Abstract (now 182 words)

Physical health deteriorates more rapidly with age among men and women with lower socioeconomic status (SES) than among those with higher SES. The biological processes underlying these differences are best understood by adopting a life-course approach. In this paper we introduce the European LIFEPATH project designed to investigate SES and ageing as a phenomenon with two broad stages across life: build-up and decline. LIFEPATH adopts a study design that integrates social science and public health approaches with biology (including molecular epidemiology), using (a) national census-based follow-up data to obtain mortality by socio-economic status, (b) 17 well-characterised population cohorts, and (c) omics measurements (particularly epigenomics). The majority of cohorts include “hard” outcomes (diabetes, cancer, CVD, total mortality), and some extensively phenotyped cohorts also include measurements of the functional components of healthy ageing, including frailty, impaired vision, cognitive function, renal and brain function, osteoporosis, sleep disturbances and mental health. All age groups are represented with two birth cohorts, one cohort of adolescents and several cohorts encompassing young adults (age 18 and above). Furthermore, there is a strong representation of elderly subjects in 7 cohorts.

Key words: social inequalities, socioeconomic status, healthy ageing, life-course, omics, biology.
Introduction

The striking difference in healthy ageing, quality of life and life expectancy observed between individuals from different socioeconomic groups is a major societal challenge that Europe is currently facing. Healthy ageing is an achievable goal in society as it is already experienced by individuals in the highest socioeconomic groups. Individuals with high socioeconomic status (SES) experience much better health and healthier ageing than groups with low SES. Healthy ageing is also strongly related to cumulative exposure to harmful events during the life-course, and particularly in sensitive or critical periods. There is strong evidence that (a) the risk of disease is influenced by early exposures, including \textit{in utero} exposures; (b) the life-course is characterised by \textit{critical} periods (during which changes in exposure have long term effects on disease risks) and \textit{sensitive} periods (during which an exposure has stronger effects on development and, hence, disease risk than at other times). The LIFEPATH project is an example of the integration of social and biological sciences to provide evidence for public health policies directed at meeting the challenges that the socioeconomic gradient and other factors in healthy ageing represent. The present paper describes the design and some initial results.

Context and rationale

LIFEPATH is based on a few assumptions that we describe below and have been addressed through the design choices we have made.

1. The healthy ageing model

Socioeconomic differences in health are striking and are seen in all European countries (Mackenbach et al., 2008). Physical health deteriorates more rapidly with age for men and women from lower socioeconomic groups than among those from higher socioeconomic backgrounds. In addition, there is a large amount of evidence that this holds true also for mental health (see for instance Melchior et al., 2013).

This creates a progressively increasing health differential between social groups such that the average physical health of a 70-year-old man or woman with high SES is similar to that of a person with low SES (occupational grade) who is eight years younger (Chandola, T., Ferrie, J.,
Sacker, A. and Marmot, M., 2007). These differences, and the biological processes underlying them, cannot be understood without adopting a life-course approach. In the project we describe below we use the revised Strachan-Sheikh Ben-Shlomo, Y. and Kuh, D., 2002) model of life-course functioning (Blane et al, 2013; Kuh, D., 2007, 2014;), to describe ageing over a lifetime. This model presents ageing as a phenomenon with two broad stages: build-up and decline. The ‘build-up’ stage, from conception and early intra-uterine life to late adolescence or early twenties, is characterised by rapid successions of developmentally and socially sensitive periods. This stage strongly determines subsequent ageing trajectories as it influences the maximum attained level of health. The second stage, starting in early adulthood, is a period of 'decline' from maximum attained health to loss of function, overt disease and death. Lifestyle and exposures during the second stage can influence the rate at which functioning is lost (Figure 1- dashed line). We are aware that this working scheme is a simplification and does not incorporate the complex relationships that underlie ageing processes, but we use it as a conceptual tool to organize our life-course observations. (Figure 1 here)

