ABSTRACT

Objectives: Vaccination is a key strategy to reduce infection risk in RA patients and is advocated in internationally recognised rheumatology society guidelines. The aim was to evaluate the impact of anti-rheumatic drugs on influenza and pneumococcal vaccine immunogenicity.

Methods: We conducted a systematic literature review and meta-analysis comparing the humoral response to influenza (pandemic and seasonal trivalent subunit vaccines) and pneumococcal (PPV23, PCV-7, PCV-13) vaccination in adult RA patients treated with anti-rheumatic drugs. Vaccine immunogenicity was assessed by seroprotection rates measured 3 to 6-weeks post immunisation. Risk ratios and 95% CIs were pooled.
**Results:** Nine studies were included in the meta-analysis (7 studies investigating anti-rheumatic drug exposures and influenza humoral response, 2 studies investigating pneumococcal vaccine response). Influenza vaccine responses to all subunit strains (H1N1, H3N2, B strain) were preserved with methotrexate and TNF inhibitor drug exposure. Methotrexate but not TNF inhibitor drug exposure was associated with reduced 6B and 23F serotype pneumococcal vaccine response (risk ratio 0.42, 95% CI 0.28 to 0.63) vs. 0.98 (95% CI 0.58 to 1.67), however limited data were available to draw any firm conclusions. Combination of methotrexate with tocilizumab or tofacitinib was associated with reduced pneumococcal and influenza vaccine responses.

**Conclusions:** Anti-rheumatic drugs may negatively impact humoral responses to vaccination as evidenced by pneumococcal responses with methotrexate exposure, however they are safe and should not preclude immunisation against vaccine preventable disease. Vaccination should be considered in all RA patients and encouraged as part of routine care. Systematic review registration number: PROSPERO 2016: CRD42016048093.

**INTRODUCTION**

Rheumatoid arthritis (RA) patients are at an increased risk of infection compared to healthy subjects (1). The is due to a multifactorial complex interaction between inherent immune dysfunction, comorbidity, disease activity and immunosuppression (2). Highly targeted therapies (including Tumour Necrosis Factor inhibitor drugs (TNFi), Rituximab (RTX), Tocilizumab (TOC) and Abatacept (ABA) and most recently Tofacitinib (TOF)) have revolutionised RA management, however the infection risk associated with these drugs is a concern for clinicians and
patients.

British Society for Rheumatology (BSR), European League Against Rheumatism (EULAR) and American College of Rheumatology (ACR) guidelines (3, 4) recommend vaccination against vaccine preventable diseases (including influenza and pneumococcal infections). The literature supports the safety of common vaccinations in autoimmune disease and the Swedish EIRA study has reported no increased risk of developing RA following common vaccination (5, 6).

In the U.K., routine vaccination schedules advise annual influenza and single PPV23 vaccination in individuals over the age of 65 or anybody with chronic comorbid illness including pulmonary, cardiac, renal or liver disease. Immunocompromised patients (of any cause) should also be offered vaccination. Historically uptake of vaccination in RA populations has been poor, particularly with pneumococcal vaccination (7, 8). The reasons may include a lack of awareness about the indications for vaccination amongst primary or secondary care providers, concerns pertaining to vaccine safety, efficacy or fear of worsening disease activity.

The seasonal influenza vaccine is an inactivated trivalent subunit vaccine comprised of 3 viral antigens (2 ‘A’ strains, H1N1 and H3N2 and a single ‘B’ strain). The pandemic influenza vaccine (pH1N1) is utilised when necessary. In the U.K., two commercially available pneumococcal vaccines are currently used, a 23-valent polysaccharide vaccine (PPV23) and a 13-valent conjugate vaccine (PCV-13) which superseded a 7-valent conjugate vaccine (PCV-7) in 2010. Vaccine immunogenicity depends upon vaccine type and vaccine strain but post-vaccination antibody (Ab) titres to assess vaccine response are not routinely measured (9).

