies.

2. IC design: These companies only design and sell wafers and do not have equipment or utilities for wafer manufacturing. They can be regarded as fabless companies in the semiconductor supply chain. They outsource packaging, testing and other work to professional wafer manufacturers and packaging & testing companies. Semiconductor Energy Lab., Sun Microsystems and IMEC are IC design companies examined in this study.

3. Foundry: These companies have professional equipment and technologies in wafer production and they mainly produce wafers for their clients. TSMC, UMC and GlobalFoundries are representatives of foundries.

4. Packaging & testing: These companies possess equipment for wafer packaging and they primarily package and test a variety of wafers for their clients. Packaging is an activity that leads the function signal on the chip to external circuits through a carrier and provides protection against impact and corrosion. There are two stages of testing—before and after packaging. It is essential to test chips to verify the quality of the product. ASE, STATS ChipPAC and Amkor are semiconductor packing & testing companies discussed in this study.

5. IC Equipment: Providers of equipment and devices for semiconductor manufacturing, chip packaging and testing. Applied Materials, Shin-Etsu Chemical and Agilent Technologies represent IC equipment companies in the semiconductor industry chain.

Results

The Involvement of Knowledge Spillovers based on the Different Technology Positions and the Different Roles of Companies in the Industry Chain

First, we observe the shares of the different technology positions among the companies and further explore the differences based on their positions in the knowledge spillovers network. When a company’s position is more central than the others, it has a higher degree of knowledge...
spillovers in the network and more knowledge spillover relations when compared to other companies. Table 1 is the proportion and number of companies based on the different technology positions, divided by three periods. The total number of companies during the 6-inch, 8-inch and 12-inch wafer periods are 129, 194 and 292, respectively. Examining the proportion of companies according to their technology positions, technology isolated companies count for more than 50% across all three periods. Technology followers come next at around 27% and increase to 35% during the 12-inch wafer period. Technology leaders only account for 13% and decrease to less than 10% in the 12-inch wafer period. Last, technology brokers account for the least share, at only 1% during the 6-inch and 12-inch wafer periods and 6% in the 8-inch wafer period.

Second, we observe the proportion of companies based on their different roles in the industry chain. This is followed by an investigation of the differences in the knowledge spillovers networks based on the roles of companies in the industry chain. Table 2 presents the proportion and number of companies based on the six roles in the industry chain across three periods. Companies that are classified as “Others” account for the largest share, which comprise 29% of all companies during the 6-inch and 8-inch wafer periods and rise to 32% in the 12-inch wafer period. IDMs are the second largest group, which account for 37% during the 6-inch wafer period and fall to 22% during the 12-inch wafer period. IC design companies account for 13% in the 6-inch wafer period and slightly rise to 21% during the 12-inch wafer period. The proportions of foundries and packaging & testing companies slightly increased from the 6-inch to the 12-inch wafer period, but neither type of company comprises over 10% of the total share. IC Equipment companies show a decreasing trend from the first to the last period, accounting for 7% to 5% of all semiconductor companies.

Knowledge Spillovers from Companies with Different Technology Positions over Time

By examining the network diagrams during the three periods, we can examine the performance of knowledge spillovers of companies based on their different technology positions. Technology leaders gradually moved to central positions in the network from the 6-inch to the 12-inch wafer period. By contrast, the network positions of technology brokers have decentralized over the three periods. As for technology followers and technology isolated companies, only a few companies occasionally move close to the center of the network.

We conduct an ANOVA to test the network centrality values of companies grouped by technology position over three periods. Table 3 shows the results of a multiple comparison analysis of network centrality between companies with different technological positions; only significant post-hoc test results are presented. In both strong ties and weak ties of knowledge spillover networks, the involvement of technology leaders are significantly higher than both technology followers and technology isolated companies. In other words, technology leading companies connect to more companies through the strong ties and weak ties of knowledge spillovers during all three periods. Secondly, technology brokers have significantly higher involvement and more connections through strong ties and weak ties of knowledge spillovers than technology followers or technology isolated companies during the 8-inch wafer period.

</tbody>
</table>

Note: L=Technology Leaders, B=Technology brokers, F=Technology followers, I=Technology Isolated Companies. The mean difference is significant at the .05 level.

