Abstract

Online reviews have become a popular portal among customers making decisions about purchasing products. A number of corpora of reviews have been widely investigated in NLP in general, and, in particular, in argument mining. This is a subset of NLP that deals with extracting arguments and the relations among them from user-based content. A major problem faced by argument mining research is the lack of human-annotated data. In this paper, we investigate the use of weakly supervised and semi-supervised methods for automatically annotating data, and thus providing large annotated datasets. We do this by building on previous work that explores the classification of opinions present in reviews based on whether the stance is expressed explicitly or implicitly. In the work described here, we automatically annotate stance as implicit or explicit and our results show that the datasets we generate, although noisy, can be used to learn better models for implicit/explicit opinion classification.

1 Introduction

Sentiment analysis and opinion mining are widely researched NLP sub-fields that have extensively investigated opinion-based data such as online reviews (Pang et al., 2008; Cui et al., 2006). Reviews contain a wide range of opinions posted by users, and are useful for customers in deciding whether to buy a product or not. With abundant data available online, analysing online reviews becomes difficult, and tasks such as sentiment analysis are inadequate to identify the reasoning behind a user’s review. Argument mining is an emerging research field that attempts to solve this problem by identifying arguments and the relation between them using ideas from argumentation theory (Palau and Moens, 2009).

An argument can be defined in two different ways — (1) abstract arguments which do not refer to any internal structure (Dung, 1995) and (2) structured arguments where an argument is a collection of premises leading to a conclusion. One major problem that is faced by argument mining researchers is the variation in the definition of an argument, which is highly dependent on the data at hand. Previous work in argument mining has mostly focussed on a particular domain (Grosse et al., 2015; Villalba and Saint-Dizier, 2012; Ghosh et al., 2014; Boltuzic and Snajder, 2014; Park and Cardie, 2014; Cabrio and Villata, 2012). Furthermore, an argument can be defined in a variety of ways depending on the problem being solved. As a result, we focus on the specific domain of opinionated texts such as those found in online reviews.

Prior work (Carstens et al., 2014; Rajendran et al., 2016a) in identifying arguments in online reviews has considered sentence-level statements to be arguments based on abstract argumentation models. However, to extract arguments at a finer level based on the idea of structured arguments is a harder task, requiring us to manually annotate argument components such that they can be used by supervised learning techniques. Because of the heterogenous nature of user-based content, this labelling task is time-consuming and expensive (Khatib et al., 2016; Habernal and Gurevych, 2015) and often domain-dependent.

Here, we are interested in analysing the problem of using supervised learning where the quantity of human-annotated or labelled data is small, and investigating how this issue can be handled by using weakly-supervised and semi-supervised techniques. We build on our prior work (Rajendran et al., 2016b), which created a small manually annotated dataset for the supervised binary classification of opinions present in online reviews, based
Opinion Stance Aspect Annotation
Great hotel! direct hotel Explicit
don’t get fooled by book reviews and movies, this hotel is not a five star luxury experience, it doesn’t even have sanitary standards! direct hotel Explicit
another annoyance was the internet access, for which you can buy a card for 5 dollars and this is supposed to give you 25 mins of access, but if you use the card more than once, it debits an access charge and rounds minutes to the nearest five.
indirect internet Implicit
the other times that we contacted front desk/guest services (very difficult to tell them apart) we were met by unhelpful unknowledgable staff for very straightforward requests verging on the sarcastic and rude indirect staff Implicit
the attitude of all the staff we met was awful, they made us feel totally unwelcome direct and indirect staff Explicit
Table 1: Examples of opinions along with the following information: whether the stance is directly (and) or indirectly expressed, the aspect present and whether the opinion is annotated explicit or implicit.

on how the stance is expressed linguistically in the structure of these opinions. One disadvantage of that work is the lack of a large labelled dataset, but there is a large amount of unannotated (unlabelled) online reviews available from the same source, TripAdvisor.

Our aim in this paper is to investigate whether automatically labelling a large set of unlabelled opinions as implicit/explicit can assist in creating deep learning models for the implicit/explicit classification task and also for other related tasks that depend on this classification. In our investigation, we are interested in automatically labelling such a dataset using the previously proposed supervised approach described in (Rajendran et al., 2016b).