2. The complex causal network underlying SES and health

There is much evidence that low SES across the life-course is associated with poor ageing trajectories and early death (Chetty, R. et al, 2016; House, J.S. et al, 2005; Mackenbach, J. et al 2008; Stringhini, S. et al, 2010). There is evidence that the impact of SES on ageing is partly mediated by risk factors for non-communicable diseases (NCD), but this is not the only pathway. Also, the features of low SES in high-income countries have dramatically changed over the last century. In Europe, low SES is often associated with food abundance (but of poor quality), lack of physical exercise, and psychosocial stress (including sleep deprivation and mental problems) (Dugravot, A. et al, 2010; Kivimäki, M. et al, 2002, 2012, 2015; Stringhini, S. et al, 2010, 2012;). This adds to the traditional stressors, such as physical fatigue related to occupation and housework. Analyses in the Gazel cohort, which is part of Lifepath (Kivimaki, M. et al, 2008; Platts et al, 2016) show that demanding jobs were associated with fewer life years spent in good health.
SES is linked to many determinants of health, including: 1) access to and use of medical care; 2) access to health information; 3) patterns of unhealthy behaviors (smoking, heavy drinking, unhealthy diet, physical inactivity, drug use); 4) exposure to environmental and occupational hazards; 5) exposure to stressful life events; 6) access to resources mediating the physiological consequences of stress (social relationships and support and cultural capital); 7) early life adverse experiences; 8) age and time-related susceptibilities (Abel, T., 2008; James WP et al. 1997; Kelly-Irving, M. et al. 2011; Lantz, P.M. et al. 2005; Lynch, J.W. et al. 1997; Mitchell, R. et al. 2002; Siegrist, J. et al. 2004; van Doorslaer, E. et al. 2006; ). The Whitehall studies (part of LIFEPATH) have shown that the SES gradient in unhealthy ageing and cardiovascular disease (CVD) in particular is not completely explained by traditional risk factors, even when they are reduced to the lowest levels for the whole population (Kivimäki, M. et al, 2008; Marmot, M. et al, 2008). In addition, global changes in the economy are accompanied by rising social inequalities. Instability of markets and lack of growth may lead to instability of health indicators and of ageing trajectories as well. The issue of social inequalities (and their health impact) is increasingly being recognized as a global challenge and priority by the global scientific and policy community, as demonstrated by the publication of an issue of the Science magazine devoted to socio-economic differentials, their projections, and their impact on health (Chin, G. and Culotta, E., 2014; Piketty, T. and Saez, E., 2014).

3. Role of behavioural risk factors
Though epidemiology has extensively investigated chemical, physical and behavioural risk factors (such as smoking, diet, alcohol, physical exercise, and occupational factors), these still explain only a fraction of the burden of non-communicable diseases (NCD’s) and of common disabilities. For example, a large fraction of breast, colon and prostate cancers is not explained by known risk factors, and the causes of common conditions such as cognitive impairment are largely unknown. The United Nations 25x25 strategy for NCDs (aiming to reduce mortality from NCDs by 25% by the year 2025) lists diabetes/obesity, alcohol, physical exercise, tobacco, raised blood pressure and salt as the main targets of preventive programmes. The strategy is limited by (a) referring exclusively to known risk factors, (b) excluding highly prevalent conditions that limit individual functioning, such as cognitive decline and musculoskeletal disorders, and (c) not accounting for the social structure that underpins the distribution of known risk factors and the effectiveness of preventive strategies and policies.
A considerable amount of evidence shows that socioeconomic factors are as important as lifestyle-related risk factors, and chemical and physical agents, in determining healthy ageing (House, J.S. et al, 2005; Kelly-Irving, M. et al, 2013, Stringhini, S. et al, 2010, 2017;). Low SES is one of the strongest predictors of healthy ageing in Europe, where, on average, disability-free life expectancy at age 65 is 4.5 years shorter in the lowest SES group than in the highest group (Majer, I.M., Nusselder, W.J., Mackenbach, J.P. and Kunst, A.E., 2011). Differences in the actual life expectancy to age 65 in the US are even larger because social conditions predict a higher likelihood of premature death due to violence or unintentional injury (Muennig, P., Fiscella, K., Tancredi, D. and Franks, P, 2010).

4. Biological pathways linking determinants to healthy ageing

What is missing in linking overarching determinants of SES with health and poor ageing is an understanding of the intermediate mechanisms and pathways that relate low SES with deterioration of organic parameters. For example, research on immune markers in the Whitehall II study [Appendix 1] has shown that glucocorticoids (a class of steroid hormones) and inflammation may in part explain how the body mediates the effects of low SES thus leading to disease, and this is partly independent of common known risk factors (Stringhini, S. et al, 2013). More generally, recent studies have shown that SES can influence the global physiological dysregulation across the life-course, measured using allostatic load, a measure of biological multisystem wastage (Barboza Solís, C. et al. 2015; Delpierre et al, 2016 Merkin, S.S. et al. 2014; Nicod, E. et al. 2014).