Table 4 shows the results of a multiple comparison analysis testing the average number of connections between one type of company and another based on technological position; only significant post hoc test results are presented. Between the four types of companies, there are a total of 10 possible pairings in the undirected strong ties network and a total of 16 pairings in the directed weak ties network. Thus, we can examine which two types of companies tend to connect to each other in the knowledge spillover networks. The results indicate that all four types of companies tend to make more connections with technology leaders through both strong ties and weak ties in the network, while a significantly lesser number of connections exist between their pairings with the other three types of companies. Technology brokers also make significantly more connections with other companies, especially when compared to technology followers or technology isolated companies during the 6-inch and 8-inch wafer periods.

Knowledge Spillovers from Companies with Different Roles in the Industry Chain over Time

Through observation of the network diagrams over three different periods, we can understand the knowledge spillover performance of companies based on their different roles in the industry chain. IDM's were located at central positions in the network during the 6-inch and 8-inch wafer periods, while foundries began to appear in central positions in the 8-inch wafer period. By the time of the 12-inch wafer, the central positions in the network were mostly occupied by IDM's and foundries. As for IC design companies, packaging & testing companies, IC equipment companies and others, there are a few companies that occasionally approach the central positions of the network. Table 5 shows the results of a multiple comparison analysis of network centrality between companies with different roles in the industry chain; only significant post-
hoc test results are presented. Firstly, considering the strong ties and weak ties of knowledge spillovers, the network centrality of IDM s are significantly higher than IC design companies, foundries, IC equipment companies and others. That is to say, IDMs make more connections through both strong strong ties and weak ties of the knowledge spillover network with other companies than the other five roles in the industry chain during the three periods. Secondly, foundries participate in knowledge spillover activities mostly through strong ties in the 6-inch wafer period. Lastly, the knowledge spillover activities of others are significantly higher than packaging & testing companies through weak ties in the 8-inch period.

Table 6 represents the results of a multiple comparison analysis testing the average number of connections between one type of company and another based on their roles in the industry chain; only significant post hoc results are presented. There are a total of 21 possible pairings in the undirected strong ties network and 36 possible pairings in the directed weak ties network. This way, we can examine which two categories of companies more frequently link to each other in the different types of knowledge spillover networks. The results show that through the strong ties of knowledge spillovers, IDMs on average make significantly more connections with other types of companies than those with the other five roles in the industry chain. During the 6-inch wafer period, IDMs and IC design companies built significantly more R&D connections with IDMs than companies with other roles in the industry chain. In the 8-inch wafer period, IDMs, IC design companies and other companies all had significantly more R&D cooperation activities with IDMs than that with other types of companies. Moving to the 12-inch period, all
types of companies excepting IC equipment companies had a significantly higher number of connections with IDMs than with the other roles in the industry chain.

Next, results from the weak ties of knowledge spillovers show that IDMs are on average significantly more likely to be the receivers of knowledge spillovers than the other types of companies. In the 6-inch wafer period, IDMs received significantly more connections from other IDMs than from other roles in the industry chain. During the 8-inch wafer period, a significantly higher number of weak ties flowed from IDMs, IC equipment companies and other companies to IDMs than from other types of companies. Entering the 12-inch wafer period, all types of companies had significantly more knowledge spillovers through weak ties to IDMs than to other roles in the industry chain. Furthermore, the number of weak tie relations was significantly higher from foundry to foundry, from IC design companies to foundries and to other IC design companies, and from packaging & testing companies to other packaging & testing companies.

**Conclusions**

*Technology Leaders are the Main Receivers of Semiconductor Knowledge Spillovers among all Technology Positions*

This study analyzed the differences between types of receivers of knowledge spillovers using four categories of technology positions in the semiconductor industry. We found that technology leaders are the major receivers in both the strong ties and weak ties of knowledge.
spillover networks during all three periods. Particularly, semiconductor knowledge spilled through strong ties between all types of companies and technology leaders, except for that of technology isolated companies during the 6-inch and 8-inch wafer periods. As for the weak ties network of knowledge spillovers, knowledge primarily flowed from other types of companies to both technology leaders and technology brokers during the 6-inch and 8-inch wafer periods. Technology leaders became the major receivers of knowledge through the weak ties of knowledge spillovers by the time of the 12-inch wafer period. However, the knowledge significantly flows out from all types to leaders, it not means leaders’ R&D depends on other types.