EULAR guidance recommends that influenza and pneumococcal vaccines should be administered prior to immunosuppression. Vaccination can be
administered during non-biologic disease modifying anti-rheumatic drugs (nbDMARDs) and TNFi treatment but ideally prior to commencing RTX (3). This is because immunosuppression may blunt serological responses to vaccination.

The rationale for undertaking this systematic review of the literature and meta-analysis was to evaluate the impact of immunosuppressive drugs commonly used in RA on humoral immune responses to influenza and pneumococcal vaccination.

MATERIALS AND METHODS

The study was conducted in accordance with the preferred reporting items for systematic reviews and meta-analysis guidelines (10). The systematic review was registered with the international prospective register of systematic reviews (registration number: PROSPERO 2016: CRD42016048093). Ethics board approval was not required for this study.

Search strategy and information sources

The literature was searched systematically by two investigators (S.S. and K.B.) using MEDLINE and EMBASE databases. The vaccines of interest were influenza (seasonal, pH1N1) and pneumococcal (PCV-7, PCV-13, PPV23) vaccines. The search terms were ‘inflammatory arthritis’ or ‘rheumatoid arthritis’ and ‘immunisation’ or ‘vaccination’ or ‘influenza’ or ‘pneumovax’ or ‘prevenar’.

The search was undertaken in 6th October 2016 and re-run on 12th October 2017 prior to the final analysis to identify further studies that could be retrieved for analysis.

Eligibility criteria and study selection

English language publications of prospective cohort studies and randomised control trials published between 1st January 2000 and 6th October 2016 were
sought. Case reports and conference abstracts were excluded. RA patients aged over 18 years treated with anti-rheumatic drugs who had received influenza and/or pneumococcal vaccines were considered. Alternative diagnoses of inflammatory arthritis were excluded. Drugs exposures studied included methotrexate (MTX), TNFi, RTX, TOC, ABA and TOF. Other nbDMARDs were not studied.

The primary outcome of interest was evidence of seroprotection (SP) as a surrogate measure of vaccine immunogenicity, classified by anti-rheumatic drug exposure. Seroconversion (SC) and/or SR were considered if SP rates were not published or calculable from the data presented. For influenza vaccination, SP was considered as a post-vaccination Ab titre measured by haemagglutination inhibition assay (HI) of ≥ 1:40, SR or SC a 4-fold increase in post vaccine Ab titre. For this study and in the absence of an accepted universal correlate of vaccine protection, a post-vaccination Ab titre of 1 mcg/ml was used as a marker of likely protection following pneumococcal vaccination, SR was defined as ≥2-fold increase in post-vaccine Ab titres. Studies reporting only on geometric mean titres (GMT), opsonisation index (OI) or Ab response rates were excluded. Vaccine response was assessed between 3 and 6-weeks post influenza and pneumococcal vaccination. Healthy controls (HC) or RA subjects not taking anti-rheumatic or immunosuppressive therapies served as the comparator groups.

Titles and abstracts of studies retrieved using the search strategy detailed above and those from additional sources (including reference lists of selected publications) were screened independently (by S.S. and K.B.). The full text of the potential studies for inclusion were retrieved and assessed for eligibility. The full electronic search strategy is available in the supplementary material accompanying this manuscript.
Data collection process and outcomes and quality assessment

Data were extracted independently (by S.S. and K.B.). Disagreements over study eligibility, quality (as assessed using the Newcastle-Ottawa Score (NOS) for cohort studies) or risk of bias were resolved through discussion with a third reviewer (J.G.) where necessary. Details of the assessment of study quality are available in the supplementary material (supplementary Table 1). Data collated included the source (main author, journal, publication date), study design, vaccination intervention, anti-rheumatic drug exposure and patient characteristics (age, disease duration, disease activity, quality of life measures where available). SP, SR and SC rates were documented or calculated from data available.