We report experiments that are carried out using two different approaches — weakly-supervised and semi-supervised learning (Section. 4). In the weakly-supervised approach, we randomly divide the manually annotated implicit/explicit opinions into different training sets that are used to train SVM classifiers for automatically labelling unannotated opinions. The unannotated opinions are labelled based on different voting criteria — Fully-Strict, Partially-Strict and No-Strict. In the semi-supervised approach, an SVM classifier is either trained on a portion of the annotated implicit/explicit opinions or using the entire data. The resulting classifier is then used to predict the unannotated opinions and those with highest confidence are appended to the training data. This process is repeated for m iterations.

All the approaches give us a set of automatically labelled opinions. A Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) model is trained on this data and tested on the original manually-annotated dataset. Results show that the maximum overall accuracy of 0.84 on the annotated dataset is obtained using an LSTM model trained using the labelled data generated by the weakly-supervised approach using the Partially-Strict voting criterion.

2 Related work
Research in argument mining attempts to automatically identify arguments and their relations that are present in natural language texts. Lippi and Torroni (2016) present a detailed survey of existing work in argument mining. This is carried out on different domains such as debates (Cabrio and Villata, 2012; Habernal and Gurevych, 2016), reviews (Wyner et al., 2012; Gabbriellini and Santini, 2015), tweets (Bosc et al., 2016), and dialogues (Biran and Rambow, 2011). Amgoud et al. (2015) find arguments in such texts as not formally structured with most of the content left implicit. An argument, in general, is treated as a set of premises that are linked to a claim or conclusion and, those arguments in which the major premises are left implicit are termed as enthymemes. It is important to understand whether the content that is left implicit in natural language texts are to be dealt as enthymemes or not. In our earlier work (Rajendran et al., 2016b), we propose an approach for reconstructing structures similar to enthymemes in opinions that are present in online reviews. However, the annotated dataset used in our approach was small and not useful for deep learning models. Recent work in argument mining is able to achieve better performance for the argument identification task using neural network models with the availability of a large corpus of annotated arguments (Habernal et al., 2018; Eger et al., 2017). Annotating a large corpus by hand is a tedious task and little existing work in argument mining has explored alternative ways to
do it. Naderi and Hirst (2014) propose a frame-based approach for dealing with arguments present in parliamentary discourse and suggest that using a semi-supervised approach can help in developing their dataset into a large corpus. Habernal and Gurevych (2015) have proposed a semi-supervised based approach for identifying arguments using a clustering based approach on unlabelled data. Their results outperform several baselines and provide a way of developing their corpus without having to manually annotate the entire dataset. In this paper, we show that a small labelled dataset trained using an existing SVM-based classifier with the best features can help in automatically labelling a large dataset and we also evaluate its usefulness for modelling deep learning models.

3 Implicit/Explicit classification

Our prior work (Rajendran et al., 2016b) defines a sentence-level statement that is of a positive/negative sentiment and talks about a target as being a stance-containing opinion. Biber and Finegan (1988) define stance as the expression of the user’s attitude and judgement in their message to convince the audience towards the standpoint taken by them. This is different from the definition used for stance detection in NLP, in which, a given piece of text is classified as being for or against a given claim. Based on the definition given in Biber and Finegan (1988), we take stance-containing opinions to be classified as being implicit or explicit based on how the stance or the standpoint of the reviewer towards the target is expressed in the linguistic structure of the opinion. This definition of what we term implicit or explicit may depend on the audience interpretation and may vary for every individual. In order to make the human annotation task less subjective, Rajendran et al. (2016b) use the following cues to label the opinions as implicit or explicit. These opinions are extracted from hotel reviews present in the ArguAna corpus (Wachsmuth et al., 2014). Some examples from Rajendran et al. (2016b) are given in Table 1.

