Abstract:

Twin researchers face the challenge of accurately determining the zygosity of twins for research. As part of the annual questionnaire between 1999 and 2006, 8,307 twins from the TwinsUK registry were asked to complete 5 questions (independently from their co-twin) to ascertain their self-perceived zygosity during childhood on up to 5 separate occasions. This questionnaire is known as the “peas in the pod” questionnaire (PPQ) but there is little evidence of its validation. Answers were scored and classified as monozygotic (MZ), dizygotic (DZ) or unknown zygosity (UZ) and were compared with 4,484 twins with genotyping data who had not been selected for zygosity. Of these, 3,859 individuals (46.5% of those that had a zygosity from PPQ) had zygosity classified by both the PPQ and genotyping.

Of the 708 individual twins whose answers meant that they were consistently classed as MZ in the PPQ, 683 (96.5%) were MZ within the genotype data. Of the 945 individual twins consistently classed as DZ within questionnaire, 936 (99.0%) were DZ in the genotype data. Where both twins scored MZ consistently across questionnaires, 99.6% were MZ on genotyping; 99.7% were DZ on genotyping if both twins consistently scored DZ. However, at initial questionnaire 88.6% of those scoring as MZ were genotypically MZ and 98.7% DZ. For twin pairs where both scored UZ, 94.7% were DZ. Using the PPQ on a single occasion provided a definitive classification of whether the twin was monozygotic or dizygotic with an overall accuracy of 86.9%, increasing to 97.9% when there was a consistent classification of zygosity across multiple questionnaires.

This study has shown that the “peas in the pod” questionnaire is an excellent proxy indicator of zygosity in the absence of genotyping information.
Zygosity assessment using peas in the pod questionnaire

**Introduction:**

A common misunderstanding, until relatively recently, was that the presence of two placentae at birth must mean that twins are non-identical or dizygotic (DZ) whilst one placenta meant that the twins are identical or monozygotic (MZ) (Ooki et al., 2004). Opposite sex twins are DZ, but there are issues arising when using this methodology to determine the zygosity of same sex twins. This meant that between 20-25% of MZ twins with two separate placentae were misclassified as DZ at birth, with approximately 9% of DZ twins with placental fusing wrongly classed as MZ (Ooki et al., 2004). As a result a number of twin pairs have grown to adulthood understanding that they are identical or non-identical when they are not. This misclassification of zygosity at birth has implications on not only the medical treatment of twins during gestation, after their birth and in later life, but also has personal implications on the twins who may grow up questioning their zygosity.

Within the scientific community, an essential component of any twin registry is the knowledge of the zygosity of the twins registered. There are a number of different methods of determining the zygosity in adult twins. These include self-report methods, for example asking the twins whether they are identical or non-identical, asking twins questions on how similar they are or were during childhood and growing up (Cederlöf et al. 1961, Sarna et al. 1978, Magnus et al. 1983, Bønnelykke et al. 1988, Ooki et al. 1989, Song 2010) or asking the parents to report on the similarity of twins (Peeters 1998).

Determination of zygosity by self-report raises concerns that misclassification may have occurred at birth by an authoritative medical professional. More reliable methods include testing by blood group (Cederlöf et al. 1961, Kasriel & Eaves 1976, Lykken 1978) or using genetic tests (Song 2010) but these may not necessarily be fast or cost-effective. Song et al used 16 short tandem repeat genetic markers and demonstrated that using questions about similarities during childhood provided a sensitivity of 98.8% for MZ twin pairs and 88.9% for DZ twin pairs.
Genotypic data is the “gold” standard for determining the zygosity of twins, but as this is costly and time consuming when testing a large scale study at one time, alternative methods of accessing zygosity are necessary, and as a result latent class analysis has been used with good success (Eaves et al. 1993, Heath et al. 2003).

The TwinsUK Adult Twin Registry started in 1992 (Spector & Williams 2006, Moayyeri et al. 2013, Moayyeri et al. 2013) and as with all twin registries, has faced the challenge of determining the zygosity of the twins. The aims of this study were to compare the accuracy of zygosity determined by a “peas in the pod” similarity questionnaire (the PPQ) for both single twins and twin pairs with the zygosity determined by genotype data, the “gold standard”, and to examine the consistency of responses when the PPQ is administered annually compared to initial self-report and PPQ.
**Materials and Method:**

Using a short similarity questionnaire used by the Australian Twin Registry as a basis (unpublished, and known as the peas in the pod questionnaire or PPQ), the TwinsUK registry has adapted this to be more specific to the cohort. Between 1999 and 2006, the TwinsUK registry asked same sex twins (aged 18 to 89 years of age) the PPQ (see S1) as part of their annual questionnaire. The accompanying instructions asked for the questionnaire to be completed by each twin separately to ensure that the twins were not influenced in the answers they gave by their co-twin. Written, informed consent was obtained from participants of the study and all procedures contributing to this work comply with the ethical standards in the Helsinki Declaration of 1975, as revised in 2008.

