Key words: WNT pathway, septo-optic dysplasia, congenital hypopituitarism, Tcf7l1, pituitary
Abstract

Aberrant embryonic development of the hypothalamus and/or pituitary gland in humans results in congenital hypopituitarism (CH). TCF7L1, an important regulator of the WNT/β-catenin signaling pathway, is expressed in the developing forebrain and pituitary gland but its role during hypothalamo-pituitary (HP) axis formation or involvement in human CH remains elusive. Using a conditional genetic approach in the mouse, we first demonstrate that TCF7L1 is required in the prospective hypothalamus to maintain normal expression of the hypothalamic signals involved in the induction and subsequent expansion of Rathke’s pouch progenitors. Next, we reveal that the function of TCF7L1 during HP axis development depends exclusively on its repressing activity and does not require its interaction with β-catenin. Finally, we report the identification of two independent missense variants in human TCF7L1, p.R92P and p.R400Q, in a cohort of patients with forebrain and/or pituitary defects. We demonstrate that these variants exhibit reduced repressing activity in vitro and in vivo relative to wild-type TCF7L1. Together, our data provide support for a conserved molecular function of TCF7L1 as a transcriptional repressor during HP axis development in mammals and identify variants in this transcription factor that are likely to contribute to the etiology of CH.
**Significance Statement**

The relevance of TCF7L1 during hypothalamo-pituitary (HP) axis development remains unknown. Using mouse genetics, we show that TCF7L1 acts as a transcriptional repressor to regulate the expression of the hypothalamic signals involved in pituitary formation. In addition, we screened a cohort of human patients with forebrain and/or pituitary defects and report two independent novel missense variants, p.R92P and p.R400Q, in human TCF7L1. Functional studies *in vitro* and rescue experiments in zebrafish mutants deficient for tcf7l1a and tcf7l1b, show that the p.R92P and p.R400Q variants exhibit reduced repressing activity compared with wild-type TCF7L1. In summary, we identify TCF7L1 as a novel determinant for the establishment of HP axis development and as a potential candidate gene to be mutated in congenital hypopituitarism.
Introduction

Congenital hypopituitarism (CH) is a complex condition defined by the deficiency of one or more pituitary hormones, and can be present in isolation or as part of a syndrome (1-3). Septo-optic dysplasia (SOD) is a rare form of CH (1 in 10,000) that manifests in conjunction with defects in the telencephalon (e.g. corpus callosum and septum pellucidum) and/or eyes (e.g. optic nerve hypoplasia), and is associated with high morbidity and occasional mortality (4).

Abnormal embryonic development of the Hypothalamo-Pituitary (HP) axis is a major cause of CH. The pituitary gland, comprising the anterior and posterior lobes, is an organ of dual embryonic origin, and derives from oral and neural ectoderm respectively. In the mouse at around 9.5 days post coitum (dpc), secreted signals from the hypothalamic primordium such as FGF8, FGF10, BMP4 and SHH induce Rathke’s pouch (RP), the primordium of the anterior pituitary (5, 6). Upon specification, RP progenitors proliferate rapidly, exit the cell cycle and activate the expression of cell fate commitment genes such as Pou1f1 (Pit1), Tpit and Sf1. This culminates in the differentiation of all hormone-producing cells by the end of gestation (7, 8); somatotrophs (growth hormone, GH), lactotrophs (prolactin, PRL), thyrotrophs (thyroid-stimulating hormone, TSH), gonadotrophs (follicle-stimulating hormone, FSH and lutenizing hormone, LH), corticotrophs (adrenocorticotropic hormone, ACTH) and melanotrophs (melanocyte-stimulating hormone, MSH) (2, 9). A small proportion of cells remain in the postnatal anterior pituitary as tissue-specific stem cells, which have the capacity to self-propagate and differentiate in vivo and in vitro (10-12).
Mutations in several developmental genes regulating HP development in the mouse have been identified in patients suffering from CH and SOD (4). One of these is the homeobox gene *Hesx1/HESX1*, which acts as a transcriptional repressor of the WNT/β-catenin signaling pathway (13, 14).

The stability of β-catenin, which is a strong transcriptional activator devoid of a DNA binding domain, is critical for normal WNT/β-catenin function (15-17). In the absence of WNT ligands, β-catenin is phosphorylated by a destruction complex and degraded rendering the pathway inactive (18, 19). The binding of WNT ligands leads to β-catenin dephosphorylation and stabilization (20, 21). It can then translocate into the nucleus and interact with mainly, but not exclusively, members of the T-cell factor/lymphoid enhancer factor (TCF/LEF) family to activate the expression of target genes (22, 23). In mammals, TCF/LEF factors include TCF7 (formerly TCF1), TCF7L1 (formerly TCF3), TCF7L2 (formerly TCF4) and LEF1, which all bind the same consensus DNA motif 5’-(A/T)(A/T)CAAAG-3’ and have a β-catenin-interacting domain at the N-terminus (24, 25). It is believed that, in the absence of stable β-catenin, TCF/LEF factors can repress target genes of the pathway through interactions with corepressors (26, 27), although cell context-specific functions have been demonstrated where specific factors are mostly required as either activators (28, 29) or repressors (30-33).

In the developing HP axis, this pathway coordinates proliferation of RP progenitors and differentiation of hormone-producing cells (34-41). TCF7L1 has been shown to play critical roles in maintenance of stem cell pluripotency (42, 43), tissue homeostasis of the skin epithelia (44), cell lineage determination during gastrulation (45,
46) and brain development in vertebrates (47, 48). However, the function of this important transcriptional factor during HP axis development has not been investigated to date. Moreover, despite the solid evidence demonstrating the critical function of the WNT/β-catenin pathway during HP axis development in the mouse, so far mutations in components of this pathway have not been identified in patients with CH. In this manuscript we reveal that the β-catenin-independent repressor activity of TCF7L1 is required for normal HP axis formation in mice and humans.