A research approach based on intermediate biomarkers is more powerful in identifying the links between SES and healthy ageing than one based on traditional risk factors alone because (a) it may explain subtle chronic effects acting throughout the life-course (like chronic stress) that are not easily captured by questionnaire-based epidemiology; (b) it allows tracing signals that start in early life through to health effects in later life; (c) it provides an approach to the discovery of new pathways and causes of disease, particularly through the new omic technologies (Box 1). By analysing intermediate biomarkers potentially involved in various diseases, this approach is likely to reveal some common (currently unknown) roots of many NCDs (multi-morbidity), thus improving our ability to implement successful interventions, with a wide range of actions.
Research strategy

1. Aims of the project

The specific objectives of LIFEPATH are:

- To demonstrate that healthy ageing is highly variable in society, due to multiple environmental, behavioural and social circumstances that affect individual life trajectories.
- To improve the understanding of the mechanisms through which healthy ageing pathways diverge by social circumstances, by investigating life-course biological pathways using omic technologies.
- To provide evidence on the reversibility of the poorer ageing trajectories experienced by individuals exposed to the strongest adversities, by using an experimental approach (randomised experiments of an earned income tax credit programme in New York and Atlanta and a "conditional cash transfer" experiment for poverty reduction in New York City carried out by MDRC, the Manpower Demonstration Research Corporation); and to analyse the health consequences of the current economic recession in Europe (i.e. changes in social and economic circumstances).
- To provide updated, relevant and innovative evidence to inform future policies.

The project objectives will be accomplished by using different data sources:

- Europe-wide and national surveys (updated to 2014), including EU-27;
- Longitudinal cohorts (across Europe) with intense phenotyping and repeat biological samples;
- Other large cohorts with biological samples
- A large registry dataset with over a million individuals and very detailed information on work trajectories and health;
- A randomized experiment on conditional cash transfer for poverty reduction in New York City.
- A randomised experiment of an earned income tax credit programme in New York and Atlanta
Publicly available cohort data.

The geographic location of the studies is shown in Figure 2. A detailed description of the cohorts and corresponding datasets is presented in Table 1 (Appendix 1) (not including Europe-wide national surveys). Data are harmonized and integrated to conceptualize healthy ageing as a composite outcome at different stages of life, resulting from life-course environmental, behavioural and social determinants.

(Figure 2 here)

2. Cohorts participating in the study

LIFEPATH includes information and biological samples from 8 longitudinal population-based cohorts with extensive phenotyping and repeat biological samples, 9 large longitudinal population-based cohorts with biological samples, and a very large cohort without biological samples (WHIP, Work and Health Histories Italian Panel, from Italy). The countries that are covered by the cohorts are France, Italy, Portugal, Ireland, UK, Finland, Switzerland and Australia. These cohorts are only a small proportion of all cohorts available in Europe, but we have chosen them for the combination of good measures of socio-economic status, risk factors for NCD and biomarkers already measured (or availability of blood samples for further testing). The majority of cohorts include “hard” outcomes (diabetes, cancer, cardiovascular disease - CVD, total mortality), and the extensively phenotyped cohorts also include several measurements of the functional components of healthy ageing, including frailty, impaired vision, cognitive function, renal and brain function, osteoporosis, sleep disturbances and mental health. All age groups are represented with two birth cohorts, one cohort of adolescents and several cohorts encompassing young adults (age 18 and above). Furthermore, there is a strong representation of elderly subjects in 7 cohorts (Appendix 1. Table 1). This age structure allows us to address the first challenge, the lifecourse perspective (model described in Figure 1).

3. Experimental studies to test policy strategies

Data from cohorts are complemented by data from the evaluation of two randomised experiments in the United States carried out by MDRC (Non-profit research organisation
working to improve programs and policies affecting people with low SES) in New York: (a) the *Opportunity NYC—Family Rewards study*, a randomized experiment of conditional cash transfers (CCT) to help families break the cycle of poverty, and the first CCT program in a high-income country. The program was evaluated through a randomized controlled trial involving approximately 4,800 families and 11,000 children, half of whom could receive the cash rewards if they met the required conditions, and half who were assigned to a control group that could not receive the rewards. Data include extensive measures of social and economic conditions as well as extensive health assessments, which the present project plans to complement with additional biological measures. (b) The *Paycheck Plus*, a randomized experiment of tax credits to help adults without dependent children break the cycle of poverty. The Earned Income Tax Credit is a federal program in which low-income individuals and families receive an annual credit that varies according to their working income. The program was evaluated through a randomized controlled trial involving approximately 10,000 participants, with control participants assigned to the current maximum $500 annual return and experimental participants assigned to a maximum $2000 return. Data include extensive measures of social and economic conditions and we will collect data on serum cholesterol, C-reactive protein (a marker of inflammation), glycosylated haemoglobin (a marker of diabetes), blood pressure, abdominal circumference, height, and weight after the intervention. These experimental studies are relevant to the *second challenge*, the complexity of causal relationships and the demonstration of reversibility of some effects.