Data synthesis and statistical analysis

Analyses were performed using Review Manager software version 5.3 (Cochrane Collaboration, Oxford, U.K.). Sensitivity analyses compared vaccine response within immunosuppression class and descriptive analysis was undertaken to assess the effect of vaccine response in patients with RA by drug class. Summary data rather than individual level data were aggregated for quantitative analyses. Summary estimates of response were tabulated and compared using a meta-synthesis approach with forest plots.

RESULTS

Literature search and study characteristics

The initial search strategy yielded 3893 articles for screening which was reduced to 47 after application of filters and screening of titles and abstracts. Nine studies were selected for inclusion (7 influenza (seasonal or pandemic) and 2 pneumococcal vaccine studies). The search strategy is detailed in Figure 1. The
characteristics of studies examining influenza and pneumococcal vaccine immunogenicity are detailed in Tables 1 and 2, forest plots for the risk ratio (RR) of response rates for influenza vaccine strains and pneumococcal serotype responses separated by anti-rheumatic drug exposure (MTX or TNFi) are represented in Figures 2 and 3. All studies included in the meta-analyses were prospective cohort studies. There was good agreement between reviewers on the quality of included studies; all included studies scored between 5 and 7 on the NOS scale (see supplementary material Table 1). It was not possible to evaluate the impact of RTX, ABA, TOC or TOF in meta-analyses either due to an absence of HC or comparator groups, unpublished vaccine response rates or limited number of studies available for analysis. These studies are discussed further as part of a narrative review. Studies examining the immunogenicity of pneumococcal vaccine in the context of anti-rheumatic drug exposures have been included in a supplementary material (supplementary Table 2).

**Influenza vaccine responses**

**MTX and influenza vaccination response**

Five studies including 787 subjects (350 RA patients, 437 controls) assessed MTX exposure and influenza vaccine humoral responses (11-15). Three studies assessed the response to pH1N1 influenza vaccination, these results were pooled with seasonal influenza H1N1 responses (15-17). MTX exposure was not associated with reduced SP responses to H1N1 (pooled (RR) 0.88 [95% Confidence Interval (CI) 0.69 to 1.11], H3N2 (pooled RR 0.94 95% CI 0.85 to 1.04) or B strain (pooled RR 1.15, 95% CI 0.63 to 2.10).

**TNFi and influenza vaccination response**
In total, 803 subjects from 7 studies were pooled in the meta-analysis examining TNFi impact on influenza vaccine immunogenicity (304 RA patients, 499 controls) (11-17). Three studies exclusively examined the influence of TNFi exposure on pH1N1 influenza response, these results were combined with seasonal influenza H1N1 responses (15-17). TNFi exposure was not associated with reduced SP responses to H1N1 (pooled RR 0.86, 95% CI 0.72 to 1.04), H3N2 (pooled RR 0.98, 95% CI 0.74 to 1.31) or B strain (pooled RR 1.38, 95% CI 0.70 to 2.72).

**RTX and influenza vaccine response**

Two studies have described reduced seasonal influenza vaccine responses in RTX treated patients compared to nbDMARD treated patients and HC (18, 19). Arad et al. (18) reported that a longer interval between RTX administration and influenza vaccination was associated with an improved Ab response in contrast to Oren et al. (19) who found no such relationship.

**ABA and influenza vaccine response**

Ribeiro et al. (20) reported a significantly poorer humoral response to pH1N1 vaccination in ABA treated patients compared to age matched MTX treated patients and HC. Alten et al. described preserved influenza vaccine responses in 296 ABA exposed patients pooling the results from 2 multi-centre, open-label sub-studies (21). In total, 49.5% of patients achieved an appropriate post-vaccine humoral response. Despite vaccine responses not being compared against a comparator group, the authors felt the vaccine responses were preserved.

