Abstract.

Background: Chronic obstructive pulmonary disease (COPD) is a major disease burden which accounts for 5% of all deaths globally, with most of those (>90%) occurring in lower to middle income countries (LMIC). It is also emerging as an important modifiable dementia risk factor.

Objective: To address the knowledge gap surrounding the nature of the associations between COPD, dementia, and mortality, and the geographical variation of those associations in LMIC.

Methods: Data from the 10/66 study surveying 15,394 participants (mean age 74 years, 62% female) across 8 countries was used to estimate the prevalence of self-reported COPD and its association with incident dementia and premature death. Proportional sub-hazards models using a cumulative incidence function were applied to identify the probability of incident dementia onset given the risk of premature death, with estimates pooled across countries via random effect meta-analysis.

Results: Over the 3-year follow-up, almost 10% of participants developed dementia and 14% were deceased. COPD was not significantly associated with dementia incidence except in Cuba. However, fully adjusted models indicated that individuals with COPD were at a 28% increased risk of premature death, a trend present across most countries when analyzed individually.

Conclusion: The link between COPD and dementia is currently somewhat different and weaker in LMIC than in developed countries. This may be because premature death in the populations studied mask the development of clinical dementia. Given the global trend toward increased life expectancy, it is critical that the disease burden associated with COPD be addressed without delay if a further rise in dementia prevalence associated with COPD is to be avoided in LMIC.

Keywords: Chronic obstructive pulmonary disease, lower to middle income countries, mild cognitive impairment, premature death, prevalence

INTRODUCTION

The prevalence of dementia is projected to increase substantially worldwide in the coming decades from

46.8 million in 2015 to 131.5 million in 2050 [1]. While currently it is estimated that 58% of people with dementia live in low to middle-income countries (LMIC), this proportion is forecast to increase to 68% by mid-century due to the different demographic profiles of these regions [1].

In the absence of disease modifying treatment availability and/or affordability, this increase in dementia prevalence will lead to dramatic increase in disease burden in countries that can least afford

¹Statistical analysis.

41 it unless non-pharmacological interventions can be
42 developed to delay the onset of dementia. It is there-
43 fore essential to better understand the associations
44 between risk factors and dementia risk in LMICs.

45 One emerging risk factor particularly relevant
46 to LMIC is chronic obstructive pulmonary disease
47 (COPD). COPD is a major disease burden which
48 accounts for 5% of all deaths globally, with most of
49 those (>90%) occurring in LMIC (WHO). Its preva-
50 lence is about 12% worldwide with higher rates in
51 the Americas (~15%) and lower rates in South East
52 Asia (10%) [2]. COPD is characterized by persistent
53 lung airflow limitation, typically progressive, which
54 is associated with chronic inflammation of the air-
55 ways and lungs [3]. Tobacco smoke is the main cause
56 of COPD worldwide. Both in human and animal mod-
57 els, tobacco smoke leads to an inflammatory response
58 within minutes or hours of inhalation [4, 5]. Sustained
59 use of tobacco leads to chronic lung inflammation
60 which contributes to lung tissue damage, impairs its
61 repair, and leads to emphysema, increased risk of
62 infection, and increased production of mucus [6].
63 Excess mucus accumulates in smaller airways and
64 alveoli, and obstructs large airways thus decreas-
65 ing airflow and total lung capacity [7] and leads to
66 increasing breathlessness, coughing, and expectora-
67 tion [8].

68 The systemic effects of COPD are not completely
69 understood, but it is thought to increase chronic
70 peripheral inflammation which can contribute to vas-
71 cular pathology, including in the brain, increased
72 apoptosis, accelerated tissue senescence, and neu-
73 rodegeneration [9–11]. COPD is also thought to
74 impair cerebral perfusion and promote hypoxia thus
75 further contributing to neurodegeneration and cog-
76 nitive impairment [12]. While smoking is the main
77 cause of COPD, other risk factors including air pollu-
78 tion, childhood disadvantage, professional exposure
79 to chemicals, lifestyle (obesity, exercise, diet), and
80 genetics are also thought to contribute to the devel-
81 opment of the disease [13].