4. Outcomes and definition of healthy ageing

Indicators of healthy ageing are being developed using the wealth of individual information collected in the cohorts participating in LIFEPATH (Appendix 1. Table 1) as well as from publicly available datasets. Four “hard” indicators of healthy ageing are being used (incident diabetes, cancer, cardiovascular disease, and death), and several functional and physiological indicators are also available (blood pressure, anthropometry, frailty, physical strength, walking speed and grip strength, eye macular health, sleep, cognitive function including dementia, mental health, bone health, renal function, urinary electrolytes and cardiometabolic measures). The World Health Organisation increasingly emphasizes the need to shift from a definition of health based on hard indicators like mortality and diseases, to ability and disability indicators. In addition to being analysed separately, in LIFEPATH these measures will be incorporated
into composite indicators of (un)healthy ageing. The contribution of each outcome to the composite indicators will be weighted based on the severity of the outcome (with premature death having the highest weight). To achieve this, we will incorporate methods and estimates from other projects such as the Global Burden of Diseases Collaboration (Lim, S.S. et al, 2012), taking into account life stages and gender. Because the GBD system is controversial, we will also test other systems of weighting such as those based on mobility, impairment of usual activities, pain/discomfort and anxiety/depression derived from a systematic review of the literature. Early-life health events (such as sleep disturbances and changes in blood pressure) will be separated from typically late-life problems like frailty, osteoporosis, macular and cognitive impairment.

In LIFEPATH we have operationally defined healthy ageing with two components. First, through a general statement about healthy ageing and second, through recommendations about variable selection and choice of analyses across the life-course using longitudinal datasets; these are provided below:

- Statement on Healthy Ageing: “Healthy ageing is the optimal state of performance and wellbeing capable for each particular phase of the lifecourse that can be expected in a society, across social and cultural groups of a population”.

- Key to variable selection is that the component variables be: a) appropriate to the life-course stage, and b) the wellbeing variables capture something of perception and lived experience.

5. Risk factors and healthy ageing

One of the leading hypotheses of LIFEPATH is that SES operates partially through an unequal distribution of conventional risk factors for poor health across SES strata, but that there is also an additional effect of SES on healthy ageing that is not explained by these conventional risk factors (third challenge). Therefore, having good information on a number of risk factors for disease is key to ensuring the success of the project. Also crucial, is the ability to encompass the whole trajectory that links SES with healthy ageing by modelling risk factors (and omics, see below) with proper analytic tools and study designs. These include mediation analysis, structural equation models, randomized experiments and natural experiments. Once the data are harmonized across cohorts, LIFEPATH will assess:
(a) the relationship between SES measures and risk factors;
(b) the relationship between individual risk factors for poor health and their combinations with multiple diseases and (composite) indicators of healthy ageing;
(c) the intermediate role of risk factors in the relationship of SES with healthy ageing (including interaction between risk factors);
(d) the proportion of the variance in healthy ageing that remains unexplained by measured risk factors.

6. Biological embedding and omic biomarkers over the life span

Differentiating the analysis of ageing in terms of the two stages of build-up and decline allows an appropriate and detailed exploration of ageing mechanisms, and the use of iterative biological measures from cohorts at different ages. For example, an analysis of the first ‘build-up’ stage may use as its embodiment measure a biological indicator collected in childhood or early adulthood; whereas an analysis of the ‘decline’ stage may treat mid-life biological indicators as mediating variables, and measures of physical functioning in later life or diseases as an outcome. This dynamic approach to life-course analyses is central in LIFEPATH and will be made possible by the integrated use of longitudinal cohorts capturing different life stages with repeat measures and biological samples.

(Box 1 here)

Box 1. What are omics technologies?

Omic technologies allow us to measure the whole set of compounds in a certain compartment (e.g. proteomics is about all proteins). These are the definitions of the omics available or measured de novo in LIFEPATH:

Epigenomics: The analysis of epigenetic changes in DNA, histones, and chromatin that regulate gene expression. Epigenetic changes are changes other than changes in DNA sequence that are involved in gene silencing.