Materials and Methods

Mice

The Hesx1\textsuperscript{Cre/+} (49), Tcf7l1\textsuperscript{lox/lox} (44) and Tcf7l1\textsuperscript{ΔN/ΔN} (33) have been previously described. We have previously shown that the Hesx1-Cre mouse line drives efficient recombination of loxP-flanked DNA in RP progenitors from 9.5 dpc (49, 50). Hesx1\textsuperscript{Cre/+};R26\textsuperscript{loxP-YFP/+} 18.5 dpc embryos display widespread yellow fluorescent protein (YFP) expression in the vast majority of cells of the anterior pituitary, suggesting that the Hesx1-expressing RP progenitors give rise to all hormone-producing cells (Hesx1-cell lineage). In addition to RP, Hesx1\textsuperscript{Cre/+};R26\textsuperscript{loxP-YFP/+} and Hesx1\textsuperscript{Cre/+};R26\textsuperscript{loxP-lacZ/+} embryos show reporter expression in the ventral telencephalon and pre-optic hypothalamic area from 9.5 dpc (49-51). Tcf7l1 is expressed in the forebrain, including the hypothalamic area, as well as in the anterior pituitary until 14.5 dpc (37). To reveal the function of Tcf7l1 during normal HP axis development we used the Tcf7l1\textsuperscript{lox/lox} conditional mouse line (44, 47). To generate pituitary-specific Tcf7l1 genetic deletions, Tcf7l1\textsuperscript{lox/lox} mice
were initially crossed to β-actin:Cre animals (52) to generate Tcf7l1+/− heterozygous mice. These mice were subsequently crossed to Hesx1Cre/+ to generate Hesx1Cre/++;Tcf7l1+/− double heterozygotes, which upon crossing with Tcf7l1floxfloxFmcrflox mice, were used to generate the Hesx1Cre/++;Tcf7l1floxflox mice and embryos analyzed in this study. Genotyping of mice and embryos was carried out by PCR on ear punch biopsies or pieces of tissue from embryos digested in DNAreleasy (Anachem) as per manufacturer’s instructions. The data presented in this work are representative of examples of at least 3 individual embryos per genotype. All the experiments performed in mice were carried out according to UK Home Office guidance and approved by a local ethical committee.

Patient recruitment

Patients with congenital hypopituitarism (CH) disorders were recruited into the study from both national and international pediatric and adult endocrinology centers between 1998 and 2005. A total of 215 probands (129 male, 86 female) were screened for mutations within TCF7L1. These included 31 patients with CH without any midline or eye defects, 6 with holoprosencephaly (HPE), 148 patients with septo-optic dysplasia (SOD) (characterized by optic nerve hypoplasia in association with hypopituitarism and/or midline defects), and 30 patients with anophthalmia (n = 12) or microphthalmia (n = 18). Ethical committee approval was obtained from the Institute of Child Health/Great Ormond Street Hospital for Children Joint Research Ethics Committee (Institute of Child Health, London, United Kingdom). Informed written consent was obtained from the parents and, where applicable, the patients prior to collection of samples and genomic analysis.
Mutation analysis of TCF7L1

The entire coding region of TCF7L1 (NM_031283) was PCR-amplified and subjected to direct-sequencing in our cohort. Detailed PCR and sequencing conditions are available upon request. For any mutations identified, control databases were consulted including 1000 Genomes (www.1000genomes.org), Single Nucleotide Polymorphism Database (dbSNP), Exome Variant Server (EVS) and the Exome Aggregation Consortium (ExAC; comprising >61,000 genomes) Browser (http://exac.broadinstitute.org/). Patients 1 and 2 were screened and found not to carry mutations in other relevant genes involved in CH and SOD, specifically: Patient 1 was screened for mutations in HESX1, CHD7, KAL1, PROKR2, FGFR1 and FGF8; and Patient 2 in HESX1, SOX3, KAL1, PROKR2, FGFR1 and FGF8.

In situ hybridization on histological sections

Histological processing of embryos and in situ hybridization on paraffin sections was performed as previously described (53, 54). The antisense riboprobes used in this study (Gh, Cga, Pomc1, Prop1, Lh, Tsh, Fgf10, Fgf8, Bmp4, Lhx3, Bmp4, Tbx2, Tbx3 and Pit1) have been described (51, 53-55). Human TCF7L1 riboprobe was generated using a full-length cDNA cloned into pCMV-Sport6 (SalI 5’, NotI 3’) (SourceBioscience, clone number: IRATp970D0681D, IMAGE: #6141641).

Immunohistochemistry
Embryos were fixed in 4% PFA and processed for immunodetection as previously described (11, 51). Detection of hormones was carried out using antibodies for α-ACTH (10C-CR1096M1), α-TSH (NHPP AFP-1274789), α-PRL (NHPP AFP-425-10-91), α-LH (NHPP AFP-C697071P) and α-FSH (AFP-7798-1289) (Developmental Studies Hybridoma Bank) at a 1:1000 dilution. α-SHH (AF464; R&D Systems) and α-TCF7L1 (33) were used at a 1:100 dilution and signal amplified using the Tyramide Signal Amplification kit (Perkin Elmer, NEL741001KT). α-Cleaved Caspase 3 was used at a 1:300 dilution (9661; Cell Signaling Technologies) and α-phosphorylated-histone H3 at a 1:1000 dilution (06-570; Upstate). The mitotic index of pituitary periluminal progenitors represents the percentage of proliferating cells (phosphorylated-histone H3 positive cells) from total number of DAPI-positive nuclei. Anti-phosphorylated-histone H3 (1:1000) (rabbit polyclonal; Upstate) was used for this study.