82 In high income countries, COPD is associated with
83 an almost two-fold increased risk of minor and major
84 neurocognitive disorders [14, 15] and a two-fold
85 increased risk of premature death [16]. However, lit-
86 tle is known about the association between COPD and
87 dementia, and its complex relationship with poverty
88 and lower life expectancy, in LMIC. Recent evi-
89 dence suggests that while smoking is also strongly
90 associated with COPD in LMIC, the main mortal-
91 ity risk in these countries may be more strongly
92 linked to poverty and environmental factors than

93 to smoking [17]. A possible implication of these
94 findings is that the association between COPD and
95 dementia risk may be different in LMIC compared
96 to high income countries. In addition, the lower life
97 expectancy prevalent in LMIC is likely to mask the
98 late-life adverse impact of COPD and particularly
99 with respect to the development of clinical dementia.
100 It is therefore critical to consider the contribution of
101 COPD-related mortality when interpreting dementia
102 risk in LMIC.

103 Few normative datasets are available to query com-
104 plex interactions between COPD, dementia risk, and
105 mortality in LMIC while contrasting regional differ-
106 ences. The 10/66 study [18] is the first large-scale
107 study focused on investigating dementia prevalence
108 and risk factors in large LMIC populations using a
109 consistent and comparable methodology. Although
110 the main focus of the study was around the epidemi-
111 ology of dementia, the scope of the research is much
112 broader, including other health domains (chronic dis-
113 eases, disability, frailty, poly-morbidity) and social
114 aspects of aging.

115 Leveraging against this rich resource, the aims
116 of this study were to investigate 1) the prevalence
117 of COPD and 2) the prospective risk of demen-
118 tia and mortality attributable to COPD in older
119 community-living individuals living in 8 LMIC
120 (Cuba, Dominican Republic, Peru, Venezuela, Mex-
121 ico, China, India, Puerto Rico) using data from the
122 10/66 study.

123 METHODS

124 *Study population*

125 Population-based surveys were carried across
126 eleven catchment areas across seven low- and middle-
127 income countries, selected on the basis of a paucity
128 of information about dementia in those regions
129 (Dominican Republic, Peru, Venezuela, Mexico,
130 China, India, and Puerto Rico). This was part of
131 the baseline phase of the 10/66 Dementia Research
132 project, described in depth elsewhere [19]. Briefly,
133 urban and rural catchment areas were identified such
134 that the sample included both high urban density
135 and low-population agrarian lifestyles. Participants
136 were identified by systematic door-knocking of every
137 household within these precisely defined and mapped
138 catchment areas. Those aged 65 years and over were
139 eligible for participation. Initial baseline data collec-
140 tion took place between 2003 and 2005. Follow-up

Table 1
Sample selection and size, by country

Site	Baseline				Lost (% of baseline N)	Follow-up

Int., number of participants interviewed; MC, missing COPD data; N, total number of participants available at baseline; Lost, number of participants lost between baseline and follow-up. India is excluded from follow-up due to lack of robust dementia information. Urban and rural populations are pooled to maximize sample size for subsequent analyses.

took place approximately three years later, between 2007 and 2010. Based on the estimated sample size required to detect the typical dementia prevalence in this age group (4.5%), a target of ~1000 individuals per catchment was set. Response rates ranged from 74% to 98%. Of an initial 17,031 participants, 1,637 participants were excluded due to missing COPD data or existent dementia diagnoses at baseline (Table 1), resulting in a sample size of 15,394. The ethical aspects of this research were approved by ethics committees local to data collection, and the Institute of Psychiatry, King's College London. Written consent was obtained from participants or next of kin if the individual lacked capacity. Oral consent, witnessed in writing by someone literate, was taken from illiterate participants.

Interviews and key measures

The baseline assessment took 60–180 minutes, and included self and informant report questionnaires, structured clinical interviews, and physical examination on a range of social, physical, and psychological health topics. This was conducted in the native language of each catchment area. COPD was ascertained via self-report at baseline as in Sousa et al. [20], via the question “Do you usually cough up phlegm from your chest first thing in the morning?”. This is based on findings that show that 75% of individuals suffering from COPD report chronic coughing and sputum production [21]. In contrast, only 12% of adults report chronic cough in the general population [22], and those who do are at a three-fold increased risk of developing COPD (i.e., 75% of those with