Metabolomics: The scientific study of small molecules (metabolites) that are created from chemicals that originate inside the body (endogenously) or outside the body (exogenously). For purposes of the present report, metabolomics is assumed to include exogenous chemicals found in biological systems in their unmetabolized forms.
Proteomics: The analysis of the proteins produced by cells, tissues, or organisms. Analysis is conducted to understand the location, abundance, and post-translational modification of proteins in a biological sample.

Transcriptomics: Qualitative and quantitative analysis of the transcriptome, that is, the set of transcripts (mRNAs, noncoding RNAs, and miRNAs) that is present in a biological sample.

By combining existing information from birth and adult longitudinal studies, LIFEPATH is organised into three main interacting streams, illustrated in Figure 3:

(a) **an outer layer of the project: overarching DETERMINANTS.** The focus is on healthy ageing as a continuous process in life ("life-path") and on SES differentials as key determinants, based on the well-documented assumption that SES over time is one of the strongest predictors (and also a summary measure) of the development and preservation of good health and of later-life diseases and disabilities;

(b) **a middle layer of the project: RISK FACTORS.** The project studies the influences SES has on healthy ageing and life expectancy via behavioural, occupational, nutritional, environmental and other modifiable risk factors for poor health, from childhood to adulthood;

(c) **an inner layer of the project: BIOLOGICAL PATHWAYS and human social genomics. (Figure 3 here)**

Omics data (in particular epigenomics, metabolomics and transcriptomics), is already available in several cohorts, and is being used to follow and compare the lifetime ageing pathways of individuals in different SES groups or with different exposure to risk factors from across the life-course. This will allow us to reconstruct biologically-embedded life-course ageing trajectories through the integration of (i) early- and later-life SES and risk factors, and (ii) early- and later-life omic measurements and markers of inflammation or immune response. The scheme in Figure 3 explains the different components and outcomes of the project, as well as the types of biomarkers that can be developed as intermediate steps between socio-economic status (SES), risk factors and unhealthy ageing: (a) epigenetic markers, both short-term (and amenable to modification), and long-term (irreversible changes that can be attributed to early-life and late-life exposures); (b) markers of stress and HPA-axis
dysregulation (hypothalamic–pituitary–adrenal axis, a major neuroendocrine system); (c) markers of inflammation and immune response (particularly important in cardiometabolic disease and cancer); (d) markers of neural function and structure.

The following biomarkers are already available or will be measured with existing funds: methylome (n=4,250)(see Box 1); inflammation markers (n=61,000); metabolomics (n=23,000)(Box 1). Most cohorts have C - reactive protein (CRP), and many have cytokines measurements (small proteins involved in cell signaling as immunomodulating agents).

New methylome analyses will be performed for 2,500 new subjects and new transcriptomic analyses for about 600 subjects. Peripheral blood is a convenient source for epigenetic testing, but cellular heterogeneity can confound or mask the results (Adalsteinsson, B.T. et al, 2012; Consortium TEP, 2012; Liu, Y. et al, 2013), because epigenetic signatures differ from one cell subtype to another (Reinius, L.E. et al, 2012). Moreover, the composition of the blood cells can change under a plethora of pathophysiological conditions, and this can also be influenced by SES. The importance of measuring epigenetic patterns across specific cell subtypes also depends on disease status, and subtle differences are likely more important for multifactorial traits. For these reasons, the first analyses of the methylome will be performed in two specific blood cell types in 500 Whitehall II subjects. We will then validate the findings in PBMC (peripheral blood mononuclear cell) in cohorts with cell counts available. Also, the biomarker stock will be enriched by measuring IL6 (interleukin that acts as pro-inflammatory cytokine) and other cytokines in 6,600 additional subjects in Whitehall II (funded by the US National Institutes of Health) and in Skipogh (Table 1), in which also the methylome and RNA sequencing will be measured (n=750).