**Cell transfection, luciferase assays and immunoblotting**

HEK293T cells were grown in DMEM supplemented with 10% fetal bovine serum. Two reporters were used to assess the repressing activity of human wild-type TCF7L1 and the p.R92P and p.R400Q variants: (1) the TOPflash reporter plasmid carrying six wild-type binding sites for the TCF/LEF1 factors upstream of the firefly luciferase gene; (2) the LEF1-promoter-luc reporter, which contains a DNA fragment (-6713 to -1 bp) of the human LEF1 promoter inserted upstream of a luciferase reporter gene (33). Approximately 250,000 cells were seeded per well of 24-well tissue culture plates and the following day subjected to DNA transfection. A total of 100 ng of TOPflash or 200 ng of LEF1-promoter-luc reporter were co-transfected with constructs expressing wild-type and
mutant hTCF7L1 proteins (10 and 50 ng) and 80 ng Renilla luciferase plasmid as internal control using Lipofectamine 2000 (Life Technologies) according to the manufacturer’s protocol. The total amount of DNA was kept constant in all the transfections by complementing with pBluescript plasmid up to 350 ng. Activation of the TOPflash reporter was achieved by culturing the cells in the presence of 10 µM SB216763 (Sigma), a potent GSK3-β inhibitor resulting in the stabilization of β-catenin. The LEF1-promoter-luc was activated with 30 µM SB216763. The repressing activity of wild-type hTCF7L1 and the variants was assessed 48 hours post-transfection using the Dual-Luciferase Reporter Assay System (Promega) following the manufacturer’s instructions. Total levels of repression caused by the hTCF7L1 p.R92P and p.R400Q proteins were represented as a percentage of the maximum repression caused by wild-type hTCF7L1. Experiments were repeated 4 times in triplicates and statistical analysis was done using one-way ANOVA with Tukey’s post-hoc analysis.

Zebrfish Experiments

Zebrfish were bred and raised under standard conditions. hdl/tcf7l1a^m881/^;tcf7l1b^f157Tg/^ (from now on tcf7l1a^+/--; tcf3l1b^+/+) zebrfish embryos were generated from crossing tcf7l1a^+/--;tcf3l1b^+/+ males with tcf7l1a^+/-- females (56), raised at 28°C and staged according to Kimmel et al. (57) Embryos were microinjected with 100 picograms (5 nanoliters) of mRNA encoding either wild-type, p.R92P or p.R400Q hTCF7L1 at one to two cell stage. mRNA encoding wild-type or mutant hTCF7L1 proteins was co-injected with mRNA encoding GFP, and embryos with low or no GFP fluorescence were excluded from the
Analysis. *tcf7l1a* alleles were genotyped by KASP assays (LCG Group). *The tcf7l1b* viral insertion was identified by genomic DNA PCR using the following primers:

GSP2-F: 5'-GGATAACGTGAGTATCTTCTC-3’; and LTR2-R: 5’-TCTGTTCCCTGACCTTGATCTGA-3’.

**Statistics**

Mendelian ratios were evaluated using the chi-squared test. For all other analyses, a one-way ANOVA was utilised. Values less than 0.05 were considered statistically significant. Quantitative data are presented as mean ± standard error of the mean (SEM). Clonogenic potential of control and *Hesx1Cre/+;Tcf7l1+/-* mutant stem cells was evaluated using a paired t-test. Total cell counts of control and *Hesx1Cre/+;Tcf7l1+/-* mutant pituitaries were analyzed by unpaired t-test.

**Results**

*Hesx1Cre/+;Tcf7l1flax/-* mutants exhibit forebrain and pituitary defects

Genotyping analysis of 9.5-18.5 dpc embryos from crosses between *Hesx1Cre/+;Tcf7l1+/-* and *Tcf7l1flax/flax* showed a normal Mendelian distribution of genotypes, implying that the lack of *Tcf7l1* in the *Hesx1*-cell lineage is not embryonic lethal (Table 1). *Hesx1Cre/+;Tcf7l1flax/-* mutant embryos displayed variable degrees of anterior forebrain defects, including eye defects (i.e. microphthalmia or anophthalmia) and telencephalic abnormalities (i.e. small or absent telencephalic vesicles), as previously described (47) (Fig. S1C). Additionally, we observed neural tube closure defects resulting in exencephaly in around 10% of these mutants (Fig. S1B). Genotyping analyses of mice at
3 weeks of age revealed no significant differences of the expected Mendelian ratios for the $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mutants when compared with control littermates, but perinatal death was observed in some $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mice (Table 1). Most of the surviving mutants did not exhibit any gross morphological defects, but around 25% of these showed dwarfism with reduced size and weight compared with their littermates, suggesting a potential functional compromise of the HP axis (Fig. S1A, D and E). We observed unilateral microphthalmia with no compromise of the telencephalic vesicles in around 20% of the $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ embryos as previously reported (47).