*IDMs and Foundries are the Major Receivers of Knowledge Spillovers in the Semiconductor Industry among all Roles in the Industry Chain*

In order to discuss the different types of knowledge spillover receivers in the semiconductor industry, this study divided companies into six categories based on their roles in industry chain. The results show that IDMs are the primary receivers in both the strong ties and weak ties of knowledge spillovers networks over the three wafer diameters periods. In addition, foundries have become major receivers of both strong ties and weak ties of knowledge spillovers during the 8-inch and 12-inch wafer periods. Focusing on the 6-inch wafer period, IDMs were the dominant participants of R&D activities in the semiconductor industry, while IC design companies and foundries accounted for only a very small fraction of knowledge spillover connections. However, foundries have increased in importance due to the specialization and division of labour within the semiconductor industry. By the time of the 12-inch wafer period, several IDMs have outsourced all of their wafer production to foundries and have thus transformed to purely IC design companies. Reflecting such trends, which include the increase in participation of foundries and the role transformation of IDMs, the recipients of semiconductor knowledge spillovers have changed as well. The division of labour within the semiconductor industry is dynamic, and many IDMs have converted to fabless companies; in other words, their roles have gradually transformed to professional IC design in the industry chain. Hence, the relationship between IDMs and other companies with different roles in the industry chain have also transformed from competitive to cooperative. Moreover, we may conclude that the relationship between IDMs and foundries are getting closer based on the increasing number of knowledge spillover connections between each other.

*Overseeing the Strategy of Semiconductor Technology Development from the R&D Dynamics of Technology Leaders*

This paper measures the involvement of companies in knowledge spillover activities and concludes that technology leaders are located in central positions in the network among all different technology positions. IDMs and foundries are major participants in semiconductor technology research and development among companies with various roles in the industry chain. Technology leaders, IDMs and foundries all have high involvement in both strong ties and weak ties of knowledge spillovers, and play the role of knowledge providers in the semiconductor industry. As a result, we suggest that interested parties may monitor the technology developments of an industry by filtering out companies that are both technology leaders and IDMs or both technology leaders and foundries, to be used as references in the formulation of R&D strategies.

*The Relationship between Foundries and IDMs have changed from Vertical Outsourcing to Horizontal Cooperation*

The rise of foundries is due to the need to compensate for the insufficiencies in production capabilities of IDMs. As the semiconductor industry evolved into highly specialized divisions
of labour, many IDM s have transformed into fabless companies and focus on their expertise in IC design. AMD is one representative of such transformation. On the other hand, foundries have become in charge of R&D in wafer production. This study found that beginning in the 8-inch wafer period, foundries have become one of the major receivers of strong ties and weak ties of knowledge spillovers, second to IDMs. In other words, foundries have become major participants in the strong ties and weak ties of knowledge spillovers. We can further observe that in 12-inch wafer period, the patent count of TSMC (a foundry) has reached AMD (an IDM) in our case study. What is more, the involvement of TSMC in the strong ties of knowledge spillovers is even higher than IDMs such as AMD and Samsung. Hence, we conclude that the relationships between foundries and IDMs are no longer vertical contract manufacturing but horizontal R&D cooperation.

Suggestions for Future Research
This research applied two indices—technological crowding and technological prestige to further divide semiconductor companies into technology leaders, technology brokers, technology followers and technology isolated companies. As the development of wafer diameters increases, the technology position of a company might change. In the analysis of the changes in a company’s technological position, we suggest to not only compare a company’s technological position with its role in the industry chain, but to also examine the differences of performances between companies whose technological positions have changed with those whose technological positions remained unchanged. Thus we may more fully investigate how the variation in technological positions may influence the performance of companies in knowledge spillovers activities.

Abstract
Both direct citation and Bibliographic Coupling (BC) are valid tools in detecting similarity or relatedness among patents. This study is then motivated by the question: what is the difference between a direct citation and a strong BC but without direct citation? We found that the latter, referred to as missing link here, seems to be useful in capturing the technology relatedness among patents filed or issued at close times where direct citations are less likely to be established. We then applied the Main Path Analysis to a patent citation network involving 38,652 patents/publications, 188,721 direct citations, and 9,213 missing links, and derived two main paths with and without the missing links added. By comparing these main paths, we found that the missing links, merely accounting for less than 5% of all connections in this case, may identify a series of intermediate and related patents reflecting elaborative evolvement, which may well be overlooked when only direct citations are considered.