In some cohorts we also have genetic data (Appendix 1. Table 1). This allows three types of analyses: first, we can measure the relative importance of genetic predisposition to disease vs environmental variables including SES; second, we can look at gene-environment interactions with our non-genetic variables including SES (low-penetrance susceptibility); third, we can apply the concept of Mendelian Randomization, i.e. identify gene variants that are associated with intermediate factors that connect SES with health outcomes, and reinforce causal reasoning (given that no genetic variants have been clearly identified that directly influence SES itself). Genotyping will be performed (or is already available) through other funds for 17,000 subjects from Airwave, 6,600 from Whitehall II, 1,100 from Skipogh and 6,000 from Colaus (Table 1).
7. **Statistical Methods**

This project is working towards developing novel statistical models integrating the different features determining healthy life trajectories. Statistical models are designed to (a) test different conceptual pathways to (un)healthy ageing, integrating information from risk factors, SES, omics and outcomes that contribute to healthy ageing; (b) provide estimates of the weight of different causes, distal/fundamental or proximal, to enable the simulation of different scenarios of public health policies or interventions which might improve healthy living.

(Table 2 here)

An outline of the different aspects of statistical analyses is provided in Table 2. Statistical methods are also being developed to investigate the association between SES and healthy ageing, between SES and risk factors, and between risk factors and healthy ageing indices as conceptualised above. Additional methodological efforts will rely on the development of omics profiling techniques integrating data arising from different platforms, and mechanistic models investigating the interplay of these different sets of markers.

**Omic signatures** - As summarised in Table 3, numerous analyses rely on the identification, from high dimensional omics profiles, of potential omic signatures of SES-related exposures/patterns.

**Biological mechanisms** – The full exploration of biological mechanisms involved in the SES-affected regulatory cascades relies on in-depth exploration of the correlation structures and the potential effect mediations among the candidate markers found within and across the different platforms.

**Time-related patterns** - In order to exploit longitudinal data available in LIFEPATH, specific time-related patterns are sought, which are predictive of the quality of ageing.

**Conceptual model of ageing and predictive score** - At the end of the process, LIFEPATH will construct a holistic conceptual model of ageing by confronting it in an iterative way to data from cohorts involved in the project. This model will integrate the three layers (outer:
determinants; intermediate: risk factors; inner: biomarkers and omics), so that plausible evidence-based pathways encompassing the layers can be built.

8. Age and sex/gender disparities
From birth onwards, a sex-based mortality divide is present, with males having a greater mortality risk than females. Conversely, women have longer life-expectancies but live with higher rates of morbidity and disability. These differences vary in their nature across the lifespan. Sex and gender are central to any research into the processes of ageing, healthy or otherwise. The difficult task in disentangling sex and gender has been highlighted in epidemiology by Krieger (2003) who advocates more complex formulations such as “biologic expressions of gender” and “gendered expression of biology”. Here, we conceptualise sex/gender “as a domain of complex phenomena that are simultaneously biological and social, rather than a domain in which the social and biological “overlap”” (Springer, K.W., Hankivsky, O. and Bates, L.M., 2012).

Policy aims
LIFEPATH is devoted to develop policy implications of the scientific findings. Early work in this project will develop conceptual models of the intermediate mechanisms and pathways through which SES gradients influence organic parameters. These models will be empirically examined using data from the study countries to produce evidence of the importance of different pathways in explaining SES inequalities in chronic disease occurrence. In particular, we are interested in the reversibility of certain biological changes (such as inflammation and epigenetics), and in the identification of sensitivity windows in the life course that may inform policies. For example, many policy interventions to mitigate the effects of poverty have so far addressed elderly people, but evidence is emerging that children and even foetuses are susceptible to the multiple effects of low SES (Kramer, M. S., Seguin, L., Lydon, J. and Goulet, L., 2000), and early damage can be carried on to the adult life. The LIFEPATH project takes the innovative step of combining biomarker results with the existing scientific and policy literatures, with the aim of developing a health impact assessment framework (HIA) which will allow the research team to simulate the impact of different policy choices on the overall
occurrence of disease and its distribution across different SES groups. A number of HIA models for specific disease groups are already available. These will be further developed to capture healthy ageing using the results from the LIFEPATH project. In particular, a model using Markov chains has been developed by the Erasmus group (DynamoOHIA) for application to routine data. The model can be expanded and enriched with socio-economic variables from the LIFEPATH cohorts and it can be tested among the different European cohorts.

**Early achievements so far**

We describe here a few early achievements of the project that support some of the basic assumptions and respond to the first challenges we have identified in LIFEPATH.