**TOC and influenza vaccine response**

Iwamoto et al. (15) reported appropriate humoral responses to pH1N1 vaccination in TOC treated patients compared to HC. However, combination MTX+TOC compared to TOC monotherapy has been associated with a blunted
vaccine response in subjects receiving pH1N1 vaccination (22). Tsuru et al. (23) reported preserved SP rates for all 3 strains of seasonal influenza vaccine in TOC exposed compared to TNFi/nbDMARD treated patients.

**TOF and influenza vaccine responses**

The data on influenza vaccine response and TOF exposure are limited. Winthrop et al. reported 2 studies investigating humoral responses to trivalent influenza vaccine (24). In both studies, humoral response was considered as a 4 fold increase in at least 2 of 3 influenza antigens, assessed 5 weeks post vaccination. The first study was undertaken in TOF naïve patients randomized 1:1 to TOF 10mg BD or placebo, stratified by MTX exposure. Combination TOF+MTX therapy was associated with poorer influenza humoral response compared to placebo, TOF and MTX monotherapy. In the second study, the effect of temporary withdrawal of TOF compared to continuous therapy was investigated; temporary withdrawal of TOF (1 week pre and post vaccination) had no significant impact on humoral vaccine responses.

**Pneumococcal vaccination**

**MTX and pneumococcal vaccination response**

Two studies reporting on 254 subjects (122 RA patients, 132 healthy controls) examining MTX exposure and 6B and 23F pneumococcal serotype responses were included in the meta-analysis (25, 26). From the limited data for the two serotype studies, MTX exposure was associated with a reduced vaccine response compared to HC (pooled RR 0.42, 95% CI 0.28 to 0.63).

**TNFi and pneumococcal vaccination response**

Two studies reporting on 273 subjects (141 RA patients, 132 healthy controls) assessing 6B and 23F pneumococcal serotype responses with TNFi exposure (25,
26) were included in the meta-analysis. From the limited data, TNFi exposure had no significant negative impact on vaccine response compared to HC, (pooled RR 0.98, 95% CI 0.58 to 1.67).

**RTX and pneumococcal vaccine response**

Comparing RA patients treated with RTX+MTX (n = 65) with MTX monotherapy (n = 28), Bingham et al. (27) reported that RTX exposed patients had a reduced response to vaccination for each of the 12 PPV23 serotypes tested. The proportions of RTX treated patients with a positive vaccine response (to at least 1, 2, 3, 4, 5, and 6 serotypes) was also decreased compared to MTX monotherapy.

**ABA and pneumococcal vaccine response**

The data on ABA exposure and humoral vaccine response are conflicting. Migita et al. (28) found significantly decreased Ab response rates for 6B and combined 6B/23F SR rates in ABA exposed patients compared to MTX and RA control groups. In contrast, Alten et al. (21) described preserved SP response to PPV23 vaccination with 55.4% of ABA exposed patients achieving adequate SP response to PPV23 vaccination.

**TOC and pneumococcal vaccine response**

TOC monotherapy is not associated with impaired PPV23 vaccine response however combination with MTX has been reported to blunt 6B and combined 6B/23F serotype responses (23, 29, 30).

**TOF and pneumococcal vaccine response**

The data on TOF exposure and pneumococcal vaccine responses are limited; the results of two studies investigating pneumococcal responses in the context of TOF exposure were reported by Winthrop et al. (24). Combination of TOF+MTX was associated with reduced humoral response to PPV23 vaccine compared to placebo,
TOF or MTX monotherapy. Temporary withdrawal of TOF (1 week pre- and post PPV23 vaccination) had little effect on humoral vaccine response compared to continuous therapy.

DISCUSSION

Our meta-analysis found no detrimental effect of MTX therapy on influenza vaccination, but a diminished response to pneumococcal vaccination. There was no observation of an adverse humoral response to influenza or pneumococcal vaccination with TNFi exposure.