**Self-reported zygosity**

Upon registration with the TwinsUK registry, each twin was asked to report what they believed their zygosity to be. A total of 13,291 twins had provided a self-reported zygosity (age 18 to 84, mean age of 58; 10,796 (83%) were female, 2,226 were male and 269 had no gender assigned to them).

**Peas in the Pod Questionnaire (PPQ)**

The PPQ is a 5-item questionnaire on the degree of similarity between twins (Supplementary Material 1). It asks four questions based on whether at school-age people at school, parents, close-friends, or strangers had difficulty telling twins apart (0=yes, 1=don’t know, 2=no), and a fifth question whether the twins would be described during childhood as alike as two peas in a pod (0 points), as alike as ordinary siblings (2 points) or they didn’t know (1 point). Scores between 0 and 4 were classed as MZ; scores between 8 and 10 were classed as DZ and anything in between was scored as unknown zygosity (UZ), with each twin’s PPQ scored separately.

A total of 8,307 twins answered a PPQ zygosity (age 18 to 87, mean age of 51; 7,287(88%) were female and 1,020 were male) between 1999 and 2006.
Initial analysis looked at the zygosity provided from the first questionnaire asked and then the individual twins were matched to their co-twin. The second stage of analysis looked at all data collected from the PPQ between 1999 and 2006. The PPQ was scored separately for each questionnaire on 5 separate occasions so that the scores for each questionnaire and therefore the zygosity of the twin for each questionnaire were independent of the scores and zygosity from the other PPQ questionnaires.

To create an overall zygosity over time, individuals who consistently had the same zygosity for each of the questionnaires was scored as that zygosity (consistent answers of MZ meant an overall zygosity of MZ, consistent answers of DZ meant an overall zygosity of DZ and consistent answers of UZ meant an overall zygosity of UZ) and individuals who zygosity was inconsistent over time e.g. MZ in one questionnaire and DZ in another were scored as UZ.

The overall zygosity on an individual and paired basis was determined from all of the 5 PPQ questionnaires. If both of the twins had the same overall zygosity, they were scored as this zygosity (i.e. if both had an overall zygosity of DZ then the pair was scored as DZ) and if the twins disagreed within the pair, this was noted so that it would be possible to see which zygosity was correct after comparison with the zygosity determined via genotyping.

To determine the weight of each question within the PPQ, the final stage was to look at each individual question within the PPQ and score the answer to each question as MZ (if the answer scored 0), UZ (if the answer scored 1) and DZ (if the answer scored 2).

To assess the sensitivity of the PPQ, a standard true positive rate calculation was used and to assess the specificity of the PPQ, a standard true negative rate calculation was used.
**Genotype data**

As MZ twins share 100% of their segregating genes, only one MZ twin of a pair was routinely genotyped for GWAS, whereas both members of a DZ or UZ pair were genotyped.

TwinsUK samples were genotyped with the Infinium 317K and 610K assays (Illumina, San Diego, USA) at two different centres, the Wellcome Trust Sanger Institute and the Center for Inherited Diseases Research (USA) respectively. The normalized intensity data was pooled and the genotypes were called on the basis of the Illumina algorithm. No calls were assigned if the most likely call was less than a posterior probability of 0.95. Validation of pooling was done by visual inspection of 100 random, shared single nucleotide polymorphisms (SNPs) for overt batch effects; none were observed. We excluded SNPs that had a call rate <97% (SNPs with minor allele frequency (MAF) ≥5%) or <99% (for 1% ≤MAF< 5%), Hardy-Weinberg p values <10^{-6} and MAFs <1%. We, also removed subjects where genotyping failed for >2% of SNPs. The overall genotyping efficiency of the genome wide association (GWA) was 98.7%.

A total of 4,484 twins had zygosity determined via genotyping (age 20 to 90 mean age of 61; 4,136 (92%) were female and 348 were male).