1. **SES variables and harmonization**

The LIFEPATH consortium brings together data from early life and adult European cohorts with intense phenotyping and repeat biological samples, other large cohorts with biological samples and a large registry dataset with over a million individuals and very rich information on work trajectories and health (D’Errico, A. et al, 2017). To merge and analyse together data from the different LIFEPATH cohorts, information on occupational class, education, father’s occupational class and income has been harmonized. The harmonization was performed in the initial phases of the project for each of the early life cohorts and adult cohorts participating in the study (Appendix 1. Table 1). Detailed codebooks have been created and given that SES indicators relevant for adults differ from those important to characterize children SES, the cohorts have been harmonised using different methods.

Amongst men, the proposed three-level classification of occupational class based on the European Socio-economic Classification (ESeC) – higher, intermediate and lower professions – and education appear not to differ substantially from more detailed classifications in discriminating between main social strata, and in predicting differences in mortality between
them (D’Errico, A. et al., 2017). In spite of differences in recruitment among the cohorts, especially in terms of time, age, gender composition and type of sample, variability in the distribution of the socioeconomic indicators in the different study populations was relatively low. SES indicators categories observed in the different cohorts were also roughly comparable in their distribution to those observed in other studies conducted in Europe, including several conducted on representative samples of the general population. Despite the categories employed, both education and occupational class differed somehow from those used in the present study and the study populations did not share the same characteristics of those included in LIFEPATH. A shift toward higher occupational classes was noted between fathers’ and subjects’ occupations in most cohorts, which seem to reflect an increasing trend of social improvement in these populations.

Strong differences in mortality between genders were observed for all SES indicators, with much higher and significant associations in males than females, although characterized by variable strength in the different cohorts (Figure 4).

(Figure 4 here)

2. SES as a risk factor of physiological wear and tear
Understanding how human environments affect our health by "getting under the skin" and penetrating the cells, organs and physiological systems of our bodies is a key tenet in public health research. In LIFEPATH we examine the idea that early life socio-economic position can be biologically embodied, potentially leading to the production of health inequalities across population groups. Allostatic load (AL), a composite measure of overall physiological wear-and-tear, could allow for a better understanding of the potential biological pathways playing a role in the construction of the social gradient in adult health. We have investigated the factors mediating the link between two components of parental socio-economic position, maternal education (ME) and parental occupation (PO), and AL at 44 years. Data was used from 7,573 members of the 1958 British birth cohort follow-up to age 44. AL was constructed using 14 biomarkers representing four physiological systems. We assessed the contribution of financial/materialist, psychological/psychosocial, educational, and health behaviors/BMI pathways over the life course, in mediating the associations between ME, PO and AL. ME and
PO were mediated by three pathways: educational, material/financial, and health behaviors for both men and women. A better understanding of embodiment processes leading to disease development may contribute to developing adapted public policies aiming to reduce health inequalities (Barboza Solis, C., Fantin, R., Kelly-Irving, M., and Delpierre, C., 2016). In the same cohort we also showed that AL was associated with subsequent health status (Barboza Solis, C., Fantin, R., Kelly-Irving, M. and Delpierre, C., 2016).

3. SES as a risk factor of high grade inflammation

To explore further potential biological embedding and the consequences of socio-economic position experiences from early life to adulthood, we investigated how socio-economic position indicators at different points across the life course may be related to a combination of 28 inflammation markers. Using blood-derived inflammation profiles measured by a multiplex array in 268 participants from the Italian component of the European Prospective Investigation into Cancer and Nutrition cohort, we evaluated the association between early life, young adulthood and later adulthood socio-economic position with each inflammatory marker separately, or by combining them into an inflammatory score. We identified an increased inflammatory burden in participants whose father had a manual occupation, through increased plasma levels of CSF3 (Granulocyte-colony stimulating factor; $\beta = 0.29; P = 0.002$), and an increased inflammatory score ($\beta = 1.96; P = 0.029$). Social mobility was subsequently modelled by the interaction between father’s occupation and the highest household occupation, revealing a significant difference between "stable Non-manual" profiles over the life course versus "Manual to Non-manual" profiles ($\beta = 2.38, P = 0.023$). Low socio-economic position in childhood is associated with modest increase in adult inflammatory burden, which is more evident for stable low SES across life (Castagne, R. et al, 2016).

Outstanding issues

LIFEPATH is a large and ambitious undertaking, and it will try to address some of the main challenges in the field, but it is foreseen that some issues will remain outstanding:
- Measurement error is inherent in SES but also in biomarkers and omics, and this is likely to lead to blurring of the causal pathways
- In spite of the development of statistical methods for mediation analysis, the complex (multi-layered) nature of the relationships between SES, risk factors, biomarkers and outcomes makes it unlikely that a complete picture can be developed. This includes the heterogeneity of the cohorts involved.
- How far our inferences can be extended to other populations with a different distribution of risk factors, SES composition and life expectancy is unknown.