**Explicit opinion**

1. Direct approval/disapproval is expressed by the reviewer. Few examples are: *I do not like the hotel, I would definitely recommend this hotel*
2. Strong intensity of expression. Certain words or clauses have a strong positive/negative intensity towards a particular target. For example, *worst staff* has a strong negative intensity in comparison to *the staff were not helpful*.

**Implicit opinion**

1. Words or clauses indicate positive/negative expression but do not express it with a strong intensity. For example, *the staff were friendly and helped us with our baggages.*
2. Opinions that are expressed as personal facts. Few examples are *small room, carpets are dirty* etc.
3. Opinions that express a form of justification such as describing an incident that indirectly is meant to imply the reviewer’s satisfaction or dissatisfaction. For example, *they made us wait for a long time for the check-in and the staff completely ignored us.*

To overcome the data imbalance for the two classes, the original dataset annotated by a single annotator was undersampled in (Rajendran et al., 2016b) into 1244 opinions (495 explicit and 749 implicit). Next, two annotators were asked to independently annotate this undersampled dataset, and the inter-annotator agreement for this task is 0.70, measured using Cohen’s $\kappa$ (Cohen, 1960).

4 Methodology

4.1 Weakly-supervised Approach

Our first experiment uses a method that is similar to bagging (Breiman, 1996). Starting from a randomly selected subset of the undersampled annotated data, we first create three different training sets, $T_1$, $T_2$ and $T_3$. These training sets are then each used to train an SVM classifier which uses the highest discriminative features (Rajendran et al., 2017) identified for predicting implicit and explicit stance:

**Unigrams and Bigrams** Each word present in an opinion and each pair of consecutive words present in an opinion are considered as features.

**Noun-Adjective pattern** Let us consider $\mathcal{N}$ to represent the list of $k$ nouns in an opinion and $\mathcal{A}$ to represent the list of $l$ adjectives. The combination of each noun with an adjective is considered as a Noun tag + Adjective tag
Datasets vary in the number of explicit and implicit opinions that are randomly sampled from the labelled data to be trained by the SVM classifier. For each of the weakly supervised approach, we give size, the number of the predicted labels that are used to train an LSTM-based model. This model was then tested on the entire labelled data, and the accuracy of this LSTM model is reported.

Table 2: Datasets vary in the number of explicit and implicit opinions that are randomly sampled from the labelled data to be trained by the SVM classifier. For each of the weakly supervised approach, we give size, the number of the predicted labels that are used to train an LSTM-based model. This model was then tested on the entire labelled data, and the accuracy of this LSTM model is reported.

Average-based sentence embedding  We compute the mean of the 300-dimensional pre-trained word embedding vectors trained using GloVe (Pennington et al., 2014) to create a sentence embedding, and use each dimension in the sentence embedding as a feature in the classifier.

\[ v = \frac{1}{|S|} \sum_{i=1}^{|S|} s_i \]  

(1)

where \(|S|\) represents the size of the opinion and \(s_i\) represents the pre-trained word embedding for the \(i\)th word in the opinion.

The three resulting SVM classifiers are then used to annotate 4931 unannotated opinions, and these newly annotated opinions are then used to train an LSTM classifier. We generate the annotated opinions in two different ways — what we call the average-based method and the voting-based method — and for each method we use the resulting annotated opinions differently as described next.

Average-Based Each training set \(T_1\), \(T_2\) and \(T_3\) is used to train separate SVM classifiers, which are used to label the unlabelled opinions, giving corresponding annotated opinion sets \(U_1\), \(U_2\) and \(U_3\). Separate LSTM models are trained on each of \(U_1\), \(U_2\) and \(U_3\), and tested on the original set of annotated data. Finally, the averaged performance across the three LSTMs is reported.

Table 3: Accuracy of the LSTM model on annotated data using a set of automatically labelled unannotated opinions of size.

Voting-Based Again, each training set \(T_1\), \(T_2\) and \(T_3\) is used to train separate SVM classifiers, which are used to label the unlabelled opinions, giving corresponding annotated opinion sets \(U_1\), \(U_2\) and \(U_3\). We then followed an approach that is similar to Ng and Cardie (2003) to combine the opinions in \(U_1\), \(U_2\) and \(U_3\) into a single set, denoted by \(U_F\), using the following voting criteria:

**Fully-Strict** An opinion is included in \(U_F\) if all three SVM classifiers predict the same stance label.

**Partially-Strict** An opinion is included in \(U_F\) if all three SVM classifiers identify it as explicit, or if at least two of them classify it as implicit.