We computed identity-by-descent (IBD) estimates for all available pair of twins (n=4,484 individuals) using the Plink (Purcell S 2007) option --genome on a set of 9357 SNPs (not in linkage disequilibrium, with a minor allele frequency > 20% and overlapping among all Illumina platforms available). For ambiguous cases, IBDs were subsequently recalculation by using all the SNPs available. We defined as MZ those twin pairs with a pi hat value < 0.9 and DZ the twin pairs with a pi hat value ranging between 0.4 and 0.6.

*The results from the PPQ*
Zygosity assessment using peas in the pod questionnaire

The PPQ has been used by the TwinsUK registry since the start of the registry in 1992, but for the purpose of this study, we concentrated on the data that was available over a 7 year period of time (between 1999 and 2006), where the PPQ was asked within the annual questionnaire on 5 separate occasions. It was possible to determine the zygosity for 8,307 individuals who had answered the PPQ on at least one occasion.

Results:

Since the start of the TwinsUK registry in 1992, 13,291 twins have provided a self-reported zygosity (including 6,644 complete twin pairs). Of these, 6,129 (46.1%) reported that they were MZ, 6,359 (47.8%) reported that they were DZ and 803 (6.1%) reported that they were UZ.

Zygosity from individual twins

Looking at the first PPQ answered by each twin separately, 4,038 (48.6%) individuals had scores that indicated that they were MZ, 1,645 (19.8%) provided answers that indicated that they were DZ and 2,624 (31.5%) were graded as UZ as they scored 5-7 on the PPQ (see figure 1).

Examining repeated PPQ’s, 3,562 (42.9%) of the twins consistently scored as MZ and 1,536 (18.5%) of the twins consistently were rated as DZ on PPQ scores. The remaining 3,209 (38.6%) of twins’ answers did not always result in the same grade (MZ, DZ, UZ) over time (n=3,062, 36.9%) or were scored consistently as UZ within the PPQ (n=147, 1.7%) see figure 1.

[Insert Figure 1 here]

Zygosity within twin pairs

From the 8,307 individuals who had answered the PPQ, there were 3,697 complete twin pairs (7,394 individuals). Of these, 1,387 pairs (37.5%) both scored that they were MZ, 480 pairs (13.0%) both scored that they were DZ and 1,150 (31.1%) both scored that they were UZ. The remaining 680 (18.4%) pairs could not agree on their zygosity. Of these 10 (1.5%) had one twin scoring as MZ and
the other twin scoring as DZ, 379 (55.7%) where one twin scored as MZ and the other twin as UZ and 291 (42.8%) where one twin scored as DZ and the other twin scored as UZ.

**Comparison of zygosity from the PPQ and genotyping data**

Of the 4,484 individuals from the TwinsUK registry with zygosity determined by genotype data, 994 (23.9%) were MZ and 3,162 (76.1%) were DZ. When the zygo
tility obtained from the PPQ was matched with the “true” zygosity from the genotyping data, there were 3,859 twins with zygosity for both methodologies which included 1,806 complete twin pairs (see figure 1).

**Zygosity from individual twins**

The zygosity from the first PPQ was matched with the genotyping data, 943 twins answered that they were MZ in the PPQ, of which 735 (77.9%) were MZ in the genotyping data. 1,101 answered that they were DZ, of which 1071 (97.3%) were DZ in the genotyping data. From the 1,811 twins that were UZ from their first PPQ, 1665 (91.9%) are DZ from the genotyping data (see figure 3). Using the zygosity obtained from the first PPQ proved to have 96.1% sensitivity and 83.7% specificity.

[Insert Figure 2here]

Comparing the overall zygosity from the PPQ and genotype data there were 3,859 individuals that had zygosity determined by both methodologies (providing coverage of 46.5% of the PPQ zygosity results) (see table 2). Using the overall zygosity obtained from all of the PPQ’s proved to have 98.6% sensitivity and 97.4% specificity.

[Insert Table 2here]

Seven hundred and eight individual twins consistently indicated that they were MZ in the PPQ, of which 683 (96.5%) were MZ in the genotype data. Nine hundred and forty five twins consistently indicated that they were DZ in the PPQ, of which 936 individual twins (99.0%) were DZ in the
genotype data. From the 2,206 twins that were classed as UZ from the PPQ, 1,987 (90.1%) were DZ in the genotype data.

The first time that the PPQ is completed by an individual twin and compared to the genotyping data, there is 77.9% accuracy if the score is MZ, 97.3% accuracy if the score is DZ and when the score indicates a UZ, there is a 91.9% chance that they are in fact a DZ twin. This accuracy increases to 88.6% for MZ and 98.7% for DZ when both twins’ scores indicate that they are MZ or DZ respectively.