Conference Topic
Patent analysis

Introduction
A first patent is cited or referenced by a second, subsequent patent because the applicant of the second patent considers that the first patent provides, addresses, or discloses similar or related technical background, issue, or solution. The first patent may also be cited by the examiner of the second patent as the first patent may challenge the patentability of the second one, in addition to those reasons by the applicant.

Patent citations have long been accepted as having high bibliometric value (cf. Hall, Jaffe, & Trajtenberg, 2005; Jaffe, Fogarty, & Banks, 1997; Trajtenberg, 1990). In many applications, they are assumed to have revealed the similarity or relatedness between patents.

A representative research area based on the above assumption is the knowledge or technology spillover where knowledge flow between similar or related patents associated with different geographic areas or industries is observed. Here we list a small number of studies in this area published after 2013, demonstrating that utilizing patent citations as a proxy for knowledge flow is a widely accepted approach. Murata et al. (2014) confirmed knowledge spillover are significantly localized using cited-citing relationships between U.S. patents granted between 1975 and 1999. Figueiredo, Guimarães, and Woodward (2015) found that knowledge spillover is positively correlated with industry localization and that the localization of an industry may offset the adverse effect of distance, using a set of cited-citing pairs of U.S. patents. Li (2014) studied the effects of distance and subnational/national borders on international and intranational knowledge spillovers through patent citations across some most cited countries and metropolitan statistical areas within U.S. and claimed that border and distance effects increase over time, but fade as patents age. Karvonen and Kässi (2013) collected patent data from main players of the radio-frequency identification (RFID) value chain in EPO database,
and used citation data to investigate the emergence of new industry segment. Kim, Lee, and Sohn (2016) quantified the spillover of unmanned aerial vehicle (UAV) technology to various industries by retrieving U.S. patents that cited UAV patents and matching these citing patents to industries. Noailly and Shestalova (2017) used citations of European patents to see what technologies are built on the knowledge developed in renewable energy.

Researchers have been comparing applicant-submitted references (hereinafter, applicant citations) and examiner-located references (hereinafter, examiner citations) for their difference. Criscuolo and Verspagen (2008) found that examiners more often provide citations that may compromise patentability, and that applicants tend to ignore prior art that may endanger their patent applications. Hegde and Sampat (2009) found that examiner citations are better value indicator as they have a much stronger relationship with patent renewal probability than the applicant citations do. Cotropia, Lemley, and Sampat (2013) argued that patent examiners rely almost exclusively on prior art they find themselves, instead of applicant citations, in rejecting patent applications or in limiting patent scopes. In contrast, Thompson (2006) indicated that applicant citations are more relevant as applicants are more familiar with their inventions than the examiners are. Alcacer, Gittelman, and Sampat (2009) suggested that applicant citations express knowledge flows better than examiner citations. Park, Jeong, and Yoon (2017) found that the patents cited by applicants have higher quality than those cited by examiners in four industries.

A patent citation, whether it is from the applicant or the examiner, indeed reflect a connection between the cited and the citing. The difference seems to lie only in the degree of similarity, relatedness, or how much knowledge indeed flows from the cited to the citing. What intrigues us here is not the origin of the citation, but the absence of direct citation between two seemingly related patents.

The “missing” citation

In addition to the utilization of direct citations outlined above, another approach in detecting or measuring the similarity or relatedness between two documents or patents is Bibliographic Coupling (BC). Two documents or patents are bibliographically coupled if they both cite at least one common reference. The Bibliographic Coupling Strength (BCS) represents the number of common references. Kessler (1963) proposed the concept Bibliographic Coupling and used it to measure subject similarity. The concept then quickly drew significant interest from researchers. Various applications have been designed and we listed a small number of publications in using BC to detect or measure the similarity or relatedness of patents as follows. Wartburg, Teichert, and Rost (2005) proposed a multi-stage patent citation analysis for the measurement of inventive progress using BC. Park et al. (2015) used BC to measure technological similarity in the fuel cell membrane electrode assembly technology so as to locate potential R&D collaboration partners. Huang and Chang (2014, 2015) applied BC with sliding window to track the generation, growth, decline, and disappearance of research fronts.

If both direct citation and BC reflect the similarity or relatedness between two patents, it is interesting to notice that sometimes there is no direct citation between two patents that are strongly bibliographically coupled.