Histological and in situ hybridization analyses of $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mutant and control embryos at 17.5 dpc revealed two clearly discernable pituitary phenotypes: (i) Group 1 embryos, approximately 25% of the $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mutants, displayed severe morphological defects and ectopic pituitary tissue was often observed in the roof of the oropharyngeal cavity (Fig. 1A’-H’). In these mutants, morphologically distinguishable posterior or intermediate lobes could not be observed. This phenotype was associated with severe forebrain defects. Hormone-producing cells were detected in these mutants, even in the ectopically located pituitary tissue; (ii) Group 2 embryos, accounting for approximately 75% of $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mutants, showed a less severe phenotype with mild pituitary hyperplasia and presence of pituitary cleft bifurcations (Fig. 1D’-H’). Posterior and intermediate lobes appeared morphologically normal in mutants in this group. Total cell counting of dissociated pituitaries at 18.5 dpc revealed average cell counts of $75,300 \pm 5227.33$ for the $Hesx1^{Cre/+};Tcf7l1^{flox/-}$ mutants (n=5) and $66,200 \pm 7585.62$ for controls (n=8). Although these differences did not reach statistical significance (p=0.0584), the data suggest a trend towards mild hyperplasia in Group 2.
mutants. Differentiation of hormone-producing cells occurred normally with no apparent differences between $\text{Hesx1}^{\text{Cre}/+};\text{Tcf7l1}^{\text{flox/-}}$ Group 2 mutants and control embryos. The Sox2-positive stem cell compartment was analyzed in vitro by culturing dissociated cells in stem cell-promoting medium, which revealed no differences in clonogenic potential between Group 2 mutants and controls (Fig. S2).

Similar morphological abnormalities, including hyperplasia, cleft bifurcations and ectopically located pituitary tissue, were observed in $\text{Hesx1}^{\text{Cre}/+};\text{Tcf7l1}^{\text{flox/-}}$ mutants at 13.5 and 15.5 dpc. Nevertheless, expression of $\text{Lhx3}$, $\text{Pomc1}$, $\text{Prop1}$ and $\text{Pit1}$ at 13.5 dpc as well as $\text{Lhx3}$, $\text{Pomc1}$, $\text{Cga}$ and $\text{Pit1}$ at 15.5 dpc was detected in the developing pituitary of all mutants analyzed (Fig. 2A-P). Together, these analyses suggest that loss of $\text{Tcf7l1}$ in $\text{Hesx1}$-expressing cells leads to aberrant pituitary morphogenesis but normal cell differentiation in the majority of the embryos, with low penetrance of a phenotype characterized by ectopic pituitary tissue, possibly of anterior lobe identity, in the oropharyngeal cavity concomitant with defective terminal differentiation.

**Abnormal hypothalamic signaling and increased proliferation of Rathke’s pouch progenitors in $\text{Hesx1}^{\text{Cre}/+};\text{Tcf7l1}^{\text{flox/-}}$ mutants**

During early pituitary development, the synergistic expression of $\text{Bmp4}$, $\text{Fgf8}$ and $\text{Fgf10}$ within the developing hypothalamus is essential for the induction of $\text{Lhx3}$ in the region of the oral ectoderm fated to become Rathke’s pouch (RP) (2). The expression domains of $\text{Fgf8}$, $\text{Fgf10}$ and $\text{Bmp4}$ in the hypothalamic anlage (Fig. 3A-L), and of $\text{Lhx3}$ in the underlying RP (Fig. 3M-P), were rostrally expanded in the $\text{Hesx1}^{\text{Cre}/+};\text{Tcf7l1}^{\text{flox/-}}$ mutants relative to controls at 9.5 dpc. Enlargement of the $\text{Lhx3}$-expression domain suggests the
recruitment of additional oral ectoderm into Rathke’s pouch epithelium, which may contribute to the hyperplasia observed at subsequent developmental stages. The expression of SHH, another critical signal required for normal RP development (58, 59), in the preoptic area of the hypothalamus was shifted anteriorly and slightly reduced in the Hesx1\textsuperscript{Cre/+};Tcf7l1\textsuperscript{floxed/} mutants in comparison with controls (Fig. 4I-L). In agreement with this observation, the expression domains of Tbx3, and to a lesser extent Tbx2, which normally act as repressors of Shh expression in the hypothalamus (55), were rostrally shifted thus invading the caudal region of the preoptic area, where SHH expression appears reduced (Fig. 4A-H).

Proliferation analysis revealed a mild but statistically significant increase in the mitotic index of RP periluminal progenitors in Hesx1\textsuperscript{Cre/+};Tcf7l1\textsuperscript{floxed/} mutant pituitaries at 13.5 dpc (p <0.05), but this was transient and not observed at 15.5 dpc (p >0.05) (Fig. 2Q-S). This phenotype is entirely consistent with the deletion of Tcf7l1 in both the hypothalamus and RP in the Hesx1\textsuperscript{Cre/+};Tcf7l1\textsuperscript{floxed/} mutant pituitaries (Fig. S3C and D). Caspase 3 immunostaining revealed the presence of a few apoptotic cells in the ventral regions of RP in both the mutant and control embryos (Fig. S3A and B). Together, these studies suggest that Tcf7l1 is required for proper patterning of the prospective hypothalamus and for establishment of the normal expression domains of critical hypothalamic signals involved in the induction and proliferation of RP progenitors.

**TCF7L1 functions as a repressor during normal pituitary organogenesis**

Next, we sought to assess whether the requirement of TCF7L1 within the developing hypothalamus and pituitary gland was dependent or independent of β-catenin. To achieve
this, we used a recently generated mouse line (Tcf7l1ΔN/ΔN) expressing a TCF7L1 mutant protein lacking the β-catenin-interacting domain at the N-terminus. This truncated form of TCF7L1 (TCF7L1ΔN) shows similar DNA binding and repressing activities to wild-type TCF7L1, but its interaction with β-catenin is abolished (33).