**Zygosity within twin pairs**

Taking the answer from both twins from the first PPQ that they had answered showed that there were 343 pairs that both agreed that they were MZ, of which 304 (88.6%) were MZ in the genotype data. From the 390 pairs that both answered that they were DZ, 385 (98.7%) were DZ in the genotyping data (see figure 2).

[Insert Figure 3 here]

For twin pairs where it was not possible to determine the zygosity, 703 had both scored as UZ and 666 (94.7%) of these were DZ from the genotype data and 370 did not agree on their zygosity, of which 296 (80%) were DZ in the genotype data.

Looking at the overall PPQ scores from all questionnaires, there were 274 twin pairs where both scored as MZ consistently, of which 273 (99.6%) were MZ in the genotype data. From the 312 twin pairs where both twins consistently scored as DZ within the PPQ, 311 (99.7%) were DZ in the genotype data. There were 901 twin pairs where it was not possible to ascertain the zygosity of either twin from the PPQ (both twins scored UZ, 5-7 points). From these UZ pairs, 837 (92.9%) of the twins were DZ in the genotype data (see table 3).

[Insert Table 3 here]
There are a number of twin pairs, where only one twin had scored as a consistent zygosity within the PPQ over time. When one twin consistently scored as MZ in the PPQ and the other twin as UZ, comparison with the genotype data showed that the MZ twin score was correct on 87.8% occasions. When one twin consistently scored as DZ in the PPQ over time and the other twin as UZ, comparison with the genotype data showed that the DZ twin score was correct on 99.1% occasions.

**Weighting of the individual questions within the PPQ**

The answer for each question within the questionnaire was scored as MZ, DZ or UZ and compared with the result on zygosity obtained from the genotyping.

For determining both MZ and DZ twins (see figure 4), the most accurate question is question “e) In childhood, which of the following would best describe you and your twin”. This had an accuracy of 92.5% for MZ twins and an accuracy of 97.2% for DZ twins when compared to the genotyping data. The least accurate question for MZ twins was question “a) At school, did people have trouble telling you apart?” with an accuracy of 48.5% and for DZ twins question “b) Were your parents able to tell you apart?” with an accuracy of 80.3%.

These results suggest that it is possible to ascertain the zygosity of both MZ and DZ twins using just one question “e) In childhood, which of the following would best describe you and your twin” with the possible answers being “As alike as two peas in a pod”, “Ordinary sibling likeness (Like sisters or brothers) and “I don’t know” (see Supplementary Material 1).

[Insert Figure 4here]

**Comparison between self-reported zygosity, zygosity from PPQ and genotyping data**

Eighty-eight percent of the twins self-reported that they were MZ at registration were also MZ within the first PPQ that they answered (see figure 5). Eighty two percent of those that self-reported MZ’s remained MZ for the overall zygosity and 95.9% of those that self-reported as MZ remained as
MZ within the genotyping data. However, reporting that they were DZ at registration did not appear to be as consistently accurate as 36.3% were DZ within the first PPQ that they answered; 34.3% were DZ with the overall zygosity from all of the PPQ’s that they answered. However, 94.4% of those that had self-reported as DZ were also DZ within the genotyping data.

[Insert Figure 5 here]
Zygosity assessment using peas in the pod questionnaire

**Discussion:**

It may well be that the historical misclassification of zygosity according to number of placentae explains the discrepancies between the self-report zygosity and genotyping results, particularly in our cohort of twins born before human genomic testing was practical. 95% of individuals who self-reported as MZ and 94.4% as DZ had their zygosity confirmed by genotyping. In addition to self-report data, the TwinsUK registry has used the PPQ as an initial indicator of zygosity, and in the main now has the luxury of genetic techniques to confirm the zygosity of a twin pair. *Traditionally, genetic determination of zygosity has been seen as costly, particularly in large-scale research studies. However, with the reduction in costs of genotyping in recent years, it is not expensive when compared to the pregnancy and childbirth costs of twin pregnancies. We would certainly advocate routine genotypic testing of twins at birth, to allow families to have definitive zygosity ascertained.*

Interestingly, although the PPQ was designed to improve classification of zygosity from self-report, the score obtained from the first time that the PPQ is answered appears to be less predictive of true zygosity - only 77% who were scored from PPQ as MZ were confirmed as MZ from the genotyping data, compared to 97% genetically confirmed as DZ from those who were scored as DZ.