Taking two U.S. utility patents, US8,622,222 and US8,623,202 as an example, they are both related to membrane bioreactor technologies, were both filed by the same company, one in January 2011 and the other October 2012, but with different inventors. They were both granted
within January 2014 (therefore, their patent numbers are very close) after being examined by different examiners. The two patents do not have direction citation between them, but their similarity is clearly reflected by their exceptionally high BCS 1,039 (US8,622,222 has total 1,109 references and US8,623,202 has 1,108 references).

Taking another two more distant U.S. utility patents, US8,585,882 and US9,586,842, as an example, they are both related to water treatment, but filed by different companies, one in December 2008 and the other December 2015. They are granted in November 2013 and March 2017, respectively, by different examiners. The two patents do not have direction citation, but their similarity is also clearly reflected by their high BCS 465 (US8,585,882 has 558 references and US9,586,842 has 622 references).

The term missing link is often used loosely to describe a newly found evidence indicating a possible evolution path between a predecessor and a successor such as a new piece of fossil manifests a possible ancestor to the human lineage. We borrowed the term here to denote this latent connection between patents suggested by their strong BC.

Some researchers had already noticed the occurrence of missing links and made use of them. Chen et al. (2011) used missing links to construct more comprehensive technological clusters using light emitting diode (LED) as a case study. Yeh et al. (2013) took one step further by filtering out direct citations between patents with weak BC, in addition to incorporating missing links into a patent citation network.

Why do missing links occur? One possible explanation for the lack of direct citation is that applicant citations or examiner citations are by no means exhaustive, and it is surely possible that the applicant or examiner of one patent fails to learn or discover the presence of the other.

On the other hand, Chen et al. (2011) calculated the time lags for missing links and found that, for a majority of them (65.52%) in their case study, one has application date before the other’s issued date (i.e., their application processes are overlapped in time). The authors then argued that the later patents’ applicants at the times of filing could not be aware of and cite the earlier ones since information about the earlier ones was not available to the public then.

We are then motivated by the question: what is the difference between a direct citation and a strong BC but without direction citation? Prompted by Chen et al. (2011), the answer seems to lie in the timing characteristics of missing links, and an empirical study was conducted for this purpose.

**Empirical Data**

We chose the technical area of carbon dioxide (CO₂) capture, storage, recovery, delivery, and regeneration as our empirical case. We collected the related utility patents and their references (including U.S. patents and publications) all issued or published after 1976 and before 2017/03/28 from USPTO database. These patents/publications have at least one of some specific keywords in at least one of the relevant fields (i.e., title, abstract, specification, and claims) and also have at least one of some specific Cooperative Patent Classification (CPC) symbol prefixes. There are then total 38,652 patents and publications with 188,721 pairs having direct citations and 1,609,549 bibliographically coupled pairs.
The 1,609,549 BC pairs have a significantly skewed BCS distribution with a mean 2.74 (μ), a standard deviation 15.66 (σ), and a maximum 1,123. Among them, 1,477,783 pairs, accounting for 92% of all BC pairs, have BCS not greater than 3 (the closest integer to the mean BCS). Since missing links do not actually exist, we decided to be conservative and considered only BC pairs having BCS greater than 34 (=μ+2σ). There are only 13,013 such pairs, accounting for only 0.81% of all BC pairs. We then further removed 3,800 of them that already have direct citations. Finally we were left with as few as 9,213 (=13,013-3800) BC pairs having a range of the BCS between 35 and 1,123. The BCS distribution of these BC pairs is shown in Figure 1. A great majority of the BC pairs (8,674 or 94%) have BCS less than or equal to 300.

![Figure 1. The BCS distribution of the 9,213 BC pairs (vertical axis is in log scale).](image)

Figure 2 shows the distributions of time spans between the filing dates (in lighter bars) and between the issued dates (in darker bars) for the 9,213 BC pairs. As illustrated, 58% of the 9,213 BC pairs have filing date differences fall within 2 years, and 65% have issued date differences fall within 2 years. Then, as the time span between patents’ filing and issued dates increases, it seems that they are less likely to form strong BC pairs as manifested by the BC pairs’ decreasing trends to the right shown in Figure 2.

This seems to confirm the observation of Chen et al. (2011) that, if two patents are filed or issued within a short time span, their applicants or examiners are more difficult to be aware of each other, as both patents may remain undisclosed before filing or remain pending in the patent office before issuance.