consistent cough/sputum will develop COPD) over 10 years [23]. Dementia was assessed using cross-culturally specific criteria developed for the 10/66 program [24]. A diagnosis was established based on a cognitive tests battery, clinical interviews, and informant reports (including Community Screening Instrument for Dementia; the CERAD 10 word list learning and animal naming tests; the Geriatric Mental State Examination, and the History and Aetiology Schedule – Dementia Diagnosis and Subtype), and was validated against local clinicians DSM-IV diagnoses (see Prince et al. [25] for more information). The same method was applied at baseline and follow-up, and death information obtained from key informants to determine vital status, date of death of those deceased and a verbal autopsy on those deceased. As described in Ferri et al. [26], this consisted of the World Health Organization's “Standard Verbal Autopsy Questionnaire 3: Death of a Person Aged 15 Years and Above”, a formal interview with individuals familiar with the deceased persons, as records are typically unavailable). Individuals who were thought to have died with dementia (via verbal autopsy) were coded as incident dementia, rather than death. Covariate information was obtained at baseline. Sex, age, education, smoking status (non-smoker, ex-smoker, current smoker), physical activity (very, fairly, not very, or not at all physically active), diabetes (participant told by a doctor), stroke (participant told by a doctor), hazardous alcohol consumption (more than 14 units per week for women and more than 21 for men), and depression (any major depressive episode according to F32 depressive episode, specified as mild,

207 moderate or severe according to ICD-10 criteria
 208 [27] based on a computerized algorithm, AGE-CAT,
 209 applied to the Geriatric Mental State Examination
 210 which was administered to all participants [28])
 211 were obtained by self-report. Hypertension was
 212 obtained by self-report, or meeting International
 213 Society for Hypertension criteria [29] during physical
 214 examination.

215 Statistical analyses

216 The analysis method was consistent with other
 217 studies in the 10/66 dataset [19]. Analyses were
 218 carried out on STATA (version 14) and R (ver-
 219 sion 3.2.0) for Windows, following procedures used
 220 previously with 10/66 data [30]. The impact of inclu-
 221 sion/exclusion criterion and attrition was evaluated
 222 with *t* and chi-square tests. The association between
 223 COPD prevalence and covariates (sex, age, educa-
 224 tion, smoking status, physical activity, hypertension,
 225 diabetes, stroke, hazardous alcohol use, and depres-
 226 sion) were investigated via mutually-adjusted preva-
 227 lence ratios from Poisson regression. The prevalence
 228 of COPD at baseline was adjusted for compositional
 229 effects of age (grouped into 65–69, 70–74, and 75–79,
 230 and 80+ rather than specified as a continuous vari-
 231 able to make it more interpretable particularly given
 232 the substantial variation in life expectancy across
 233 countries), sex, and education. After accounting for
 234 household clusters using the sandwich estimator of
 235 variance (*vce (robust)* command in STATA), these
 236 adjusted prevalence proportions are reported with
 237 robust 95% confidence intervals.

238 The association between COPD and dementia inci-
 239 dence and COPD and mortality was modelled using
 240 Fine and Gray proportional subhazards model [31], a
 241 cumulative incidence function that disentangles prob-
 242 ability of dementia onset given the risk of competing
 243 events (e.g., death before dementia onset). Urban and
 244 rural populations were pooled to maximize sample
 245 size. Although sensitivity analyses contrasting urban
 246 and rural populations were originally planned, pilot
 247 analyses showed that estimates could not be reliably
 248 computed due to unstable/non-converging models
 249 possibly linked to differences in attrition rates in rural
 250 and urban settings. Both uncontrolled (no covariates)
 251 and fully controlled (adjusting for sex, age, educa-
 252 tion, smoking status, physical activity, hypertension,
 253 diabetes, and stroke) models were fitted. Participants
 254 were nested by household in all models.

255 All analyses were carried out for each coun-
 256 try separately, and then pooled in a fixed-effects

257 meta-analysis [32]. Heterogeneity was examined via
 258 Higgin's I^2 . Significance was inferred by robust con-
 259 fidence intervals, with alpha set at 0.05.