In situ hybridization analysis revealed the absence of morphological defects in the pituitary gland and the normal expression of terminal differentiation markers (Gh, PompC, Cga, Tsh and Lh) in Tcf7l1ΔN/ΔN mutants relative to control embryos at 18.5 dpc (Fig. 5I-R). Likewise, the expression domain of Fgf10 within the hypothalamus and Lhx3 in the developing RP were comparable between genotypes (Fig. 5A-H). Note that Tcf7l1ΔN/ΔN mutants show a general developmental delay and are smaller than control littermates, which accounts for the slight size differences in the expression domains (Fig. 5C and D) (33). The absence of any apparent defects in Tcf7l1ΔN/ΔN mutants demonstrates that TCF7L1 acts primarily as a transcriptional repressor within the developing hypothalamus and pituitary gland and that its function is independent of β-catenin. Additionally, these data imply that the defects observed in Hesx1Cre/+, Tcf7l1flox−/− mutants are a consequence of the de-repression of TCF7L1 transcriptional targets.

**Variants in TCF7L1 are associated with forebrain and pituitary defects in humans**

The forebrain and pituitary defects observed in the Hesx1Cre/+, Tcf7l1flox−/− mutants are very similar to those previously described in Hesx1-deficient embryos, suggesting that these transcriptional repressors may control the same genetic program (49, 54). Since mutations in HESX1 have been associated with congenital hypopituitarism in humans, including SOD (60, 61), we hypothesized that mutations in TCF7L1 may also be
implicated in these conditions. Indeed, in situ hybridization showed that TCF7L1 is expressed during human embryonic development within brain tissue, including the hypothalamus, and the developing pituitary gland (Fig. 6).

To investigate this possibility, we screened a total of 215 patients with hypopituitarism including SOD for mutations in the TCF7L1 locus by Sanger sequencing. Two heterozygous sequence variants resulting in amino acid changes in highly conserved residues of TCF7L1 were identified in two unrelated patients (clinical details are presented in Table 2 and SI).

Patient 1 of Caucasian (Finnish; non-consanguineous) descent, showing forebrain defects (i.e. partial agenesis of the corpus callosum, thin right optic tract and thin anterior commissure), and normal pituitary function, carried a missense G to C sequence variant at position 275 (c.275G>C), which causes the substitution of arginine 92 by proline (p.R92P) (Fig. 7A and B). This variant was not identified in online databases (listed previously) or 392 additional Caucasian controls (including 200 healthy Finnish). The variant was inherited from the father, and was also present in the paternal uncle, who were both asymptomatic.

Patient 2, of Pakistani (non-consanguineous) descent, was diagnosed with classical SOD and showed small optic nerves and chiasm, an absent posterior pituitary, a very small anterior pituitary and absent septum pellucidum. The proband harbored a missense G to A sequence variant (c.1199G>A) resulting in an arginine to glutamine change at position 400 (p.R400Q) (Fig. 7A and B). Although this variant was not identified in our healthy controls, the dbSNP or the ESP databases, it is present in 14 individuals in the ExAC database with an allelic frequency of 2.958e-05, in
heterozygosity. The variant was inherited from the unaffected mother, and 2 unaffected siblings also carried the variant.

**TCF7L1 p.R92P and p.R400Q variants show impaired repressing activity in vitro and in vivo**

We sought to assess the capacity of wild-type and hTCF7L1 p.R92P and p.R400Q proteins to repress WNT/β-catenin-mediated transcriptional activation *in vitro*. We used two different reporters in transfected HEK293 cells cultured in the presence of a GSK3β inhibitor. Using the TOPflash reporter, the repressing activity of the TCF7L1 (p.R92P) variant was reduced by 34% - 40% (10 ng and 50 ng, respectively; p<0.05) relative to wild-type TCF7L1 (Fig. 7C, left graph). Likewise, the repressing activity of the TCF7L1 (p.R400Q) variant on the TOPflash reporter was diminished by 41% - 55% (10 ng and 50 ng, respectively; p<0.05) compared with wild-type TCF7L1 (Fig. 7C, left graph). A reduction of the transcriptional repressing activity of these variants was also observed when using the *hLEF1*-promoter-luc reporter (30% reduction for TCF7L1 (p.R92P) and 27% reduction for the TCF7L1 (p.R400Q) (p <0.05)) (Fig. 7C, right graph). In these transfection experiments wild-type and mutant hTCF7L1 proteins were expressed at similar levels, as revealed by western blot analysis using a specific anti-TCF7L1 antibody (Fig. 7D). No dominant-negative effects were observed in co-transfection experiments combining wild-type and hTCF7L1 p.R92P and p.R400Q variants (Fig. S4).

Finally, to assess the repressing activities of the two variants *in vivo*, we took advantage of a zebrafish model with a lower gene dosage of the *hTCF7L1* orthologues tcf7lla and tcf7llb. tcf7lla<sup>−/−</sup> and tcf3llb<sup>−/−</sup> single mutants show no phenotype, but tcf7lla<sup>−/−</sup>
double mutants exhibit an eyeless phenotype due to the ectopic activation of the Wnt/β-catenin signalling pathway and de-repression of targets of this pathway in the forebrain (including the eye field) (30, 31). We injected double \textit{tcf7ll\textasciitilde{};tcf3l\textasciitilde{}} double mutant zebrafish embryos, which normally develop no eyes, with mRNA encoding either wild-type hTCF7L1 or the two variants identified aiming to determine their ability to rescue the eyeless phenotype. Microinjection of wild-type \textit{hTCF7L1} mRNA fully rescued the eyeless phenotype of \textit{tcf7ll\textasciitilde{};tcf3l\textasciitilde{}} double mutants (Fig. 8; \textit{n}=18 mutants, 3 independent experiments). However, only 67.7\% (21 out of 31 mutants) and 50\% (12 out of 24 mutants) of the eyeless \textit{tcf7ll\textasciitilde{};tcf3l\textasciitilde{}} embryos were rescued by injection of mRNA encoding the p.R92P and p.R400Q hTCF7L1 variants, respectively (Fig. 8). These results support the \textit{in vitro} findings previously presented and add further evidence to the notion that the hTCF7L1 variants p.R92P and p.R400Q exhibit reduced repressing activity \textit{in vivo}.