Overall, the above observation seems to suggest that the missing links would be most useful in capturing those technology relatedness among patents where they are filed or issued at close times and where direct citations are less likely, in not impossible, to be established.

To further investigate whether our speculation is reasonable, we conducted the so-called Main Path Analysis for our empirical case.
Main Path Analysis

Main Path Analysis (MPA) was first taught by Hummon and Doreian (1989) to discover the major development trajectory of a scientific field through identifying the most significant chain of citations in a citation network. This method generally involves the following steps: (a) constructing a citation network from relevant documents of the scientific field; (b) calculating a weight for each link of the citation network related to the link’s traversal counts; and (c) searching for a series of connected links across the network according to their weight. This series of links is then referred to as the main path of the scientific field, and considered as having embodied a development trajectory of the field.

Since its inception, researchers have been applying this method in, for example, detecting technological changes, knowledge transformation (Lucio-Arias & Leydesdorff, 2008; Martinelli, 2012; Mina et al., 2007), and reviewing literatures (Bhupatiraju et al., 2012; Calero-Medina & Noyons, 2008; Colicchia & Strozzi, 2012; Harris et al., 2011; Liu et al., 2013; Lu, Hsieh, & Liu, 2016). The same method is also applied to patent citation networks in mapping technological evolvements (Fontana, Nuvolari, & Verspagen, 2009; Park & Magee, 2017; Verspagen, 2007). MPA capability is built in the well-known network analysis application Pajek (Batagelj & Mrvar, 1998).

The rationale of MPA is to consider each link of the citation network as a path of knowledge flow from the cited to the citing. Then, an algorithm is applied to determine a weight for each link related to the number of times the link is traversed. For example, Figure 3 is a fictitious citation network where the link weights are determined using the algorithm Search Path Link Count (SPLC) (Hummon & Doreian, 1989). The weight of the link 5→6 (i.e., from node 5 to node 6) is 15, because it counts the number of traversals of the link 5→6 from all preceding nodes (1 to 5) to the sink nodes (7, 8, 9). Similarly, the weight of the link 6→7 is 6 because there are 6 preceding nodes (1 to 6) and each traverses the link 6→7 once to reach the sink node 7.
There are other algorithms for weight calculation such as SPC (search path count) (Batagelj & Mrvar, 1998), SPNP (Search Path Node Pair) (Hummon & Doreian, 1989), etc. These algorithms all determine the weight solely based on the topological location of the link, and a link would have a greater weight if it can be reached from more nodes or more nodes may be reached through it. The link weight based on the traversal count therefore functions as a proxy to the total amount of knowledge flow through the link.

There are also different methods in determining the main path once the link weights are set. The main path of Figure 3 is denoted by black nodes using global search method (Liu and Lu, 2012) which selects a path with the greatest total weight from source to sink nodes. The local search method starts from the source or sink nodes and selects the link(s) from/to the source/sink nodes with the greatest weight(s) and works forward/backward for the next search until a sink/source node is reached (Hummon & Doreian, 1989). The key-route method (Liu and Lu, 2012) determines one or more main paths by locating the link(s) with the greatest weight first and tracing backward and forward until a source or sink node is reached.

By treating missing links as real citations and applying MPA, we are able to see whether the missing links would lead to any difference in the resulted main path. We then may gain some insight into the effect of missing links if some major difference does occur.

Main Paths
A patent citation network (PCN) was constructed out of our empirical case and involved 38,652 nodes and 188,721 arcs. We then adjusted the original patent citation network (OPCN) by incorporating 9,213 missing links as real citations. Each missing link always originates from the lower numbered patent to the higher numbered patent. As there are 188,721 links in the OPCN, these missing links account for only 4.6% (=9,213/ (188,721+9,213)) of the links of the adjusted citation network (APCN).

In determining the main path, we chose to use the SPLC algorithm in calculating the link weights as prior researches had reported that algorithms SPC, SPLC, SPNP, etc. all derive similar results (cf. Batagelj, 2003; Verspagen, 2007). Further, we chose to use the global search method (Liu & Lu, 2012) in developing the main path. The key-route method is a recent variant to the MPA, but it will usually produce more than one main path. To simplify the comparison, we therefore chose the global search method as it will usually produce a single main path having the globally greatest total weight.