260 RESULTS

261 Sample selection and baseline characteristics

262 From 15,394 dementia-free participants with
 263 COPD data available at baseline, 2,476 were lost
 264 to follow-up, including all of the data from India
 265 (there was no follow-up in India), resulting in a final
 266 sample of 11,098 (Table 1). Excluded and included
 267 participants did not significantly differ in terms of
 268 smoking status, hypertension, or diabetes. Excluded
 269 participants were significantly older ($t = 31.12$, 95%
 270 [6.98, 6.15]; mean age of 80.16 versus 73.59) more
 271 likely to be female ($\chi^2 = 26.36$, $p < 0.01$; 69% ver-
 272 sus 62% female), have a higher level of education
 273 ($\chi^2 = 238$, $p < 0.01$; 93% versus 89% having com-
 274 pleted secondary education), and be less physically
 275 active ($\chi^2 = 1749$, $p < 0.01$; 4% versus 95% being
 276 very physically active). COPD prevalence for the
 277 included 11,098 participants is summarized by site

Fig. 1. COPD Prevalence by site. Figures in white boxed refer to absolute number of individuals with COPD per site, while bars refer to percentage of total sample at each site with COPD. Note y axis is truncated at 7%, the zoomed-in view here is to allow clearer comparisons between sites. Prevalence is unadjusted. See Supplementary Table 1 for descriptive statistics for covariates, both overall and grouped by with and without COPD.

in (Fig. 1) (see Supplementary Table 1 for additional statistics). Over the 3-year follow-up, almost 10% of participants developed dementia and 14% were deceased. There were 171 individuals who had died due to dementia (ascertained via verbal autopsy) and so were coded as having dementia (versus 894 who had dementia but had not died at the time of sampling).

COPD at baseline

COPD prevalence was less than 10% across all countries, and was highest in Venezuela (8%) and lowest in China (2%). Associations between COPD and covariates at baseline are presented in (Table 3). No single variable was significantly associated with COPD across all countries; however, current smoking or physical activity (not at all) were associated with COPD in more than half of the countries included. In pooled analyses across all countries, being a current smoker was associated with an 84% increased likelihood of having COPD, while significant prevalence ratio estimates in individual countries ranged from approximately two- to four-fold. Pooled estimates indicated stroke was associated with an 18% increased likelihood of having of COPD, a trend present but not significant in any individual country. In contrast, physical activity was associated with a 69% decreased likelihood of having COPD in pooled analyses, with significant estimates for individual countries ranging from two- to five-fold. Pooled estimates indicated that higher education was associated with a 7% lower likelihood of having COPD. A similar trend was observed in most countries individually, but only significantly so in India (22% lower).

In countries for which this information was available, the prevalence of COPD was somewhat higher in rural than urban settings for India (7.6% versus 1.8%) and Mexico (8% versus 6%), but lower for Peru (2% versus 5.9%) and China (1.6% versus 3.1%).

COPD and dementia

Pooled effects across all countries indicated that COPD was not significantly associated with dementia incidence (Table 4). However, there was a significant association in Cuba in all (unadjusted to fully adjusted) models, indicating that individuals with COPD had a 95% higher likelihood of developing dementia within the study duration than those without COPD.

T2DM, type 2 diabetes mellitus. *indicates significance at $\alpha < 0.05$. Base group for comparison in sex is female, smoking status is 'never smoked', physical activity is 'very often', and hypertension, T2DM and stroke are 'no'. Figures in brackets are 95% confidence intervals. Coefficients for alcohol consumption in Peru and Venezuela were removed due to substantial instability (estimates and associated confidence intervals < 0.00001), stemming from low hazardous alcohol consumption rates (0.43% in Peru, 1.48% in Venezuela, while the average across other countries is 3.48%) resulting in no cases of both hazardous alcohol consumption and COPD in these samples.

SHR, sub-hazard ratio, *indicates significance at $\alpha < 0.05$.

COPD and mortality

I² was noticeably low (<0.01 for all models), indicating that variation across studies was most likely due to heterogeneity rather than chance, thus pooled effects should be interpreted with caution. Pooled effects indicated that COPD was significantly associated with premature death in all (unadjusted to fully adjusted) models, such that individuals with COPD had a 28% increased likelihood of premature death in the fully adjusted models. This association was significant for most countries in unadjusted models, but only remained significant across models in the Dominican Republic (61% increased prevalence ratio).