\textbf{Discussion}

In this manuscript we have provided genetic and molecular evidence demonstrating that the repressing activity of the transcription factor TCF7L1 is required for normal establishment of the HP axis in mice and humans.

The pituitary defects of the \textit{Hesx1\textasciitilde{};Tcf7ll\textasciitilde{}} mouse mutants are very similar to those observed in \textit{Hesx1\textasciitilde{}} embryos; increased proliferation leading to abnormal pituitary morphogenesis but overall normal terminal differentiation (14, 54). We show the absence of mTCF7L1 protein in both the hypothalamus and the developing RP by 10.5 dpc in \textit{Hesx1\textasciitilde{};Tcf7ll\textasciitilde{}} mutants, thus validating the genetic approach. Within the
hypothesised, we have revealed a critical role for mTCF7L1 in the regulation of antero-posterior patterning, as there is an overall anterior shift in the expression domains of caudal hypothalamic signals and markers (e.g. Fgf8, Fgf10, Bmp4, Tbx2 and Tbx3), which is concomitant with a reduction in SHH expression in the anterior hypothalamic area (Fig. 3 and 4). This abnormal hypothalamic signaling results in the recruitment of additional ectoderm into RP, as detected by the rostral expansion in the Lhx3 expression domain and increased proliferation in the developing pituitary of Hesx1\(^{-/-}\);Tcf7l1\(^{-/-}\) mutants at 13.5 dpc. In addition, there may be a contribution to the phenotype due to the lack of TCF7L1 within RP, which we cannot rule out.

There is a marked variability of expressivity of the pituitary phenotype in Hesx1\(^{\text{Cre}+/\text{+}}\);Tcf7l1\(^{-/-}\) mouse mutants (Fig. 1 and 2), which is reminiscent of that observed in Hesx1-deficient embryos. In most of the Hesx1\(^{\text{Cre}+/\text{+}}\);Tcf7l1\(^{-/-}\) mutants (Group 2), there is an overall increase in pituitary tissue and anterior, posterior and intermediate lobes can be identified. However, in the most severely affected mutants (Group 1), the posterior and intermediate lobes cannot be morphologically detected from 13.5 to 17.5 dpc. Incidentally, some Hesx1\(^{\text{Cre}+/\text{+}}\);Tcf7l1\(^{-/-}\) mutants at 9.5 dpc show a lack of contact between the developing infundibulum and RP, which may contribute to the development of the ectopic pituitary in the roof of the oropharyngeal cavity. It is likely that this phenotypic variability observed from 13.5 dpc, is brought about by the differential dysregulation of the hypothalamic signals normally involved in induction and proliferation of RP progenitors, an idea that is difficult to test experimentally.

Previously, we have shown that the cooperation between HESX1 and TCF7L1 is required to repress the activation of the WNT/\(\beta\)-catenin pathway in the anterior neural
plate of zebrafish and mouse embryos (47). Our data are in support of the idea that TCF7L1 acts as a repressor during normal pituitary development in mice. Functional studies in mice have demonstrated a temporally specific function of the WNT/β-catenin signaling pathway during pituitary organogenesis. This pathway must be repressed at early stages of pituitary development and activated from 14.5 dpc for normal differentiation of the Pou1f1-cell lineage (37). In agreement with this notion, the permanent activation of the WNT/β-catenin pathway in RP progenitors at 9.5 dpc, by expression of a degradation-resistant form of β-catenin, results in severe pituitary hyperplasia during embryogenesis (50). Mice deficient for Tcf7l2, a TCF/LEF factor shown to act as either an activator or a repressor depending on the cell context, show anterior pituitary hyperplasia but no defects in the differentiation of hormone-producing cells (41). The similarities in the pituitary phenotype between Tcf7l2−/−, Hesx1−/− and Hesx1Cre+;Tcf7lflox−/− mutants suggest that these factors are likely to act as transcriptional repressors of WNT/β-catenin pathway targets during HP axis development. Indeed, the expression of a mutant form of TCF7L1 unable to interact with β-catenin, but maintaining repressing activity, does not lead to any hypothalamic or pituitary defects, demonstrating that TCF7L1 is required as a repressor (Fig. 5).

Our data also provide evidence that the repressing activity of TCF7L1 is required for normal HP axis development in humans. Firstly, we show the expression of hTCF7L1 mRNA in the developing human embryo (Fig. 6). Furthermore, we have identified two TCF7L1 variants, p.R92P and p.R400Q, in unrelated families with SOD, which substitute highly conserved residues, and shown that these variants are functionally compromised. These mutant proteins show reduced repressing activity relative to wild-type TCF7L1.
using both the TOPflash reporter plasmid and a luciferase reporter containing a fragment of the human \textit{LEF1} promoter (Fig. 7) (33). In addition, we show that the TCF7L1 p.R92P and p.R400Q variants cannot rescue the eye defects of zebrafish mutants with a reduced gene dosage of \textit{tcf7l1} (Fig. 8). Given the presence of the variants in the phenotypically unaffected father and paternal uncle, our data suggest that they are not uniquely responsible for disease development, but may be variably penetrant. The concept of variable penetrance has been observed in a variety of human genetic disorders. These include Kallmann syndrome, where recent data have suggested an oligogenic basis to the disorder (62). Additionally, mutations in \textit{SHH} and \textit{GLI2}, a mediator of \textit{SHH}, are associated with variably penetrant holoprosencephaly. Sequence variants in \textit{LHX4} and \textit{GLI2} are also associated with variably penetrant CH (63, 64). Of note, variable phenotypic expressivity is also observed in the \textit{Hexx1}^{\text{Cre}+};\textit{Tcf7l1}^{\text{fl}+/-} mouse mutants and in the \textit{tcf7l1a}^{+/-};\textit{tcf3l1b}^{+/-} zebrafish mutants injected with the hTCF7L1 variants identified in this study.