Meta-analysis of pneumococcal vaccination responses with immunosuppression exposure was challenging due to the significant heterogeneity in reporting vaccine response; we only considered responses to 6B and 23F serotypes. Despite not being the most prevalent serotypes, bacterial pneumonia associated with 6B and 23F have a high mortality risk (31). We accept that vaccine response may differ across individual pneumococcal vaccine serotypes. Despite achieving a satisfactory response to one serotype, it is not appropriate to assume that vaccine responses for other serotypes will be equal. Vaccine efficacy was defined as achievement of post-vaccination SP Ab titres, however subjects could achieve SP without SR or SC. SP doesn't provide information on vaccine efficacy and we acknowledge alternative methods of reporting vaccine immunogenicity and efficacy, e.g. OI or GMT rises.

Vaccine responses for PCV-7 and PPV23 responses were pooled. PCV-7 however is no longer part of the routine U.K vaccine schedule and was replaced by PCV-13. Both PCV-7 and PCV-13 include 6B and 23F serotypes. Although comparing a conjugated and polysaccharide vaccination may not be appropriate
when considering long term vaccine responses, comparison of vaccine immunogenicity at 3 to 6 weeks post vaccination is similar (32).

Although it was not possible to undertake meta-analysis of the impact of RTX on humoral responses to influenza and pneumococcal vaccination, there are consistent reports in the literature of poorer serological responses to immunisation (19, 27, 33-35). The timing of RTX has also been an important consideration in the assessment of vaccine immunogenicity; a greater interval between RTX administration and vaccination has been associated with an improved vaccine response (18). There were limited data to perform meta-analysis on TOC exposure on vaccine responses compared to healthy controls, although review of the literature suggests there no significant effect on PPV or influenza vaccine immunogenicity (22, 29). Comparatively, ABA has been reported to impair the responses to pH1N1 and PPV23 response (20, 28). TOF in combination with MTX is associated with reduced influenza and pneumococcal vaccine responses. Temporary withdrawal of TOF no significant effect on influenza or PPV vaccine immunogenicity.

EULAR guidelines recommend vaccination against influenza and pneumococcal disease should be undertaken prior to commencement of TNFi or nbDMARD therapy, we accept that in practice this is challenging and may be unrealistic. EULAR guidance (3) also advises vaccination should be undertaken in a period of disease stability however in U.K. practice, biologic drugs (often a trigger to administer vaccinations) are only considered in patients with persistent high disease activity states (DAS28 >5.1). There is limited evidence that vaccine responses are attenuated in RA in patients with high disease activity states. A key clinical decision is determining the best time to vaccination, either before immunosuppressive therapy or in a period of disease stability. Live vaccines are currently contraindicated in the
setting of immunosuppression. If a live vaccine is indicated, vaccination should be administered 2 to 4 weeks prior to immunosuppression, or at least 3 months after stopping nbDMARDs. The Centers for Disease Control and Prevention have provided guidance on the safety of the shingles vaccine in the context of immunosuppression; it is safe to administer the shingles vaccine in patients on nbDMARDs including Azathioprine and MTX but it avoided in patients on biologics and high-dose prednisolone (>20 mg per day) (36).

Only 2 studies included in the meta-analyses reported specifically on the effect of vaccination on disease activity however several confirm no evidence of a detrimental effect on parameters of disease activity post vaccination (13, 17-19, 33, 34, 37-40).

To our knowledge, there has been 1 previous meta-analysis assessing the influence of anti-rheumatic drug therapies on influenza and pneumococcal vaccine responses (41). Of note, there was an alternative methodological approach to analysis and probable access to unpublished data. In Hua’s meta-analysis, the definitions and characteristics of treatment exposed and control groups differed, for example when assessing the influence of MTX on pneumococcal vaccine response, the experimental group compared MTX + TNFi exposed patients to TNFi monotherapy rather than HC.