Access to LIFEPATH resources

LIFEPATH aims to become an open-access source of data for biosocial research. The central database contains harmonized variables for socio-economic status, risk factors, biomarkers and outcomes. Access will be regulated by the Steering Committee and rules for access will be made available to interested researchers via the Principal Investigator.

Conclusions: the marriage between biology and social sciences

Accelerated ageing and many human diseases result from a complex interaction between social and biological factors. Risky behaviours, occupational and environmental exposures and psychosocial stress are rooted in societal structures, have historical foundations, and lead to alterations in physiological states (such as allostatic load) that are a prelude to overt disease. The study of the interplay of social and biological factors in LIFEPATH, poses several challenges:

Conceptual challenges: the definition of socio-economic differentials depends on different theoretical constructs that put variable emphasis on status, job position (social class), prestige, and other factors. Similar challenges are encountered in biological modelling, in relation to the relevance of certain markers (such as DNA methylation or metabolomics) to the exploration of ageing trajectories.

Practical challenges, such as the availability and harmonization of good and well measured descriptors of SES across the cohorts. The same challenges are encountered in biomarker
science, where measurements are affected by “nuisance parameters” (such as batch) and confounders, and also need harmonization.

A major challenge is to avoid reductionism in the interpretation of the findings. We seek to establish causal relations across a spectrum that encompasses societal structures, inter-individual relationships, socio-economic position, exposure to risk factors, and the underlying layers of biological mechanisms (that in turn involve whole individuals, tissues, cells and molecules). Causal models have been proposed separately in social sciences and in biological sciences, and they tend to be very different. Our ambition is to integrate them not only conceptually but also operationally and technically in the use of statistically modelling (Vineis, P., Illari, P. and Russo, F., 2017).

| **COLAUS Study**  
N=6,733  
(Firmann, M. et al., 2008) | The CoLaus (COhorte LAUSannoise) is an ongoing prospective study assessing the clinical, biological and genetic determinants of cardiovascular disease in the city of Lausanne, Switzerland (Firmann et al., 2008). The initial survey was conducted between 2003 and 2006 and included 6,733 participants aged between 35 and 75 years; the first follow-up survey was conducted 5.5 years afterwards and included 5,064 participants. In each survey, data on socio-economic status, lifestyle, mental status and cardiovascular risk factors is collected by questionnaire or clinical examination. |
| **Growing Up in Ireland (Ireland)**  
N = 19,702 | Longitudinal child cohort established in 2007/2008. The study takes place over seven years and follows the progress of two groups of children: 1) containing 11,134 participants. Chronic illness of parents and children and whether confirmed by physician. | Measured heights and weights for parents and children at each wave. |

aged 9 months at baseline with three study waves (9 months, 3 years and 5 years) and 2) containing 8,568 participants aged 9 years at baseline (9 years, 13 years). The dataset gathered contains multiple SES measures of parents at each wave and economic strain and anthropometric measures at each wave of child and parents.

Acute illness for infants at baseline.
Child psychological adjustment, cognitive function, parent/child relationship, child self-concept.

Measured head circumference for 9-month cohort at baseline.

Other large longitudinal cohorts with biological samples (n=202,555).

<tr>
<td>The Cardiovascular Risk in Young Finns Study (Finland)</td>
<td>The Cardiovascular Risk in Young Finns Study (YSF) collected data on 4,320 children and adolescents aged 3, 6, 9, 12, 15 and 18 years at baseline who were randomly chosen from the population register of five Finnish cities with universities with medical schools to produce a representative sample of Finnish children. Of those invited (N=4,320), 3,596 (83%) participated in the first cross-sectional study in 1980. Between 1980 and 1992, these cohorts were followed up at 3-year intervals. The follow-up field studies were performed for the whole study population in 1983 and 1986, when 2,991 (83.2%) and 2,799 (78.3%) subjects participated. In 1989 and 1992 questionnaires were sent to every individual, but only a subset of individuals had their height measured in these survey years so we omit these observations from the analysis. In 2001, 2,283 subjects (63.5%) of the original cohort participated in clinical examinations. A detailed description of the sample can be found elsewhere. For the purposes of this analysis, we treat YFS as 6 different cohorts representing 3-year age bands (3, 6, 9, 12, 15, and 18 years of age upon recruitment into the study).</td>