In summary, we identify \textit{Tcf7l1} as a novel determinant for the establishment of the HP axis and as a potential candidate gene to be mutated in congenital hypopituitarism.

\textbf{Acknowledgements}

We thank Paul Le Tissier for comments on the manuscript. We thank the Developmental Studies Hybridoma Bank (University of Iowa) and the National Hormone and Peptide Program (Harbor–University of California, Los Angeles Medical Center) for providing some of the antibodies used in this study. We also thank Dr A. Kispert for the \textit{Tbx2} and
Tbx3 riboprobes and Dr S. Sokol, Dr B. Basu, Dr K. Itoh and Dr S. Janssens, for exploratory studies on HIPK2 phosphorylation. Figure Legends

**Figure 1. Abnormal pituitary morphogenesis in Hesx1<sup>Cre+</sup>;Tcf7l1<sup>fl</sup>- mutants.** In situ hybridization (A-C) and immunohistochemistry (D-H) of transverse histological sections of the pituitary gland of control embryos (A-H) and Hesx1<sup>Cre+</sup>;Tcf7l1<sup>fl</sup>- mutants (A’-H’ and A’’-H’’) at 17.5 dpc. (A’-H’) Mildly affected embryos show pituitary hyperplasia, cleft bifurcations (arrows in D’ and E’), but mostly normal expression of differentiation markers. (A’’-H’’) Severely affected pituitaries exhibit dysmorphic pituitary tissue that is ectopically located in the oropharyngeal cavity (arrowheads) but hormone-producing cells are present. Abbreviations: AP anterior pituitary; BS basisphenoid bone; OC oral cavity; PP posterior pituitary; Gh, growth hormone; Pomc1, pro-opiomelanocortin-alpha; ACTH, adrenocorticotroph hormone; TSH, thyroid stimulating hormone; FSH, follicle stimulating hormone; LH, luteinising hormone; Cga, glycoprotein hormone alpha. Pictures are representative of 5 embryos per genotype. Scale bar in H’’ is 100 µm.

**Figure 2. Increased proliferation of Rathke’s pouch progenitors but normal patterning of the developing anterior pituitary in Hesx1<sup>Cre+</sup>;Tcf7l1<sup>fl</sup>- mutants.** (A-P) In situ hybridization on sagittal sections through the pituitary gland of control and Hesx1<sup>Cre+</sup>;Tcf7l1<sup>fl</sup>- mutant embryos (stage and probes are indicated; anterior to the left). (A-H) Mildly affected pituitaries show bifurcations and moderate expansion of the expression domains of Lhx3 and Prop1 at 13.5 and 15.5 dpc (arrows). (I-P) Severely affected pituitaries exhibit enlarged expression domains due to the abnormal morphogenesis of the developing anterior pituitary, which extends into the oropharyngeal cavity (arrowheads). (Q-R) Anti-phospho-histone H3 immunofluorescent staining on
Quantitative analyses showing a statistically significant increase in the mitotic index in the $Hesx1^{Cre^+};Tcf7l1^{fl/-}$ developing pituitaries relative to control littermates at 13.5 dpc but not at 15.5 dpc. Abbreviations: AP, anterior pituitary; BS, basisphenoid bone; Inf, infundibulum; OC oropharyngeal cavity. Pictures are representative of 7 embryos per genotype. ***p< 0.05, one way ANOVA. Scale bar: H and P, 100 µm.

Figure 3. Dysregulation of $Fgf8$, $Fgf10$ and $Bmp4$ expression in the hypothalamus of $Hesx1^{Cre^+};Tcf7l1^{fl/-}$ mutants. In situ hybridization on sagittal histological sections revealing the expression of $Fgf10$ (A-D), $Fgf8$ (E-H) and $Bmp4$ (I-L) in the prospective hypothalamus and $Lhx3$ (M-P) in Rathke’s pouch (anterior to the left). (A-H) $Fgf10$ and $Fgf8$ expression domains are anteriorized along the neural epithelium of the ventral diencephalon (i.e. prospective hypothalamus) overlaying the oral ectoderm of RP in the $Hesx1^{Cre^+};Tcf7l1^{fl/-}$ mutants (compare arrowheads in C and D and G and H, respectively). C and D and G and H represent enlarged images of the dotted squared areas in A and B and E and F, respectively. (I-L) The expression domain of $Bmp4$ is rostrally expanded in $Hesx1^{Cre^+};Tcf7l1^{fl/-}$ prospective hypothalamus compared with control embryos (compare arrowheads K and L). K and L represent enlarged images of the squared dotted areas in I and J. (M-P) The expression domain of $Lhx3$ is rostrally extended in $Hesx1^{Cre^+};Tcf3^{fl/-}$ compared to the control embryo (arrows in O and P), indicating an expansion of the RP epithelium. O and P are enlarged images of the dotted square areas in M and N respectively. Abbreviations: VD, ventral diencephalon; RP, Rathke’s pouch. Pictures are representative of 5 embryos per genotype. Scale bar in P is 100 µm.
Figure 4. SHH and its regulators Tbx2 and Tbx3 are mis-expressed in the developing hypothalamus of Hesx1Cre/+;Tcf7l1fl/fl mutants. (A-H) In situ hybridization on sagittal sections of 10.5 dpc embryos (anterior to the left) reveals the anterior shift of the Tbx3 expression domain, and to a lesser extent Tbx2, within the developing hypothalamus of the Hesx1Cre/+;Tcf7l1fl/fl mutants compared with the control embryos. (I-L) Immunostaining showing a reduction of SHH expression in the caudal region of the preoptic area in a Hesx1Cre/+;Tcf7l1fl/fl mutant relative to a control. Note that the reduction of SHH expression in the caudal region of the preoptic area appears to overlap with the anterior extension of Tbx3 expression. Abbreviations: VD, ventral diencephalon; RP, Rathke’s pouch. Pictures are representative of 3 embryos per genotype. Scale bar in P is 100 µm.