We recognise that biologics are co-prescribed with nbDMARDs including MTX in routine clinical practice. However, by comparing drug therapies with HC groups in our analysis, we felt it would allow better assessment of the impact of drug therapy on vaccine immunogenicity, albeit to the detriment of potential number of studies and subjects that could be included in meta-analysis. Additionally, we have considered newer anti-rheumatic therapies including ABA, TOC and TOF. Our assessment of
MTX exposure negatively impacting pneumococcal vaccine response is congruent with Hua and colleagues, although we did not observe a negative influence of MTX on influenza vaccination.

The NOS was used to assess the risk of bias and grade the quality of included studies. All studies were of ‘satisfactory’ or ‘good’ quality however, there are sources of bias in our meta-analysis that we acknowledge.

Our review was potentially subject to outcome reporting bias. We only included studies reporting on post-vaccine Ab titres (rather than OI or GMT responses) as it was the most commonly reported method of assessing vaccine response. Literature review identified several studies that could not be included due to the heterogeneity in study design or differing methods of reporting vaccine efficacy, particularly those reporting on pneumococcal vaccine immunogenicity. Several studies reported on Ab response rates, GMT rises or OI without providing numerical data on response rates for SP, SR or SC. However, the conclusions drawn from each study agreed with our findings and provided further evidence that TNFi do not significantly diminish the response to pneumococcal or influenza vaccines (33, 38, 39, 42-46).

We included 2 studies from a single centre analysing vaccine responses of 2 pneumococcal serotypes (6B and 23F), thus the generalizability of our conclusions is limited. A strength is that both studies were methodologically similar and good quality with low risk of bias. There was a relative paucity of data examining newer biologic agents including RTX, ABA, TOC and TOF compared to TNFi drugs, this may be a result of publication bias.

Adjustment for confounding factors including age and smoking status or significant comorbidity which could impact on vaccine immunogenicity was not
possible. Control groups were not necessarily age matched to the RA cohorts. Older subjects are have a higher risk of serious infection and attenuated vaccine responses to vaccination, a consequence of immunosenescence (44, 47). Smoking may reduce pneumococcal vaccine responses in RA patients treated with MTX (48), however this was poorly reported in studies included. Most studies examined established RA cohorts (evidenced by RA disease duration prior to vaccination). It is uncertain whether longer disease duration (and potentially historically more immunosuppressive exposures) impacts upon vaccine response; this was outside the scope of this study.

Seasonal and pandemic influenza vaccination utilise strains that vary each season depending on the most virulent predicted strains. Although vaccine responses were broadly categorised by A or B strain responses for the meta-analysis, there may have been variation in the immunogenicity of each vaccine between studies, this was not possible to correct for.

Co-prescription of MTX with a biologic is recommended to maximise efficacy and reduce drug immunogenicity. We aimed to compare TNFi monotherapy to a HC group to prevent aberrancies due to MTX exposure. Concerning influenza vaccine responses with TNFi exposure, 3 studies included patients taking TNFi with concomitant MTX (12, 15, 16). Excluding these studies increased the heterogeneity but not RR interpretation. Three of the 4 other studies included in the meta-analysis did not explicitly comment if TNFi exposed patients were taking concurrent MTX (13, 14, 17). Additionally, the studies included different TNFi drugs. We assumed that TNFi exposure had similar class effects irrespective of whether they were a monoclonal antibody or fusion receptor protein.
Our meta-analysis and systematic review suggests that MTX exposure diminishes humoral responses to pneumococcal but not influenza vaccination. TNFi therapy does not negatively impact influenza or pneumococcal vaccine responses. Immunosuppression should not preclude vaccination against immune preventable disease. Vaccination is safe and well tolerated and should be encouraged as part of routine clinical care. Increasing the awareness and uptake of vaccinations in RA patients will require collaborative approaches between primary and secondary care.