Sensitivity analysis

Following the observation that COPD prevalence was lower than contemporary systematic reviews may suggest (e.g., [2]), analyses were re-run with a restricted age range (65–69) in order to align the

current sample with the wider literature (Supplementary Table 2). These models were unstable due to the low prevalence of dementia at that age (134 cases across all sites). When all participants in this age range across sites were combined into a single analysis ($n = 3,441$), COPD did not significantly predict dementia incidence even when it was sole predictor (HR = 1.52, 95%CI [0.74,3.11], $p = 0.25$). While the current competing risk proportional hazards regression approach has established advantages [33, 34], traditional Cox regression was also run in order to explore COPD cause-specific hazards (Table 5). Results were essentially the same, with both approaches revealing a comparable pattern of significance and magnitude of effects (Supplementary Table 3).

DISCUSSION

This study's main findings were that COPD was not consistently associated with risk of dementia across

all LMIC investigated. However, COPD was associated with premature death when all countries were pooled together. In addition, a robust association was detected between COPD and dementia incidence in Cuba and with premature death in the Dominican Republic.

A paucity of data on the prevalence of COPD and its association with incident dementia and premature death are available for LMIC. This is largely due to the high costs of conducting such investigations, which puts them out of reach of LMIC's fragile economies, and to the methodological difficulties involved in collecting accurate data in these countries. The method used in the 10/66 study was specifically developed to overcome these barriers and further our understanding of dementia prevalence and risk factors in these communities.

The present research showed that the prevalence of COPD in the regions studied ranged from 2.41% in China to 6.82% in the Dominican Republic. Our findings are therefore substantially lower than worldwide estimates reported in recent systematic reviews (~10–12%) [2]. We can only speculate as to why this may be the case. A possible explanation is that mortality associated with COPD and its risk factors is higher in the regions studied and that the relatively old age of our sample (mean ~75 years) reflects in part a survival effect that may have obscured its association with incident dementia. It is also likely that the measure of COPD used in this study, a single, indirect self-report question rather than the gold standard of spirometry, may not have identified all cases. Available evidence suggests that the overwhelming majority of adults with COPD report chronic cough and sputum production, whereas 10% or less of those without COPD report these symptoms [22, 23]. Nevertheless, this measurement limitation most likely decreased the sensitivity of our analyses. It is also possible this misclassification bias may be non-differential (e.g., due to higher rates of pneumonia in dementia) and may have obscured true associations. Another possible source of misclassification was that, while analyses included a wide range of covariates associated with both COPD and dementia, information on region-specific factors, such as poorly ventilated indoor heat and cooking sources, and air pollution levels was unavailable.

It is notable but not unexpected that smoking and physical activity were associated with COPD prevalence at baseline, although these associations did not reach significance for all countries. Current smoking was positively associated with COPD in most

countries except Mexico, and was associated with a 39% increased risk of having COPD. Past smoking was also positively associated with COPD in most countries except India, but was associated with a slightly lower risk (34%). Relative to findings from a recent systematic review reporting a 235% increased risk in ex-smokers and 351% in current smokers, the present estimates appear relatively low [35]. As reported by Burney et al., this may be due to the fact that the poorest people cannot afford to smoke and therefore countries with the weakest economies are more likely to have lower COPD rates [17]. In support of this explanation, we computed the raw correlation between the gross domestic product (GDP) of the countries investigated in the present study at the time of assessment and their prevalence of COPD (excluding China which was a major outlier with a high GDP and very low COPD prevalence) and found a positive association ($r=0.25$), though this was not significant (Fig. 2).

In contrast, physical activity was negatively associated with COPD in all countries with those who exercise fairly regularly or very regularly having a 64% and 54% lower risk of having COPD. However, these effects only reached significance in the Dominican Republic, China, India, and Puerto Rico and the direction of these effects are uncertain as while exercise may be protective, it is also the case that COPD limits physical activity. Other measures associated with COPD at baseline in pooled analyses included education (9% decreased risk), stroke (22% increased risk), and depression (81% increased risk), although the direction and strength of these effects were not completely consistent across countries (e.g., it is possible that COPD limited people's capacity to undertake physical activity, rather than lack of physical activity increasing COPD risk). Contrary to our expectation, COPD was not associated with increased dementia risk in most countries except for Cuba (95% increased likelihood). This is surprising because in developed countries COPD, and particularly the reporting of chronic cough and sputum production, are associated with poorer health outcomes and increased dementia incidence [14, 15, 21]. A plausible explanation for these findings is that those affected by COPD in LMIC are less likely to live into old age when dementia is more likely to manifest. Indeed life expectancy at birth for the cohort considered here is approximately 69 years [36] and thus it is more likely that a greater proportion of those suffering from chronic diseases such as COPD may have died before the start of the study. In contrast life