*Indecision about zygosity in questionnaire studies has previously been suggestive that twins are likely to be dizygotic (Kasriel et al. 1976). Our results are similar which show that 92.9% of twins whose answers scored as unknown zygosity on multiple questionnaires were found to be dizygotic. This percentage is higher than a previous study where both twins answered as unknown zygosity (Song 2010) and could be explained by the fact that participants in our study were asked to complete multiple questionnaires over which may have increased the accuracy of the results. Eighty-eight percent of twin pairs who answered differently to each other were found to be dizygotic. As the questionnaire was asked on several occasions, participants in our study were instructed not to confer with their fellow twin about their perceived zygosity so as not to influence their answers, and we did not ask them to come to any pair-wise decisions on zygosity.*
There is variation in the literature about the accuracy of questionnaire-based zygosity. In agreement with our study, some studies confirm DZ more frequently than MZ on questionnaire (Peeters 1998). However, other studies confirm MZ more than DZ (Cederlöf 1961). Whilst questionnaires used in different studies contain similar components, there is no standardized questionnaire used between studies, which may account for some of the differences. Also, older studies used techniques such as blood group to determine zygosity, which may be less accurate than modern genotyping technologies which have near 100% accuracy (Chen 2010). As discussed in the introduction, it may be that our particular twin population, on average born in the 1950’s, was misinformed about zygosity due to misinformation from midwives/doctors based on numbers of placentas. Finally, there may be a bias that often only one of the pairs who were consistently MZ on PPQ was genotyped, reducing the numbers of MZ pairs who would likely have been confirmed by genotyping.

The single question “In childhood, which of the following would best describe you and your twin?” where the answer was “As alike as two peas in a pod” or “Ordinary sibling likeness (like sisters or brothers)” was more predictive of the “true” zygosity of the twins compared to the overall score obtained from all of the questions from the PPQ. The accuracy of the peas in a pod questionnaire in our study was found to be 92.5% and 97.2% for MZ and DZ twins respectively. This is very similar to results from Peeters’ (1998) study which showed an accuracy of 92.8% and 97.1% for MZ and DZ twins respectively. The highly reproducible results give weight to the validity of the peas in a pod question in accurately diagnosing zygosity.

This study has demonstrated that consistency of the response to the same set of questions, administered over a period of several years demonstrated even stronger predictability and that this response represents the “true” zygosity. When both of the twins in the pair consistently agreed that they were MZ or DZ, the responses were their “true” zygosity in 99.6% and 99.7% of twin pairs respectively. 95% of individuals who were categorised as UZ across longitudinal PPQs, or whose
category changed across time, were DZ when genotyped. There are a number of limitations and biases present within this study. The study may not be generalizable to other twin populations as there is a high proportion of females within the TwinsUK cohort and a relatively older age of mean 61 years compared to other cohorts. *The TwinsUK Cohort (Moayerri 2013) is predominantly female (~80%) as historically the initial focus of the study was osteoporosis and so middle-aged female twin pairs were recruited from 1992; despite subsequent inclusion of men, like many twin cohorts there is a female volunteer bias.*

They were born in the United Kingdom and so represent the cultural norms of their society and knowledge about twinning, and may be biased in that they are volunteers in a research cohort.

A further bias might occur through the fact that the questionnaire was asked on five separate occasions. Comparisons between the first time answering the questionnaire and the overall result after answering multiple questionnaires have shown that repeating the PPQ is more accurate than asking on a single occasion, but there is however the risk that the twins “learnt” their true zygosity and therefore the answers for questionnaires completed after this subsequently are a more accurate representation of their “true” zygosity.

We have been able to compare the zygosity determined by the PPQ questionnaire with the zygosity determined via (GWAS) genotyping in a large number of twins (n=3,859), but a possible limitation is due to the fact that only one twin was sent for genotyping from twin pairs that were thought to be MZ and both twins were sent for genotyping from twin pairs that were thought to be DZ. This means that there are fewer MZ twin pairs with genotyping data, *resulting in a greater number of DZ pairs than MZ pairs available for comparison with the PPQ zygosity data. Despite this we still had genotypic data on over 340 MZ twin pairs who self-reported as MZ.*