**No-Strict** An opinion is included in \(U_F\) as implicit if at least one of the classifiers predict it to be implicit, otherwise it is included in \(U_F\) as explicit.

\(U_F\) was then used to train an LSTM classifier and this was tested on the original annotated data.

Note that moving from Fully-strict \(\rightarrow\) Partially-Strict \(\rightarrow\) No-Strict relaxes the requirement on including an opinion in \(U_F\) so that the number of opinions in the training data increases.
4.2 Semi-supervised approach

We conduct a second experiment to test the combination of both labelled (1244 opinions) and unlabelled (4931 opinions) data using the following popular semi-supervised learning methods.

**Self-training method** We train an SVM using the labelled data $D$ and use this to annotate the unannotated data $U$. The annotated opinions from $U$ which are labelled with the highest probability are then added to $D$. This process is repeated $m$ times.

**Reserved method** Here we use the method of Liu et al. (2013), where a portion of the training data $R$ is reserved, and the remainder is used for training the SVM. The resulting classifier is run on the combination of $U$ and $R$. The annotated opinions from $U$ with the highest probability and the opinions from $R$ that have the lowest probability of having a correct label generated by the SVM are appended to the training dataset. This operation is repeated $m$ times. We chose 222 explicit opinions and 287 implicit opinions as the training data, and took 273 explicit opinions and 462 implicit opinions as the reserved portion.

After the final iteration, the final set of annotations of the opinions in $U$ is used to train an LSTM model. The resulting classifier is then tested on the original set of annotated data.

5 Experiment and Results

We used Keras\footnote{https://keras.io/} to implement an LSTM model with an embedding layer using pre-trained 300 dimensional GloVe embeddings, followed by an LSTM layer of size 100 with a dropout rate of 0.5 and a sigmoid output layer. The input length is padded to 50. Parameter optimisation is done using Adam (Kingma and Ba, 2014). For the semi-supervised approaches, we consider the number of iterations, $m = 1 – 25$.

Table. 2 reports under Size the number of unannotated data that is automatically labelled using the weakly-supervised approaches. The corresponding columns Exp and Imp contain the number of manually annotated opinions that are used to train the SVM classifier used in the first-step of the proposed method. The Acc column denotes the accuracy for predicting the labels of the annotated dataset using the LSTM model trained on the automatically labelled, unannotated data.

Looking at the performance of the weakly-supervised approach in Table. 2, we observe the effect of varying the size of the explicit and the implicit opinion sets that are used to train the SVM-based classifier (see columns Emp and Imp in Table. 2). Comparing these with the accuracy scores, we find that using the largest set of explicit opinions in training the initial SVMs gives new annotated data that can train classifiers that perform best on the original annotated data. Overall, using the entire undersampled data for training the SVMs and using the Partially-Strict voting based method gives the best performance with an accuracy of 0.84.

Table. 3 reports the results obtained using the self-training method and the reserved method. These show how the size of the labelled unannotated dataset increases at each iteration and these newly annotated opinions are added to the training data. The accuracy of the LSTM model in predicting the labels of annotated opinions improves with the size of the automatically labelled dataset. However, the accuracy of the reserved method decreases in performance after 20 iterations\footnote{This is typical of such methods as less reliable examples are added to the training data.}. Of the two methods, the self-training method performs best, showing that using training data with the lowest confidence does not help in this task.

Overall, the results are positive, showing a range of methods that can create automatically labelled data which is accurate enough to be useful for deep-learning methods. The dataset is publicly available at https://goo.gl/BymZVz.

6 Conclusion

This work investigated a particular task related to argument mining where we have a small annotated dataset. Our results show that using a semi-supervised method with the available small annotated dataset is sufficient to label a larger unlabelled dataset so it can be used to train a deep learning LSTM model for argument mining.