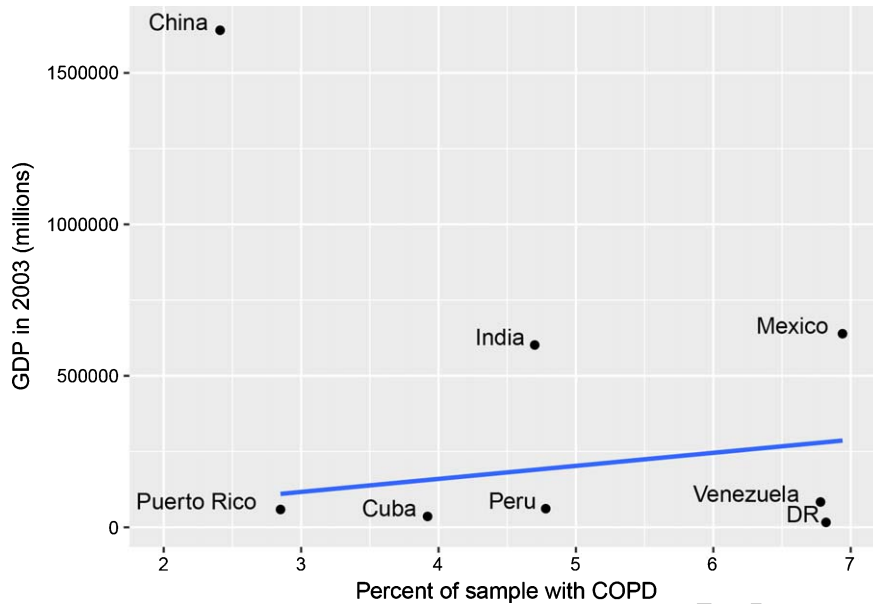

Fig. 2. GDP and percent of sample with COPD. GDP figures sourced from Classora knowledge base, accessed 30/05/2018. Unadjusted line of best fit indicates a positive, but non-significant association between GDP and COPD ($r=0.25$, $p=0.59$), where China is excluded due to being an extreme outlier.

467 expectancy in Cuba, where the only significant asso- 495
 468 ciation was found between COPD and dementia, was 496
 469 81 years at the start of the study. Alternatively, this 497
 470 finding may simply reflect methodological issues that 498
 471 would be expected in a multi-center study (e.g., sam- 499
 472 pling variation), or be due to the limitations relating 500
 473 to the COPD measure and the dementia assessment 501
 474 procedure used. 502

475 Similarly, COPD was positively associated with 503
 476 premature death in all countries but this effect only 504
 477 reached significance in the Dominican Republic 505
 478 (61% increased risk). However, unlike for demen- 506
 479 tia, when estimates were pooled across all countries, 507
 480 COPD was associated with a 32% increased risk of 508
 481 premature death. This is consistent with the expla- 509
 482 nation proposed above suggesting that the lack of 510
 483 associations found between COPD and dementia may 511
 484 be due to lower life expectancy. It is also in line with 512
 485 the literature showing a clear link between COPD 513
 486 and its underlying pathological processes and mortal- 514
 487 ity [16]. This could be investigated in future work 515
 488 collecting data on COPD exposure duration. Similar- 516
 489 ly, a longer time period may provide more sensitive 517
 490 predictions of future Dementia diagnosis. In the cur- 518
 491 rent study it is possible individuals not diagnosed 519
 492 with dementia were actually in the lengthy pre- 520
 493 morbid phase [37]. Overall, these findings indicate 521
 494 that the link between COPD and dementia is currently

503 somewhat different and weaker in LMIC than in 504
 505 developed countries, and that this difference may be 506
 507 due to premature death masking the development of 508
 509 clinical dementia, at least in the older population 509
 510 studied. The likely role of lower life expectancy in 510
 511 LMIC in modulating these associations is important 511
 512 to consider as recent world mortality reports have 512
 513 indicated that life expectancy is rising quickly in 513
 514 these countries. An implication for policy is therefore 514
 515 that unless the disease burden associated with COPD 515
 516 is addressed without delay, the future prevalence of 516
 517 dementia will reach substantially higher levels as life 517
 518 expectancy rises in LMIC. 518