Using data from adult twins in the TwinsUK cohort, we have validated the PPQ as an excellent proxy indicator of zygosity. In particular, if an initial PPQ from both twins scores as DZ, they are 98.7% likely to be DZ on genotyping (and 99.1% likely if one scores DZ and the other UZ). While only 88%
Zygosity assessment using peas in the pod questionnaire

of pairs where both initially scored MZ were truly MZ, this improved to 99.6% of pairs where they consistently scored MZ on serial PPQs. The single “alike as two peas in the pod” question was most discriminatory (92% and 97% accurate for MZ and DZ individuals). We would recommend that twin registries could use the PPQ as a quick and relatively inexpensive way of determining the zygosity of twins at registration. It may be unnecessary to genotype pairs where both twins score as DZ on the PPQ (or one as DZ and one as UZ), and similarly where both twins have MZ scores over serial questionnaires. However, depending on budget and time pressures, genotyping may be required to identify the true zygosity where there are other twin combinations (such as one twin scoring as MZ, or both UZ).
Acknowledgements:

KJW was funded by the ERC funded “EpiTwin” project (European Research Council (ERC 250157)) assessed the zygosity of the twins via the PPQ, compared the self-reported zygosity and the PPQ zygosity with the zygosity from the genotyping data and wrote the initial manuscript. ZJ made subsequent revisions in response to reviewers’ comments. MM is a Bioinformatician and Honorary Lecturer who is funded by the British Research Council and assessed the zygosity of the twins via the genotyping data and assisted in the writing and editing of the manuscript. LC adapted the original zygosity questionnaire by Nick Martin et al and acted as an advisor for this manuscript. RG, IGN and DY are funded by Wellcome Trust and advised on and edited the manuscript. TDS is an NIHR senior Investigator and is holder of an ERC Advanced Principal Investigator award and edited the manuscript, as did CJH who jointly directed the work.

Zygosity assessment using peas in the pod questionnaire

Figures and Legends:

Figure 1: Flow diagram of zygosity data available from self-report, PPQ and genotyping

13,291 individuals with zygosity from self-report (including 6,644 twin pairs)

8,307 individuals with zygosity from PPQ (including 3,705 twin pairs)

4,484 individuals with zygosity from genotyping (including 2,242 twin pairs)

From first completed PPQ:
4,038 (48.6%) reported as MZ
1,645 (19.8%) reported as DZ
2,624 (31.5%) reported as UZ

Overall zygosity from all PPQs:
3,562 (42.9%) reported as MZ
1,536 (18.5%) reported as DZ
147 (1.7%) reported as UZ
3,062 (36.9%) were inconsistent over time

8,291 twins and 3,697 twin pairs with zygosity from self-report and PPQ

3,859 twins and 1,806 twin pairs with zygosity from PPQ and genotyping

1,106 (24.67%) are MZ
3,378 (75.33%) are DZ

6,129 (46.11%) reported as MZ
6,359 (47.84%) reported as DZ
803 (6.05%) reported as UZ
Zygosity assessment using peas in the pod questionnaire

Figure 2: Percentage accuracy of the zygosity from the first PPQ with the zygosity from the genotyping data for individual twins

Figure 3: Percentage accuracy of the overall zygosity from all PPQ’s with the zygosity from the genotyping data for individual twins
Zygosity assessment using peas in the pod questionnaire

Figure 4: Percentage agreement between zygosity from PPQ and genotyping data for each question

a) At school, did people have trouble telling you apart?

b) Were your parents able to tell you apart at school age?

c) Were your close school friends able to tell you apart at school age?

d) Were strangers able to tell you apart at school?

e) In childhood, which of the following would best describe you and your twin?
Figure 5: Percentage agreement between zygosity from self-report, first time answering the PPQ, Overall PPQ and genotyping data
Dear Twin,

For research purposes we ask all twins to complete this short questionnaire so we can collect further information from which to ascertain your zygosity (i.e. whether you are an identical or non-identical twin), as some twins are uncertain about this. It is very important that you DO NOT confer with your twin otherwise it will give a false result. Please could you kindly complete the questions below and return with your questionnaire, even if you are sure about your zygosity.

Many thanks.

1. a) At school, did people have trouble telling you apart?
   (0) O Yes
   (2) O No
   (1) O I don’t know

b) Were your parents able to tell you apart at school age?
   (2) O Yes
   (0) O No
   (1) O I don’t know

c) Were your close school friends able to tell you apart at school age?
   (2) O Yes
   (0) O No
   (1) O I don’t know

d) Were strangers able to tell you apart at school age?
   (2) O Yes
   (0) O No
   (1) O I don’t know

e) In childhood, which of the following would best describe you and your twin? (Please select one)
   (0) O As alike as peas in a pod
   (2) O Ordinary sibling likeness (like sisters or brothers)
   (1) O I don’t know

NOTE: We will contact you for further information if your Zygosity on completing this Questionnaire is different from your Self Report