COHORT STUDIES

Selection (4 points in total)

Representativeness of the exposed cohort (1 point)

Yes if:
- rheumatoid arthritis (RA) diagnosis confirmed by American College of Rheumatology (ACR) 1987/2010 criteria.
- details on selection process of the RA cohort, e.g. randomly selected from a hospital clinic, or invited via postal-invitation to participate in the study

No if:
- RA patients do not fulfil ACR RA diagnostic criteria
- details on the method of recruitment of RA patients not presented

Selection of the non-exposed cohort (1 point)

Yes if:
- RA patients serving as healthy cohorts were stated to not have any immunosuppressive exposure prior to vaccination
- the healthy control cohort were randomly selected from the local population

No if:
- the control cohort were drawn from a hospital workers only
- the control drawn from a different source and not from the same community
- there was no description of the derivation of the non-exposed cohort

Ascertainment of exposure (1 point)

Yes if:
- it was documented that no recent vaccination against influenza (within the same vaccination season) and/or pneumococcal vaccine (within 5 years) had been performed
- details were from a secure record (e.g. medical records)

No if:
- there was no description of pre-vaccination antibody titres or no evidence of exclusion criteria including previous vaccination history

Demonstration that outcome of interest was not present at start of study (1 point)

Yes if:
- pre-vaccine titres were checked pre-immunisation and details provided on to calculate number/proportion of patients who achieved seroprotection, seroconversion or seroresponse

No if
☐ there was no history of vaccination within 12 months for influenza vaccination or 5 years for pneumococcal vaccination

Comparability (2 points)

Yes if:
- RA and control cohorts were age matched
- RA and control cohorts were age and sex matched
- The RA population serving as a control cohort, matched for disease duration

No if:
- Cohorts not age matched

Outcome (3 points)

Assessment of outcome (1 point)

Yes if:
- The percentages of achieving seroprotection or seroconversion calculable from data presented
- Blinded analysis of post-vaccination titres

No if:
- No data presented for post vaccination titres

Was follow-up long enough for outcomes to occur (1 point)

Yes if:
- 3-6 week follow up period for post-vaccination titres to assess seroprotection or seroconversion

No if:
- Follow up period outside set time frame

Adequacy of follow up of cohorts (1 point)

Yes if:
- Complete follow up - all subjects accounted for or >80% subject follow up rate

No if:
- Follow up rates unable to be calculated or data not presented

Interpretation of Newcastle Ottowa Scale score:
0 – 3 = poor quality study
4 – 6 = satisfactory quality study
7 – 9 = high quality study

<tr>
<td>Winthrop et al. 2016 (24)</td>
<td>RA (200, TOF + MTX 57, TOF 45, MTX 55, placebo 43)</td>
<td>PPV23</td>
<td>2-fold increase in post-vaccination titers to ≥6 of 12 antigens, 5-weeks post-vaccination. Serotypes measured 1,3,4,5,6B,7F,14,19A, 19F, 23F, 18C)</td>
<td>RA (TOF exposed) 53</td>
<td>RA (TOF exposed) 75 (73.5) RA (placebo or MTX monotherapy) 53</td>
<td>RA (TOF exposed) 6.03 (1.05) RA (placebo or MTX monotherapy) 5.78 (1.10)</td>
<td>-</td>
<td>-</td>
<td>TOF overall 46/102 (45.1%) demonstrated appropriate vaccine response. In TOF non-exposed patients, response rate was higher 67/98 (68.4%). Achievement of appropriate PPV23 vaccine response stratified by MTX use at baseline: TOF + MTX 18/57 (31.6%), TOF monotherapy 28/45 (62.2%), MTX monotherapy 34/55 (61.8%) demonstrated appropriate vaccine response compared to 33/43 (76.7%) in the placebo group. TOF exposure, particularly in combination with MTX is associated with reduced humoral response to PPV23 vaccination. Temporary withdrawal of TOF has no benefit on vaccine response compared to continuous therapy.</td>