Figure 5. Expression of a mutant form of TCF7L1 lacking the β-catenin-interacting domain (Tcf7l1ΔN/ΔN) is sufficient to sustain normal hypothalamic-pituitary axis development. (A-H) In situ hybridization on sagittal sections showing normal expression domains of Fgf10 (A-D) and Lhx3 (E-H) in Tcf7l1ΔN/ΔN mutants and control wild-type littermates at 9.5 dpc (anterior to the left). C, D, G and H are enlarged images of the dotted squared areas. The apparent difference in size in the Tcf7l1ΔN/ΔN mutants relative to the controls is caused by an overall developmental delay in the mutants. (I-R) In situ hybridization on transverse histological sections through the pituitary gland of Tcf7l1ΔN/ΔN mutants and control embryos at 18.5 dpc reveal no gross differences in the levels of expression of several differentiation markers. Note that pituitary morphogenesis is also
normal in \( Tcf7l1^{AN/AN} \) mutants relative to controls. Abbreviations: AL, anterior lobe; BS, basisphenoid bone; VD, ventral diencephalon; RP, Rathke’s pouch; PL, posterior lobe. Pictures are representative of 5 embryos per genotype. Scale bars: H and R, 100 \( \mu \text{m} \).

**Figure 6.** \( TCF7L1 \) is expressed in the developing hypothalamic-pituitary axis, central nervous system and eyes during human embryogenesis. *In situ* hybridization against \( hTCF7L1 \) on coronal (A-C and G-I) or sagittal (D-F) histological sections at Carnegie Stage (CS) 13, 18 and 20. (A-C) Note the expression of \( hTCF7L1 \) in the ventral diencephalon (VD)) neuroepithelium (i.e. prospective hypothalamus (arrowheads in B), Rathke’s pouch progenitors (arrows in B) and developing optic cups (OC; arrows in C) at CS13. (D-F) At CS18 expression of \( hTCF7L1 \) is observed throughout the neuroepithelium of the hind-, mid- and forebrain, including the hypothalamus (arrowheads in E) and telencephalon (arrows in F). Expression is also detected in the developing anterior pituitary gland (AP) (arrows in E). (G-I) At CS20 expression of \( hTCF7L1 \) is detected in the anterior and posterior lobes of the pituitary gland (AP and PP in H), neural retina (NR) (arrows in I), eyelid (arrow in G), olfactory epithelium of the nasal cavity (NC) and trigeminal ganglia. B ,C, E, F, H, I are enlarged images of the dotted squared areas. Abbreviations: VD ventral diencephalon; RP Rathke’s pouch; OC optic cup; AP anterior pituitary; hyp hypothalamus; AP anterior pituitary; PP posterior pituitary; BS basisphenoid bone; NR neural retina; ON optic nerve. Scale bars: in A, D and G are 500 \( \mu \text{m} \); in B-C, E-F and H-I are 100 \( \mu \text{m} \).
Figure 7. Identification of hTCF7L1 heterozygous missense variants in patients with septo-optic dysplasia. (A) Electropherogram showing two novel heterozygous missense variants in hTCF7L1: p.R92P and p.R400Q. (B) Both DNA variants result in the substitution of highly conserved amino acids. R92 is not conserved in Xenopus and zebrafish. (C) Transient luciferase assays on HEK293 cells co-transfected with either TOPflash (left graph) or hLEF1-promoter-luc (right graph) reporters and constructs expressing wild-type, p.R92P or p.R400Q hTCF7L1 proteins. Note the significant reduction in repressing activity of the p.R92P and p.R400Q hTCF7L1 variants relative to wild-type TCF7L1 using both reporters. ** p<0.05 one way ANOVA. (D) Western blot analysis of transfected HEK293 cells used in (C) with a specific anti-TCF7L1 antibody detects the expression of the wild-type and p.R92P or p.R400Q hTCF7L1 proteins at similar levels. GAPDH was also detected in the same membrane as loading control.

Figure 8. Incomplete rescue of the eyeless phenotype of double tcf7l1a/b zebrafish mutants with the human hTCF7L1 p.R92P and p.R400Q variants. Lateral view of 32 hours post fertilisation zebrafish embryos (anterior to left). Wild-type embryos injected with 100 picograms of hTCF7L1 (C), p.R92P (E) and p.R400Q (H) mRNA show no phenotype compared with wild-type untreated embryos (A). tcf7l1a<sup><s>-/-</s>;tcf3l1b<sup><s>+</s></sup>/- double mutants fail to develop eyes (B). Injection of tcf7l1a<sup><s>-/-</s>;tcf3l1b<sup><s>+</s></sup>/- double mutants with 100 picograms of wild-type hTCF7L1 mRNA rescues the eyeless phenotype (D). Injection of tcf7l1a<sup><s>-/-</s>;tcf3l1b<sup><s>+</s></sup>/- double mutants with 100 picograms of hTCF7L1 p.R92P (F, G) or p.R400Q (I, J) results in incomplete rescue of the eyeless phenotype. (K). Percentage of embryos with normal eyes is shown in blue and with very small or no eyes in red.
